Foreword

THIS volume of the TRANSACTIONS OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS is of the same form and size as volumes 49 and 50. It complies with the publication policy of the Society consummated in 1928 under which the TRANSACTIONS are issued in pamphlet form in order that they may become more quickly available to members.

The pamphlets, forming sections of the TRANSACTIONS, are issued periodically at the rate of about three a month, and each section is sponsored by one of the Society's professional divisions. A member of the Society may register in any three professional divisions and may receive, without cost, the sections of the Transactions which are sponsored by these divisions. The periodical publication of these sections in magazine form has a feature of timeliness which justifies the inclusion of papers of specific interest to a single group of members without the cost of distribution to all. This policy, combined with increased activity on the part of the professional divisions, has made available a much greater number of engineering papers.

COMPLETE TRANSACTIONS BOUND FOR PERMANENT RECORD

For permanent record and for reference use in depositories and libraries a number of sets comprising all of the sections of the Transactions have been bound, and are issued in two books which form parts I and II of volume 51. The division into two books is for convenience in binding and handling, and together these comprise volume 51 (1929).

NUMBERING AND ARRANGEMENT OF PAPERS IN COMPLETE TRANSACTIONS

In this volume the papers of each section are grouped together and are numbered serially. The different sections follow each other alphabetically. Each paper is designated by a symbol composed of key letters followed by the volume number and paper number. The letters refer to the section of the Transactions to which the paper is assigned. Thus AER refers to the Aeronautic section, IS is the Iron and Steel section, etc. Each of the two books forming parts I and II of volume 51 contains a complete index of subjects, authors, and discussers to both parts of the volume so that either may be consulted. The arrangement of the index and designations for locating material are explained at the beginning of the index.

CONCERNING BLANK PAGES

The papers in each section of the Transactions are printed separately so that they may be available as reprints. This makes it necessary to print each paper so that the number of pages is a multiple of four. Because of this blank pages will be found at the ends of papers which do not completely fill the printer's form. This is the reason for the blank pages which will be found scattered throughout the volume.

THE PUBLICATIONS COMMITTEE.

Progress in Aeronautics

Contributed by the Aeronautic Division

Executive Committee: Edwin E. Aldrin, *Chairman*, Alexander Klemin, *Secretary*, Archibald Black, Elmer A. Sperry, Wm. F. Durand, and Chas. H. Colvin

Power Plants[1]

THE outstanding feature in the development of aircraft engines during the past year is the great number of engines, both in quantity and in new types, which were produced for non-military activities. The various points of aircraft-engine design to give a light-weight, reliable engine are sufficiently well established that many of these engines give satisfactory performance beginning with the first article produced. However, for the protection of the public, the Department of Commerce conducts tests to determine the airworthiness of aircraft engines. (Department of Commerce Aeronautics Bulletin No. 14, "Requirements for Approved Type Certificates.") By the end of September of this year, airworthiness certificates had been issued for nine engines. Data on these engines are summarized in Table 1. Engines which have passed the standard endurance tests of the United States Army Air Corps or the United States Navy Bureau of Aeronautics will be approved by the Department of Commerce.

There are at least fifty different aircraft engines below 300 hp. at various stages of development. Most of these engines weigh below 4 lb. per b.hp. About one-third weigh 2½ lb. or less per b.hp. The air-cooled radial engine is the predominant type of engine of this class. The price per brake horsepower ranges from $25 for the small engines to as low as $15 for the larger ones.

The Allison Engineering Company has redesigned the accessory drives of the inverted Liberty engine so that both oil and water pumps are gravity fed and the ignition distributers are driven from the camshaft driveshafts instead of from the end of the camshaft. This engine has been thoroughly ground-tested and is now being flight-tested by the Army Air Corps in a Loening Amphibian plane. It is designated as the Allison V-1650.

An item of considerable interest to many is that the Army Air Corps has let the last contracts for reconditioning Liberty 12 engines. Approximately 2000 engines are being reworked, of which about two-thirds are being done by the Allison Engineering Company and the remainder by the Steel Products Company of Springfield, Ohio. Some of the principal changes being incorporated in these engines to improve their reliability are replacement of the old carbon-brush ignition distributers by the air-gap type distributers with coils tested at high temperature, new stub-tooth timing and accessory gears, replacement of bronze-backed by new steel-backed connecting-rod bearings, modifications to provide drives for a fuel pump and the inertia type of starter, selection of heavy-type crankcases, and modification of pistons and rings to reduce oil consumption. After this stock of engines is depleted, the Army Air Corps can equip all of its airplanes with the latest-type high-performance engines.

The Curtiss Aeroplane and Motor Company has produced a new six-cylinder, double-throw crankshaft, air-cooled radial engine of 600 cu. in. displacement, which they have named the "Challenger." They guarantee 170 b.hp. at 1800 r.p.m. The Army Air Corps is to test one of these engines for training-airplane service.

[1] Prepared by N. N. Tilley, Chief, Engine Development and Specification Unit, Power Plant Branch, U. S. Army Air Corps, Wright Field, Dayton, Ohio.

The Army Air Corps is flight-testing a Curtiss H-1640 ("Chieftain") engine and has adopted, as standard, Curtiss V-1570 and GV-1570 ("Conqueror") engines. The H-1460 is an air-cooled engine. The V-1570 and GV-1570 engines are water-cooled direct drive and geared engines, respectively. These engines develop 600 b.hp. The Curtiss bombing airplane with full military load, equipped with two GV-1570 engines, has a high speed and a rate of climb as good as many pursuit-type airplanes at the end of the War.

The Packard Motor Car Company is developing an air-cooled radial Diesel engine. It is reported to weigh approximately 3 lb. per hp. This marks a big step forward in the aircraft Diesel-engine project. While the fuel economy of this type of power plant may not be appreciably better than that of the aircraft gasoline engine, the use of a non-volatile fuel should considerably reduce the fire hazard.

The Pratt and Whitney Aircraft Company has brought out the series B Wasp engine, developed from the earlier model. This engine is rated at 450 hp. at 2100 r.p.m. With the power of this engine somewhat boosted at sea level by speeding up the centrifugal fan in its induction system, the new Boeing superfighter is reported to have a speed in level flight of 180 m.p.h. with full military load, and to have remarkable maneuverability.

A quantity of Pratt and Whitney Hornet engines and Wright Aeronautical Corporation Cyclone engines is being procured by the Army Air Corps for twin-engine bombing planes, and by the Navy for torpedo planes. Hornet engines are being used in the Boeing Air Mail Service. These engines are rated at 525 hp. at 1900 r.p.m., with a dry weight of not over 775 lb. Both are nine-cylinder air-cooled radial engines.

The Wright Aeronautical Corporation has developed a new J-6 series of engines, each of which will weigh less than the J-5 (Whirlwind) engine. They are 5-, 7-, and 9-cylinder, air-cooled radial engines of 160, 220, and 300 hp., respectively. They offer many new possibilities to the designers of both military and non-military airplanes.

TABLE 1 DATA ON AIRCRAFT ENGINES GRANTED AIRWORTHINESS CERTIFICATES BY THE U. S. DEPARTMENT OF COMMERCE

Certificate No.	Manufacturer	Engine name and designation	Rating B.hp.	Rating propeller r.p.m.	Max. dry weight, lb.
1	Fairchild-Caminez Engine Corp.	447-C	120	960	340
2	Warner Aircraft Corp.	Scarab (R-420)	110	1850	270
3	Kinner Airplane & Motor Corp.	Kinner K-5 (R-370)	75	1725	260
4	Velie Motors Corp.	Velie (R-250)	45	1750	210
5	Curtiss Aeroplane & Motor Co., Inc.	Challenger (R-600)	170	1800	420
6	Curtiss Aeroplane & Motor Co., Inc.	Conquerer (V-1570)	600	2400	760
7	Curtiss Aeroplane & Motor Co., Inc.	Conqueror (GV-1570)	600	1200	870
8	Curtiss Aeroplane & Motor Co., Inc.	Chieftain (H-1640)	600	2200	925
9	Aircraft Engine Co., Inc.	Comet (R-610)	115	1775	350

Large-engine development lost considerable impetus when twin engines in preference to a single engine for bombing airplanes and three-engined transports were selected by the Army Air Corps. However, larger disposable loads or maximum speed at any cost will demand larger engines, even in multi-engined planes. Large engines awaiting test by the Army Air Corps are the Allison X-

THE BOEING TRANSPORT

4520 engine and the Packard 4A-2500 engine. The X engine is air-cooled, has 24 cylinders arranged in four banks of six cylinders each, at 90 deg. to each other, is geared 2:1, and is rated at 1200 hp.

The Packard engine, one of their 800-hp. engines, modified to incorporate two gear-driven centrifugal compressors, one on each side, and has developed 950 hp. during a one-hour acceptance test. Over 1000 b.hp. should be obtained from this engine. It is expected to test these engines when the new power-plant laboratories of the Material Division are completed.

A number of refinements and new features in engine design have appeared during this past year. Among these are the finer pitch of cooling fins resulting from research at the Massachusetts Institute of Technology, radio-shielded spark plugs, flange-and-spigot-mounted aircraft magnetos, lighter propeller reduction gears, and the Chandler-Marvel mechanical fuel-metering device which may be expected to improve airplane maneuverability, to eliminate intake-manifold distribution difficulties, hot spots, and air heaters, and to facilitate two-cycle development.

Supercharger development has reached the position that all high-speed, high-rate-of-climb or altitude airplanes will employ them. The General Electric exhaust-gas-turbine type now has excellent durability. Some of these units have been in service for over a year, with hundreds of hours of operation without failure.

A standard Army pursuit airplane, equipped with the General Electric turbo supercharger, with full military load, has gone to 20,000 ft. altitude in less than eleven minutes several times, and has a rate of climb at that altitude in excess of 1500 ft. per min., and a service ceiling of 32,000 ft., which is reached in approximately 30 min. The gear-driven centrifugal supercharger is built into all the large American radial engines. The Army, Navy, National Advisory Committee for Aeronautics, and engine manufacturers are experimenting with the Roots-blower type.

During the past year the Army and Navy have agreed on many power-plant standards and are considering many more items for A-N standardization. Some of the engine parts standardized or being standardized are propeller-shaft ends and hubs, drives and mounting flanges for starters, magnetos, electric generators, fuel pumps, and tachometers. Type designations have been assigned new engines which consist of a number representing the displacement in cubic inches to the nearest 10 cu. in., and a letter prefix to designate the cylinder arrangement and whether direct drive or geared down to propeller, as R for direct-drive radial, GR for geared radial, V for direct-drive vee, GV for geared vee, and H for hexagon.

AIRPLANE DESIGN AND CONSTRUCTION[2]

In the field of design and construction the airplane is still evidencing a steady improvement in details and refinements, with no radical departures from the accepted standards. Particular attention is being paid by commercial manufacturers relative to refinements in appointments of their machines. In the matter of design details a very marked showing is manifest in the so-called "cleaning up" of the exposed portions of the machine, in order that the limit of speed may be secured. Generous fillets given to the junction of the wings and tail surfaces with the body, retraction of fittings within the wings and fuselage, and a general streamlining of the landing gear and other exposed assemblies have directly resulted in higher speeds, the power and pay load remaining the same. The recent transcontinental air races are evidence of this fact, as here such planes as the Laird and Waco, identical with former designs except for details, made speeds as much as 20 per cent in excess of former records. With the introduction of tail wheels to supplant the tail skid and the continued increase in the use of wheel brakes, the ground-handling problem of the larger as well as smaller planes is much simpler. Hydraulic or oleo shock-absorbing struts for landing gears have received numerous modifications with the use of air, rubber in compression or tension, and steel springs for the static-load or taxiing absorbing medium. Most popular of these is the Aerol strut produced by the Cleveland Pneumatic Tool Co. Triangular or elliptical tail surfaces with almost a universal application of front-spar adjusting gears for the stabilizer are to be noticed. Inset "Frise" ailerons with the remaining control surfaces carrying little or no balance appear as the trend in design regardless of the size of the machine.

More attention is being given to the comfort of the pilot and passengers. Upholstery comparable to that in motor buses and adequate ventilation and heating facilities are replacing the somewhat makeshift appointments that appeared in the earlier cabin-type airplanes. Outstanding among the transport machines is the Boeing, with an electric grill and cabin boy as standard fixtures. Color has not been lacking in the airplane, as various wing and fuselage combinations with suitable striping have brought out lines in a manner similar to that of the modern motor car. With the demand for colors has come a call for special dopes and lacquers that will give high-luster finishes. Berry Bros., du Pont, and the American Varnish Company have contributed greatly to this problem. Military aircraft are not without some vestige of color, as the olive drab is giving way to high-visibility yellow and suitable combinations.

[2] Prepared by Mac Short, Vice-President and Chief Engineer, Stearman Aircraft Co., Wichita, Kan.

THE VELIE MONOCOUPE

Types among military and commercial manufacturers are definitely appointed, and it is rare that a factory enters both fields. Among the military planes the biplane arrangement is still in the majority; however, a number of Fokker monoplanes are being used by the services for transport. In the commercial field the interest is fairly well divided between the monoplane and the biplane, and again between open and closed models. A recent summary of the licensed airplanes as approved by the Department of Commerce gives interesting facts. Of approximately 50 approved types 25 per cent are three-place open-cockpit biplanes, 16 per cent 5- to 8-place monoplanes, 6 per cent open two-place biplanes, 6 per cent open two-place monoplanes, 6 per cent closed 5-place biplanes, 4 per cent closed 3-place biplanes, and 12 per cent miscellaneous types, such as amphibians, flying boats, and large transports. The latter have received an added impetus due to the rapid establishment and growth of large transport lines. At present the majority of transport planes are monoplanes; that is, the Fokker and Ford versus the Boeing. Much interest will be centered around these machines in the next year.

That the trend is toward more power may be evidenced by the introduction of the Whirlwind engine in smaller planes and the replacement of this engine by the Pratt and Whitney Wasp in the medium-sized cabin models. A further extension in this direction is the replacement of the Hornet and Cyclone engines for the 400-hp. ones. In the military and commercial field alike the larger machines have already reached the maximum-powered units and must either introduce more units or await further development of higher-powered engines. In the multi-engined class the tri-motor of an aggregate of 1200–1500 hp. is gaining favor. With such power a pay load of 14 passengers may be transported at a speed of 140 m.p.h., and, as the air-transport operator points out, speeds of this order are becoming increasingly more necessary. The four-motored combination in which two motors are in tandem has not been without favor in the prospectus or on the drafting board, but as yet it has not appeared on American air-transport lines.

Metal construction either as a composite of steel or duralumin or entirely of the latter is making added inroads into the more common method of construction wherein wood wings and steel-tube fuselages and tail surfaces comprise the main structure. The Pruden, Thaden, Hamilton, and Flamingo are newcomers that are using steel or aluminum alloys for the main structural parts and duralumin sheets for the covering, either corrugated or flat sheets, with frequent seams turned up. Numerous manufacturers are using tail surfaces of duralumin where otherwise little or no use of this metal is made; the assumption being that the operation is easier and the moment that the weight of the assembly produces is materially reduced. Simultaneously with the use of steel and duralumin sheets and sections appear castings and forgings. Many planes show the application of this method of manufacture where in former years elaborate welded or riveted fittings were used. A fair reduction in weight and a lessening of manufacturing cost of as much as 200 per cent has been effected by cast or forged fittings. It is evident, however, that greater production, both in military and commercial craft, has permitted this improvement in methods.

Design characteristics have been improved and construction refined by advances in accessories. Metal propellers, which have substantially replaced wood for all engines of 200 hp. or more, have increased in efficiency, the so-called wide-blade type being very popular. The Curtiss Company has developed a new forged propeller with an integral hub. Hydraulic and mechanical brakes are more prevalent, the latest being the "Steel-Draulic" built by the Aircraft Products Co. Wheels and tires, both large and small, are in greater demand than before. The transport machines have exceeded the working load on 44-in. tires and wheels, and the lighter craft have demanded smaller tail wheels than the 14-in. size. At the upper end of the scale the problem is as acute as at the lower, except here it is possible to dual the tires, while with small tires the problem of mounting and of the presence of a hub for the wheel becomes difficult. Instruments have become more standard in regard to mounting dimensions, and sizes are being reduced. This latter improvement allows a more desirable grouping of important instruments on those craft that do night and "blind" flying. Electrically heated pitot tubes for the air-speed indicator have aided in flying during the icing period that planes experience in freezing weather.

Records have been broken in all manner of flying. Crossing the continent in approximately 18 hours, remaining aloft in an endurance flight for more than 55 hours, high speeds in excess of 300 m.p.h., outside loops, altitude tests, and many other records have been shattered during the past year. Records in production of all aircraft have reached values never anticipated before. Outstanding in quantity for the past year are the factories making the Monocoupe and Waco planes, where production reached the high mark of 5 to 6 machines per day. In military craft Vought showed excellent manufacturing methods by producing a "Corsair" a day.

Some foreign planes have been introduced, principally in the light field. Avro and De Havilland have both been represented by slotted and non-slotted wing biplanes using the Cirrus engine. Klemm light planes are being manufactured by Aeromarine.

Probably the most radical design evolved this year is the new Bellanca P with its odd bracing and retracting landing gear.

Aerodynamics[3]

The British Aeronautical Research Committee reports some interesting experiments with a "pilot plane." A pilot plane is an auxiliary airfoil pivoted ahead of a wing so as to provide automatically a slotted wing at high incidence without much increase of drag at fine angles with a 10 per cent pilot plane. The maximum lift coefficient of a R.A.F. 15 airfoil may be increased to 0.80 (British absolute units), and the increase of drag at top speed is less than the minimum drag of the pilot plane when tested alone. The increase in drag is greater on the climb. By making the stop which limits the pilot angle vary with the aileron angle, the pilot plane gives an efficient slot-and-aileron control, the pilot plane reversing the sign of the yawing moments at angles just above the stall.

The delivery of the lecture by F. Handley Page on slotted wings before the Society (Detroit Aeronautic Meeting, June,1928) has further increased American interest in the subject of the slot, and at least three full-scale experiments are being made with this device in the United States.

The recent flight of the Autogiro from London to Paris has increased interest in this type of aircraft. With the application of more power the Autogiro has shown increased speed, although the maximum speed attained thus far is still below 100 miles per hour. The British have been steadily continuing full-flight wind-tunnel dropping and theoretical investigations on this type of aircraft. A summary of its characteristics indicates that its performance is comparable with that which would be predicted by the application of theory. The performance of the Autogiro is inferior to that of a corresponding airplane of the same weight and horsepower as regards speed, rate of climb, and distance to take off. The Autogiro is able to land more slowly and to pull up more quickly after landing, and, in contrast with an airplane of conventional design, remains stable at large angles of incidence. The only point which remains uncertain is its ability to descend vertically at low speed. This question is not considered to be of much practical importance, however, since the actual gliding descent at an inclination of 30 deg. to the horizontal implies the possibility of vertical descent when the wind speed exceeds 20 m.p.h. The rate of rotation of the windmill is found to increase slowly with the forward speed.

The theory of performance testing is continually being discussed by British writers. In this regard it is important to determine the law of variation of engine power with height. Glauert concludes that it is more accurate to state that the power of an engine varies directly with the pressure, rather than directly as the density. A more exact statement is that the power is a function of $(\text{pressure})^{3/4} \times (\text{density})^{1/4}$.

A non-dimensional form of the stability equations of an airplane has also been devised by Glauert. The comparison of the stability criteria of different airplanes should be facilitated thereby.

The lateral stability of an airplane under control is a subject of some importance which has not hitherto received much importance. Lateral stability depends upon the values of the resistance derivatives of side force, rolling moment, and yawing moment due to side slip, rate of roll, and rate of yaw. In actual design most of these derivatives are fixed before the lateral stability is considered. Designers will be gratified to learn, therefore, that stability depends mainly on the ratio of L_v to N_v, and not on their absolute values, provided L_v is negative.

In the aerodynamic design of the airplane, both British and American designers are seeking the utmost refinement in streamline. The De Havilland Tiger Moth and the Lockheed Vega are examples of the tendency to give a commercial airplane the form of a racer. The subject of interference between parts, the cowling of air-cooled engines, and propeller interference are engaging much attention. Prof. Melville Jones arrives at two conclusions of practical importance: (1) In a perfectly streamlined airplane, interference, except of the most extreme kind, can have little influence upon overall performance, apart from a slight superiority in favor of the pusher airscrew over the tractor airscrew. (2) Serious losses due to interference must therefore be attributed to bad streamlining. An important investigation of the Deutsche Versuchsanstalt für Luftfahrt on the oscillation of the internally braced monoplane indicates that the period of vibration of such a wing varies between 500 and 900 per minute. Danger of resonance between the engines and the wing is only likely to occur when the engine is throttled down to a large extent.

The propeller research laboratory of the National Advisory Committee for Aeronautics is being used energetically for investigation of propeller and body interference, the cowling of air-cooled engines, and other problems of practical importance.

Researches at Langley Field, Wright Field, and by the Bureau of Aeronautics seem to indicate that spin, whether flat or normal, can be controlled largely by mass distribution.

The amount of aerodynamic research now being conducted by American institutions renders even a summary difficult. It may be safely said that in this respect American effort is now fully on a par with European work.

Scale effects in particular are being studied intensively in the compressed-air tunnel of the National Advisory Committee for Aeronautics.

The problem of wing flutter has been receiving much attention. Experiments by Zahm and Bear at the Washington Navy Yard have established that resonant flutter is not likely to ensue from turbulence of air flow alone past wings and tail planes in usual flying conditions. Danger of flutter is minimized by so proportioning the torsional resisting moment of the wings to the air pitching moment at high-speed angles that the torsional flexure is always small. Green's paper, "An Introduction to the Problem of Wing Flutter," recently read before the Society, is an important presentation of the present status of the problem.

The importance of the flat-top lift curve as a factor in control at the stall has long been recognized. One or two sections have been designed and tested at Langley Field. They have given the desired flat-top lift curve, combined, however, with low aerodynamic efficiency and high moment coefficients.

Air Transport and Other Civil Flying[4]

Since the preparation of the Progress Report for 1927, further and very important progress has been made in the development of air transport in the United States. A considerable number of new routes have been added, and operations on many former ones have been extended. Several air-transport companies are now earning more than the cost of operation, and some are able to show comfortable profits. Already a tendency toward consolidation has become evident, and one of the noticeable changes in this line was the taking over of Pacific Air Transport by Boeing Air Transport, giving the latter company a total operating route of 3017 miles.

Air-mail traffic has continued to increase rapidly, and the inauguration of the reduced air-mail rates on August 1 brought a further sudden increase in traffic, almost doubling it. With the new rate in effect many concerns are sending all first-class mail

[3] Prepared by Alexander Klemin, Professor of Aeronautical Engineering, Daniel Guggenheim School of Aeronautics, New York University, New York, N. Y. Mem. A.S.M.E.

[4] Prepared by Archibald Black, President and General Manager, Black & Bigelow, Inc., Air Transport Engineers, New York, N. Y. Mem. A.S.M.E.

by air. Some of the more enterprising ones have gone further and are sending out much of their advertising material under air-mail postage. The increased traffic due to this has necessitated an increase in facilities on the part of some operators, and this in turn has resulted in reducing the unit operating costs. An official of one operating company (the Boeing) has recently been quoted as estimating that its airplanes carry 15 per cent of the total first-class mail on one route, the remainder being sent by rail. One development of more than usual importance is the extension of air-mail routes from the United States to Canada and to Central America.

With the air-mail traffic now firmly established, many of the operators have begun to turn their attention to the further development of passenger traffic. It is in this class of activity that the United States has trailed behind Europe, although taking the lead in many other branches of aviation. A number of passenger routes are now in operation, and greater effort is being spent on the development of this type of traffic than heretofore. While always dangerous to make predictions in aviation, it is safe to expect that passenger air travel in this country will soon show a growth comparable with that of air mail in the past.

The recent changes in equipment used for air transport in this country have been mainly in the construction of multiple-engined passenger-carrying airplanes of larger capacity, ranging up to as high as 20 passengers. On some routes there has been a tendency to increase the scheduled speed of trips for the purpose of advancing mail connections, and this has already become reflected in the construction of mail-carrying designs of somewhat higher speed and capable of maintaining an average of about 110 m.p.h. under even adverse conditions. Miscellaneous commercial flying (including "aerial taxi" services) has increased in parallel with the increase in air-mail operations. Several large corporations have purchased airplanes for their own use and are applying them to the transport of high-salaried executives, carriage of rush orders, repair parts, and similar uses where speed is of primary importance. Private flying has similarly undergone a substantial increase, due in a large measure to the attention drawn to aviation by the numerous long-distance flights. Flying clubs are now making their appearance in various parts of the country. In some cases these are formed by wealthy men owning their own airplanes, and in others, by the less prosperous who form a club for the joint purchase of an airplane. The development of aerial express traffic has had no spectacular increase in the past year, but some progress has been made nevertheless.

One of the most significant developments of the past 12 months has been the entry of the railroads into the aviation field. Such an extension of the scope of the railway operators has been discussed frequently during the past few years, but approached reality only with the organization of Transcontinental Air Transport. This corporation was formed by some of the leading railroads, airplane operators, and builders for the purpose of creating joint air-rail services in which the passenger is carried part of the way by rail and the remainder of the trip by air. Initial operation of services of this character was started during the past summer.

As a consequence of all of this increased interest in aviation there has been a very large increase in the number of schools and of students taking flight training. Figures compiled by the Department of Commerce indicate that the number of students now taking up flying about equals the total number of pilots licensed. Interest in airport construction has been continued and has increased to the extent where most of the larger cities have at least some kind of flying field, and the city without one is coming to be regarded as behind the times.

Continued and greatly increased attention has been given to the selection, design, construction, and equipment of airports. There are now several companies scattered throughout the United States which specialize in this work. While general agreement seems to exist as regards most angles of airport work, there appears to be some variation of opinion as regards the actual layout of the airport itself. In general, this difference seems to resolve itself into a question of planning the layout with regard to the handling of heavy traffic in the future. Some rather novel plans have been advanced, both here and abroad, but it seems rather early to comment on them, and to include description herein would needlessly burden this report.

Such figures as are available on air-mail traffic and mileage in air transport are included in Tables 1 and 2, and are fully self-explanatory.

TABLE 2 MILEAGE AND TRAFFIC STATISTICS FOR PRIVATELY OPERATED AIR-MAIL ROUTES WITHIN THE U. S. A., FOR YEAR ENDING JUNE 30, 1928

(Compiled from Post Office Department figures)

Date	Pounds of mail carried	Mail revenue to operator	Airplane-miles flown with mail
July, 1927	99,589	$250,891	375,923
August	102,051	258,963	376,998
September	146,486	312,810	444,519
October	153,649	329,532	449,562
November	141,992	304,083	413,054
December	165,768	353,253	402,267
January, 1928	144,289	300,281	431,310
February	153,363	329,380	450,058
March	173,929	368,191	523,287
April	171,028	359,182	513,144
May	199,409	425,565	616,179
June	210,957	447,642	595,054
Totals for year	1,862,510	$4,039,773	5,591,355
Increase over previous years, per cent	265	205	115

TABLE 1 AIR-TRANSPORT MILEAGE OF THE WORLD[1]

(Operations of scheduled services in airplane-miles over 12-month periods as nearly possible comparable)

Progress of Naval Aviation[5]

The past year has witnessed greater aviation activity in the Fleet. The general tendency in Fleet aviation is toward reducing the size of the type for each purpose, at the same time maintaining or improving its performance.

The commissioning of the aircraft carriers *Lexington* and *Saratoga* has aided materially in solving the problem of the role of planes at sea; naturally their operation brings about new problems to be worked out, and progress in this direction is also being accomplished. More extensive use of aircraft on the battleships and cruisers has given the same result.

Further advance in connection with metal construction is in full swing. The prevention of corrosion of light alloys is progressing, and these alloys as well as high-strength non-corrosive alloys are entering into all recent construction.

Of our service aircraft on hand June 30 of this year, 82 were four years old, 16 were three years old, and the remainder had been in service two years or less, hence the Navy is outfitted with modern planes and equipment, wooden propellers and wartime engines being obsolete.

The development of air-cooled engines is in a healthy state, with two permanent companies competing vigorously and several other companies engaged on experimental projects which are of considerable interest. The same competition exists in the field of metal propellers, and experiments on instruments and accessories are also pending which promise desirable results.

Now that the demands of Fleet aviation are approaching solution, the patrol types are again being placed in production. While these planes are too large for operation from ships, they operate to great advantage with tenders or from shore bases. Recently a plane of this type, systematically developed as an experimental project, broke several world's records for endurance and weight carrying. This type is now in production, and three other types which are at present in the experimental stage will be completed before the end of the year.

Thick weather and fog still present problems to which several possible solutions have been offered, but which require extended investigation and development. Progress has been made in navigation, but the safe landing of heavier-than-air craft in a fog is yet to be satisfactorily solved.

Military requirements have resulted in improvement in design staffs of contractors. The Five-Year Building Program with its steady demand has resulted in better organization and a larger force of skilled mechanics. To a degree the same is true of materials, but in this case the increasing demands have served to develop the interest of manufacturers. These good effects are bound to increase, and therefore the Navy Department finds a direct interest in the promotion of civil aeronautics through the development of resources in skilled personnel, materials, and organization.

The Marine Expeditionary Force, particularly in Nicaragua, has gained much valuable experience with up-to-date aircraft under actual operating conditions, clearly demonstrating the value of aircraft and bringing out the lines on which progress should be made. Particularly has the field of military-transport operation and requirements, observation and attack, been well covered.

In liaison with the Army Air Corps, a number of interesting projects are being investigated; duplication is avoided by each service keeping in close contact with the other on questions of mutual interest. When practicable, specific problems are allocated to Government department especially equipped for their solution, notably the National Advisory Committee for Aeronautics, the Bureau of Standards, the Forest Products Laboratory, and the Bureau of Mines.

In the lighter-than-air field, the *Los Angeles* and the semi-rigids at Lakehurst have been steadily engaged in training and development projects. Methods of mooring and handling have been improved, and much information has been gathered which will be of benefit in the construction and equipment of the large rigids about to be contracted for. The *Los Angeles* has demonstrated that it can land aboard a carrier and be refueled, regassed, and reprovisioned, making possible a greatly extended field of usefulness as well as demonstrating that emergencies can be met. It is expected that two of the largest rigid airships ever built will visit this country shortly and give a convincing demonstration of the commercial possibilities of this type.

To sum up, the Five-Year Building Program, a wise piece of legislation, is progressing in good order, and Naval progress has been advanced thereby. The establishment of the Aviation Branch of the Department of Commerce, and of the three Secretaries for Aviation, has aided not only military development but commercial development. As shown, this commercial development is an important aid in the progress of development of military resources.

[5] Prepared by Rear-Admiral W. A. Moffett, U. S. N., Chief of the Bureau of Aeronautics, Washington, D. C.

Progress in Military Aviation[6]

Progress in military aviation and its effect upon aviation in general during the past year has been as rapid as in any preceding year, but this effect has not been so apparent because the development was more in the nature of standard types of planes than in actual change of design. The Air Corps has concentrated upon the training of pilots, refinement in tactics, engine development, and on the planes and matériel. As now established Air Corps planes constitute six principal types: Attack, Bombardment, Cargo, Observation, Pursuit, and Training. The development has been limited largely to adapting existing planes to the newly developed aircraft engines in the 500- and 600-hp. classes.

In the line of equipment, suitable electrical and inertia starters have been made available for all service engines, and initiatory development of double-voltage electric generators gives promise of a big saving in the weight of radio installations.

Progress is being made along the line of metal construction. Initial cost, difficulty of repair, corrosion prevention, and increased weight have been potent factors in retarding the extensive use of metal covering for airfoils, it being felt that a definite and favorable answer to all problems should be obtained before metal construction is generally adopted for peacetime use.

All service airplanes, except primary training, now purchased by the Air Corps are provided with separately controlled landing-wheel brakes operated by pedals on the rudder bar. Investigation of the so-called "flat spin" which caused the crash of a standard service-type airplane led to extensive flight and wind-tunnel research to determine what condition characterized this spin.

Attack Types. The present attack airplane issued to the service is a modification of the Standard 0-1 (Curtiss) Observation type known as the A-3. This airplane meets requirements of the Attack group better than any previous type heretofore used.

Bombardment Type. Continuation of the bombardment program initiated last year resulted in comparative tests of six different airplanes to determine their suitability for procurement to replace the present types.

The most suitable airplanes were found to be the XB-2 and the XLB-6, procurement being made of both models which are biplanes, the former mounting two VG-1570 (Curtiss) engines developing 600 hp. each, and the latter mounting two R-1750 (Wright) engines developing 525 hp. each. An equal quantity

[6] Prepared by Major-General J. E. Fechet, Air Corps, U. S. A., Chief of the Air Corps.

of LB-7 airplanes which differ from the LB-5 model only in the substitution of Pratt & Whitney R-1690 engines is also being procured. The performance and flying qualities of these bombers will greatly exceed those of any type now in service.

Cargo Types. In the cargo class two airplanes were adopted for service use, the three-engine C-2 (Atlantic) series as standard, and the single engine C-1 (Douglas) series as substitute standard. Following its momentous flight to the Hawaiian Islands last year, the C-2 completed a very satisfactory service test which demonstrated its reliability and utility for cargo use. On the other hand, the single-engine C-1 model affords a less costly airplane suitable for use where reliability is not such an important factor.

Observation Types. There are four standard observation airplanes at present: namely, the O-1 (Curtiss) series, the OA-1 (Loening Amphibian) series, the 0-2 (Douglas) series, and the 0-11 (Curtiss) series. All of these are equipped with Liberty engines with the exception of the 0-1 series, which uses the Curtiss D-12 engine.

Experimental development was carried on with a new model Amphibian, incorporating a new vee-type air-cooled power plant and a single landing wheel in the center of the hull.

Pursuit Types. The P-1 (Curtiss) and PW-9 (Boeing) series of airplanes, using Curtiss D-12 engines, continue as standard pursuit types.

A few supercharged P-1 type airplanes were recently procured, under model designation P-5, for high-altitude work. These are equipped with Curtiss D-12-F engines with side-type superchargers.

Training Types. The PT-3 with Wright J-5 air-cooled engine was approved as the standard training type, in addition to the PT-1 which mounts the Wright E water-cooled engine.

Other Developments. Considerable work was done in aerodynamical research studying control characteristics, automatic leading-edge slots, methods of predicting performance of airplanes, and in wind-tunnel experiments. In general airplane development, make-ups have been constructed to determine ideal cockpit arrangements for corps observation, twin-engine bombardment and twin-engine airplanes for night observation, long-range day observation, and light bombing.

Aircraft Power Plants. The outstanding characteristic in power-plant development of the year was expansion of the air-cooled-engine field, with progress centering about the conventional radial type. Demands for increased power and flight performance, however, emphasized the need for experimentation on other types of air-cooled engines, and the more important experimental developments have been in this direction.

Progress on air-cooled engine design has, while satisfactory, not warranted abandonment of the water-cooled type, because there is yet no definite assurance that high-speed supercharged engines can be cooled successfully with air, nor has the development of the air-cooled engine reached the stage where it can supplant the water-cooled engine satisfactorily for high-speed work. These reasons, together with excellent prospects of improving performance of water-cooled power plants through higher crankshaft speeds, supercharging, and higher cooling temperatures, have warranted continuance of experimental water-cooled development.

Supercharger development has continued on the exhaust-turbine type, the Roots type, and the built-in geared centrifugal type. A new exhaust-driven supercharger, the Form F-2, was developed for 600-hp. engines and incorporates several general improvements over previous models.

The most interesting and possibly the most important step in carburetor development is the application of the mechanical metering system to aircraft engines. This work started with preliminary tests of two systems. The most promising system was selected for development, and in bench tests which were highly satisfactory the distribution variation between cylinders was less than 2 per cent at all speeds. The units have been fitted to a Curtiss D-12 engine for performance and endurance tests.

The principal activity in ignition work involved double-magneto development, although some work was done on single magnetos, battery ignition systems, and spark-plug requirements.

Evaporative cooling and high-temperature cooling liquids have major considerations in cooling-system development as a means of reducing weight of radiation surface required.

The evaporative cooling system developed for the Wright E engine is undergoing service test, and experimental work has been extended to produce a similar system for other service engines.

Equipment. Development of all classes of aerial photographic, electrical, instrument, radio, and miscellaneous equipment and accessories has been characterized by a consistent effort to improve operating efficiency of aircraft, individually and collectively, by means of new and improved devices and better installation arrangements.

In cooperation with the Fairchild Aerial Camera Company, the Air Corps has now in production or in preparation for production the most complete and perfected set of aerial-camera equipment in its history, and which it is believed far surpasses the photographic equipment of any other nation.

Other of the more important projects involve the following phases of activity:

1 Development of double-voltage generators; standardization of airdrome lighting equipment, and methods of flood lighting.

2 New liquid and gaseous oxygen equipment; improved instruments and methods for navigation and fog flying, including capacity altimeters and leader-cable methods for landing.

3 Experimentation with radio beacons and short-wave sets.

4 Development of detachable and form-fitting parachutes and improvement of seat and lap types; redesign of heavy-duty refueling units; photographic trucks, and balloon winches; redesign of electric-driven orientators and development of an air-blast-controlled orientator.

5 Development of tow targets, and miscellaneous aircraft accessories.

Lighter-Than-Air Craft. The trend of airship development for training purposes is toward enclosed cars having a welded tubular structure covered with doped cloth to afford complete protection for the crew. Air-cooled power plants are preferred to water-cooled types for the reason that no maintenance of the cooling system is required.

A number of other developments have been made in airship accessory equipment, including the helium purity indicator, mooring and handling equipment, winches, and other station equipment.

The rate per thousand flying hours of accidents due to engine trouble was reduced during the past year to one-third of the average rate prevailing in the two previous years. These accident rates indicate that 63 crashes from engine troubles were prevented by new methods and equipment. The lessening of aircraft accidents has, in a measure, been due to the installation at all Air Corps activities of the visual inspection system. By means of large charts posted on the wall of the hangar adjacent to each airplane, on which notations are entered from time to time in spaces provided therefor as to the operating conditions, flying time, performance, etc., of the airplane, an exact history of each airplane is available at first hand. Special sets of tools and equipment—part of the visual inspection system—have been furnished for each airplane in commission.

The equipment of a Transport type C-2 airplane as a laboratory and its use in connection with research work on aircraft radio

problems while in the air made it possible to investigate problems and conduct tests heretofore not possible, and further, has contributed more than any one thing toward overcoming difficulties encountered in this line of work. Important investigations have been carried out in connection with radio beacons, high-frequency transmitters, and receivers, transmission phenomena, double-voltage generators, and capacity altimeters.

The increase in radius of action of planes now used by the Air Corps has necessitated closer and more general study of aerial navigation by Air Corps personnel. The Flying Laboratory has also been equipped with special instruments for the purpose of carrying out research problems in aerial navigation.

During the fiscal year 1928 the Army Air Corps photographed areas in the United States approximating 35,000 square miles for the War Department and other Governmental bureaus.

Two methods of training were placed in operation at the Air Corps Primary Flying Schools, the "all through system" at Brooks Field, and the "stage system" at March Field. Both methods of flying instruction are being carefully studied, and it is possible that at some future date a training system will be evolved incorporating the relative merits of each.

If the succeeding years show a rate of improvement in personnel, matériel, and tactics commensurate with that of this year, there is no doubt but that the United States will continue its place as one of the foremost countries in military and commercial aeronautics, if not the greatest.

Airships[7]

The outstanding airship event of the year was the voyage of the *Graf Zeppelin* with passengers and mail from Friedrichshafen to Lakehurst. The successful completion of the voyage in spite of bad weather and an accident to the port stabilizing fin proved that the airship shares with the steamship the ability to reach its destination in spite of adverse circumstances. The general public compared the time of the *Graf Zeppelin*, 110 hours from the middle of the European Continent, 3425 nautical miles from Lakehurst by the great circle, with the *Mauretania's* record of 122 hours from Sandy Hook to Cherbourg, a distance of only 2925 nautical miles. The difference in the lengths of the voyages and the fact that steamships are frequently delayed by storms and mishaps were overlooked.

TABLE 3 COMPARATIVE CHARACTERISTICS OF THE AIRSHIPS "LOS ANGELES," "GRAF ZEPPELIN," AND "ZRS-4"

	Airship		
	Los Angeles	*Graf Zeppelin*[1]	*ZRS-4*
Nominal gas volume, cu. ft.	2,470,000	3,708,000	6,500,000
Length overall, ft.	658.3	776.2	785
Maximum diameter, ft.	90.7	100.1	132.9
Height overall, ft.	104.4	110.6	146.5
Gross lift, lb.	153,000	230,000	403,000
Useful lift, lb.	60,000	108,000	182,000
Number of engines.	5	5	8
Total horsepower.	2000	2550	4480
Maximum speed, knots.	63.5	69.0	72.8
Range at 50 knots, naut. miles.	3500	6850	9180
Slenderness ratio.	7.25	7.75	5.90
Ratio of useful to gross lift.	0.39	0.47	0.45

[1] NOTE: For purposes of comparison, the *Graf Zeppelin* is assumed to be inflated with helium. When inflated with hydrogen and fuel gas, her range at 50 knots is about 9000 nautical miles.

The U. S. S. *Los Angeles* made a notable voyage in February and March to the Panama Canal Zone. The outward voyage was a non-stop flight from Lakehurst to New York and thence to Panama. Returning the ship refueled at the mooring mast of the U. S. S. *Patoka* off the south coast of Cuba.

Construction of the two great British airships, *R 100* by the Airship Guarantee Co. and *R 101* by the Air Ministry, has continued, but hopes of their getting into the air in 1928 were disappointed.

In the United States, a contract has been placed by the Navy Department with the Goodyear-Zeppelin Corporation for the construction of two rigid airships of 6,500,000 cu. ft. volume each. The designs of these ships show a very great advance over any previous airships. They will have a full speed of 72.8 knots, and a range of 9180 nautical miles without refueling at 50 knots speed, as compared with 63.5 knots full speed and 3500 nautical miles range at 50 knots for the *Los Angeles*. Their hulls will contain hangar space for five small fighting or scouting airplanes. A new type of girder construction will be employed; and the strength of the ships will be relatively about double that of the *Los Angeles*.

The principal characteristics of the *Los Angeles*, *Graf Zeppelin*, and *ZRS-4* are compared in Table 3.

Construction of the small experimental metalclad airship *MC-2* for the Navy Department has been continued by the Aircraft Development Corp., of Detroit, Mich. A decision to change the hull plating from duralumin to the new metal, alclad, which is very much more resistant to corrosion, afforded an opportunity to test to destruction the tail cone which had already been constructed of duralumin. The test showed that the structure had great tenacity, even when badly crumpled by internal suction amounting to nearly half an inch of water. It was impossible to burst the plating by an internal pressure as high as 14 in. of water.

ALEXANDER KLEMIN, *Secretary.*

AER-51-2

Problems of Commercial-Plane Production

By WALTER H. BEECH,[1] WICHITA, KANSAS

The author compares conditions in the aircraft industry today with those which obtained in the automobile industry during its infancy; there are no precedents to guide, no sources of supply established, and no types determined. He then discusses six factors which enter the construction of a commercial plane—safety, airworthiness, performance, durability, comfort, and appearance. Considerable attention is paid by the author to the airplane-engine situation, which is unfavorable to airplane manufacturers. This is followed by a discussion of factory machinery and equipment, labor, and a brief description of the straight-line production system of the Travel Air factory. The paper closes with a short discussion of production methods of the future.

ESPECIALLY in these days of the infancy of our industry is a full and free exchange of experiences of great value, that no steps of progress need be retraced and that forward-looking airplane manufacturers may, by exchange of ideas, work together for the advancement of every legitimate phase of the business as a whole.

These problems are not unlike the problems that confronted the automobile manufacturer in the early days of that now great business. There were no precedents to guide, no sources of supply established, no type or types determined. It was a case of dig, search, and dig again, with thousands of dollars spent in finding out what to do and how to do it.

The airplane industry has been able to draw heavily upon the experience of that industry which, from the standpoint of individual transportation, is our nearest and most valuable ally.

Naturally the first airplanes, like the first automobiles, were made by hand one at a time. In no other manner could the structural ideas of the designer be proved or disproved. Only through trial and test could experience be gained, stresses and strains determined, airworthiness demonstrated, and performance proved. In the machine shop, at the forge and bench experienced pilots and mechanics worked side by side to bring through working models embodying the designer's theory of construction. The fundamental factors of airplane construction were recognized by all, but the adaptation of these factors to particular types of construction challenged and is still challenging the skill, patience, and inventive genius of the best engineers and designers in the aviation world.

Out of all this experimental work, out of all the months and years of patience and unceasing effort, certain types of airplanes have been developed that are no longer considered experimental in design. These types have the approval of the United States Government through a type certificate. The airplane designer or manufacturer who has reached that place in the development of his product is then ready to consider the problem of the production of his airplane in sufficient quantities to meet competition, take care of the expense of distribution, and yet hope to save a sufficient margin of profit to justify the faith of the stockholders who stake their money on the commercial success of the venture.

Approximately four years ago the Travel Air Manufacturing Company reached the place in its development and progress where it felt justified in aggressively entering the commercial-airplane field. With this decision made, the company was immediately confronted with the even more important problem of a factory arranged, manned, and equipped for volume production at competitive selling prices yet without sacrifice of quality. Even with the experience of the automobile manufacture as a general guide, there were no airplane precedents whatsoever to follow, for this was one of the first airplane manufacturers to undertake volume production.

Study and analysis led to the conclusion that six factors enter into the construction of a good commercial airplane. These are: safety, airworthiness, performance, durability, comfort, and appearance. While the relative importance of these qualities varies somewhat with the type of ship, in all cases safety is the paramount issue.

A safe airplane must leave the ground within a reasonably short distance, be able to climb rapidly under good control, have a reliable motor and controls, be structurally substantial, not spin dangerously if stalled, come out of action quickly, and land easily.

Airworthiness embodies stability, steadiness in rough air, and controllability with light or heavy loads.

Performance includes take-off distance and time, rate of climb, ceiling, high speed, land speed, landing distance, fuel economy, and cruising range.

The other factors of durability, comfort, and appearance need no explanation.

Planning for Production

Assuming the analysis just stated to be fundamentally correct, the important problem remained of planning for production on that basis and then putting the plan into practical operation.

First, consider for a moment the steps involved in producing a new model. They are: (1) design for simplicity of construction and assembly with as many identical fittings and parts as possible, (2) engineering, (3) detail, (4) fabrication, (5) testing. The general design is first worked up in the rough. Then a stress analysis is made of the structure to determine the size of the members. Changes in the original design are frequently made at this point to improve conditions which by analysis are shown to be unsatisfactory. The detail drawings are then made and sent to the shop. The production of the first two or three planes is always more or less experimental, but if the engineering is well done, the performance is accurately calculated and is found to vary only slightly from that found by actual tests. From then on the problems of commercial production include materials, factory equipment, labor, and a production schedule.

Materials

The materials for construction should be chosen, first, for strength, durability and lightness; second, for ease of manufacture; third, for reliability of supply; and fourth, for price.

Any well-organized airplane manufacturer has no especial difficulty in selecting materials for strength, durability, and lightness, nor for ease of manufacture or assembly. The difficulty comes in the reliability of the supply and the price that must be paid.

Consider as examples of the gravity of this problem the question of the proper sizes and types of steel tubing and the matter of engines.

Every manufacturer in the industry knows from personal and expensive experience the difficulties surrounding the purchase of the steel tubing he wants from a source of supply that is depend-

---

Presented at the National Meeting of the A.S.M.E. Aeronautic Division, Wichita, Kansas, September 21, 1928.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

able in both quality of product and the delivery of that product at the time it is needed. There seems to be either a feast or a famine—a long inventory or no inventory at all, with telegrams and long-distance calls to the parts manufacturer that the week's production of ships may not be clogged. All this effort adds to the cost of the finished product, and this cost must either be absorbed, with consequent loss of profit, or passed on to the purchaser in the higher price of the ship itself. The former is disastrous to the balance sheet of the company. The latter is not practical because of contract relations with dealers and distributors at fixed list and discount figures.

The motor situation is an even greater problem. The OX-5 situation following the war is probably a large part of the reason why the manufacturers of airplane motors were reluctant about making volume production plans on definite delivery schedules. A policy of watchful waiting with an ear to the ground seems to have been, and in many instances still is, their policy. What would be the condition of all airplane manufacturers today had they waited, like the motor folks, for a clearly defined market to be established before they started to make airplanes? We all would still be making airplanes one at a time by hand in the back room of some planing mill.

It is difficult for airplane manufacturers to see why engine manufacturers could not foresee the exhaustion of the supply of OX-5 motors within a comparatively short time as well as the ultimate demand of the airplane buyer for more power or more performance than could be expected from this war-time engine. Had they done so the situation of motor production in line with the present demand would be much more nearly in balance today.

There is another phase of the motor question that challenges the attention of any airplane manufacturer who is on a regular production basis—that is the practice of many engine companies in accepting orders of one or maybe a few engines from airplane companies who are as yet in the experimental stage and with whom commercial production is at best a remote possibility.

With a limited supply at best of motors that have proved themselves of unquestioned value in an airplane, the allotment by the engine builder, from that limited supply, to everybody who wants one or perhaps a few, works a decided hardship upon the airplane companies who have large sums of money invested in buildings, equipment, personnel, and selling organizations. It is not intended to suggest denying the airplane company just started the same right to all sources of supply as the older and more firmly established companies, but it is thought that a better understanding between engine builders and airplane manufacturers who are in volume production would give the former a steadier volume of business in the years to come, and would give the commercial-plane producer a far better chance to protect his investment, as well as more aggressively to seek and develop new markets for airplanes. Both would then be benefited, where at present the engine builder is the sole temporary gainer.

Factory Machinery and Equipment

Factory machinery and equipment must be commensurate with production. It requires perhaps less equipment to manufacture an airplane than any product selling at its price. This means that any one with a few tools, an acetylene tank and blow torch, some steel tubing, and an engine on order can start "manufacturing" airplanes. This condition is unfortunate because it permits many people to enter the business who are not adequately equipped in experience and financial backing, and accounts in part for the existence of some 140 or more airplane companies in the United States today.

This situation is somewhat parallel to that of the radio of a few years ago. Radios were easy to make by hand if the maker had even a slight knowledge of electricity and could wind an armature and set up an aerial. The electrical-supply houses naturally flooded this new market with coils, wire, controls, and all other accessories. Hand-made sets went into thousands of homes. The maker could operate them, but not the average user. Nothing was standard. When there was a failure of "reception" there was no service. Not until the radio was brought to scientific standards of construction and operation by a comparatively few aggressive and far-sighted manufacturers did radio come into its own and earn a permanent place in practically every home.

The so-called saturation point will never be reached in the sale of airplanes any more than it has been reached or ever will be reached in the sale of automobiles. This means that every airplane of proved type and construction that is made can be sold and that it will stay sold and bring new business through owner satisfaction.

The danger lies in placing on the market the untried and unproved product. As yet the public as a whole is not familiar enough with types and construction to discriminate. Herein lies the danger with the "experiment" that is offered for sale and the expense of repairs and upkeep of the "orphan" for which service is not available.

No undue discouragement should be felt over this situation. The loss will have to be borne by the investor who did not get down to fundamentals before purchasing his stock and by the purchaser who did not concern himself about the untried design or the question of service after sale. It is one of the burdens of a new industry which modern factories with modern machinery building ships of proved design will overcome in time.

Labor

At the start of any new manufacturing endeavor, labor usually consists of all-round mechanics upon whose ingenuity depends the success of the project. This applies with special force to the airplane. As the organization grows the labor involved in production becomes more specialized, for specialization is the basis of efficient production. The all-round man is replaced by a craftsman who devotes his time to one particular operation and gains skill and efficiency each day. Often the all-round man develops into the specialized job. Departmentalization of the factory rapidly follows, the old and tried men becoming foremen of the various departments. Personnel work comes into being. The welfare of the workmen is found to be for the good of the product as well as the contentment and satisfaction of all employees.

With us the process of specialization is still in its infancy, but is being studied constantly that the men may be legitimately spurred on to their best efforts.

We try, wherever practical, to give our men the "feel of the air" by taking them up. This gives them a feeling of grave responsibility in their work in knowing that the lives of the users of airplanes are largely in their hands in building safety into the airplane.

Travel Air Factory and Production Scheme

At present there are fifteen departments in the Travel Air factory, each in charge of a foreman and a few with sub-foreman. These departments are: welding, two fuselage assemblies, fuselage paint, wing paint, milling, wing assembly, final assembly, testing, maintenance, transportation, office, engineering, stock room, first aid, and safety.

Let me trace the production of a ship through our factory. At the west end of factory "A" the fuselage is begun. Tubing is drawn out of the stock room nearby, cut to the proper lengths on a tubing saw, welded on jigs, the engine mount built up and bolted on. The fuselage is then passed down the line through the fuselage-assembly department. The fitting department occupies the

side of the building at this point. Here the completed fittings are assembled on the fuselage. The wire department occupies a balcony on one side, and the upholstering department occupies a balcony on the other side. The purpose of these balconies is to concentrate the parts departments near the assembly department so that wires, fittings, etc., will not have to be moved more than a few feet before they can be assembled on the ship. Next the engine is installed in the plane and the cowling and tanks are added at a point opposite the sheet-metal department. The fuselate is then covered and passes into the dope room. Dope and paint are sprayed on and the fuselage passes out into the final fuselage-assembly department. Here the landing gear, tail surfaces, and center section are assembled.

Factory "B" abuts factory "A." Passing to the far end of factory "B" we find the mill room. Here lumber is milled to the proper size and shaped for wings, turtle backs, and cabin framework on the monoplane. The parts are assembled in the wing assembly department which joins the mill room. The fittings are added and the wings covered. The wing then passes into paint and dope room No. 2. The completed wing is then moved to the final assembly and rigging department where it is dropped on the fuselage which has been moved across the court from factory "A." After the ship has been rigged it is given a final inspection and then test-flown.

From this brief outline it will be obvious that we have adhered strictly to straight-line production and a policy of specialization. We have also facilitated production in our design. Fittings which formerly were built up of many pieces are now formed from one piece. Brazing has been cut to a minimum, and by slight changes in design nearly all fittings are now welded.

Production Methods of the Future

As to the production methods of the future only a guess can be made. We feel the use of machinery will increase, and as a result metal will enter into the construction more and more. Metal wings will be justified as soon as production mounts to a scale which permits the investment in the necessary equipment for their construction. Machined fittings will replace welded fittings, when the quantity of fittings produced is such that the machinery necessary to produce them will pay for itself.

Labor incentives will play a more important part in the future. The present status of the industry is such that little work can be done on time study and incentives. We are now at the beginning of a period when this phase of production will obtain considerable proportions. Bonus systems and piecework will come as soon as the necessary preliminary time studies can be made.

Present selling prices are to be maintained or lowered as time goes on only through volume production raised to the highest point of efficiency. This means sharp and clearly defined decisions on types of planes that are to be built and a sales program to the vast potential market that has not as yet been scratched.

This only requires aggressive selling on a constructive basis to insure an even flow of business to the sales manager's desk so that an even flow of ships sold at a fair price and yielding a fair profit may daily leave the factory door.

Historical Sketch of the Development of Aerodynamic Theory

By W. F. DURAND,[1] STANFORD UNIVERSITY, CAL.

This paper is intended to give, in brief historical outline, a sketch of the development of aerodynamic theory from the time of Newton to the present day. Newton's theory of fluid motion and the resulting formula for the force reaction resulting between an inclined plane and a fluid in relative motion are briefly stated and the insufficiency of the formulas noted. Reference is then made to the various mathematical aids which were developed during the next century, and which made possible the investigation of fluid motion based on the concept of continuous change and the "perfect fluid" of the mathematician. The limitations of this concept, especially with reference to the explanation of force reactions between the body and the fluid, are then noted, together with the introduction of the idea of "circulation" and generally of the physical picture as developed by Lanchester and then in mathematical form by Prandtl and his school. These are then briefly sketched and the results of the introduction of these new ideas indicated.

Reference is then made to the problem of the drag, only in part taken care of by the Lanchester-Prandtl vortex theory, and to von Karman's work leading to his concept of the "Karman vortex street" and thence to the measurement of a further element of the drag; and finally to the third element (depending on skin friction) as at present dependent chiefly on direct physical measurement. In addition to the problem of lift and drag, the problems of stability and control in the air are briefly referred to, followed by mention of the dependence of theory on experimental research and to the vast amount of wind-tunnel investigation which has been made during the past two decades. Brief mention is then made of the two problems introduced by such work—the correction for "wall interference" and the "scale factor" due to the imperfect fulfilment of the conditions for kinematic similitude. This section closes with a mention of some of the problems which characterize the advancing fringe of progress in aerodynamic theory and which in large part still remain for future examination and study.

Then follows a brief section dealing with the screw propeller with reference to the chief stages of the development of propeller theory as suggested by the names Rankine, Froude, Drzewiecki, Prandtl, and closing with a suggestion of some of the problems which characterize the advancing fringe of this phase of general aerodynamic theory.

AVIATION in its broader aspects presents at least four well-marked divisions:

1 Aerodynamic theory
2 Aerodynamic experiment and research
3 Airplane design and construction
4 Airplane use, civil or military as the case may be.

Logically these should proceed in the order as stated.

Thus aerodynamic theory should lie at the foundation and when justified and supplemented by experiment and research should point the way to design and construction, after which come utilization in such manner as may be desired.

Historically, experiment and research, design and construction have often preceded theory. Especially was this true of the conditions a quarter century ago in their relations to the present body of aerodynamic theory.

The present paper is restricted to a sketch of the historical development of division (1), aerodynamic theory. No attempt will be made to bring in, except as incidental or auxiliary, any reference to the other three divisions.

The basic problem in aerodynamics involves the interaction between a plane or wing-shaped body and a fluid (the air) in relative motion one with the other.

We can hardly go as far back as Leonardo da Vinci for any beginnings of what properly may be called aerodynamic theory. Great as was the genius of Leonardo and interesting and suggestive as are his writings on aviation, they can hardly be said to have formed a start for aerodynamic theory.

For the first definite beginnings of such theory we must come down to Newton and his times. We find here three elements which served as foundation for the first approach to a theory of the interaction between a fluid and a plane in relative motion, one with the other. These were as follows:

1 The Newtonian concept of relativity in virtue of which the problem might be examined either by considering the fluid at rest and the plane moving through it, or the plane at rest and an infinite fluid streaming past.

2 The concept of a fluid as composed of discrete particles without interaction among themselves.

3 The Newtonian mechanics, through which it became possible with the physical picture provided by (1) and (2) to express in quantitative form the force and momentum interaction between, for example, a plane and a fluid in relative motion along a line oblique to the plane.

Based on Newton's second and third laws, it became simply necessary, in order to determine the force reaction along a line inclined at any angle to the line of relative motion, to determine the time rate of the change of momentum produced in the fluid medium estimated along this same direction; and in particular, to determine what we now call the lift, or force reaction at right angles to the line of motion, it was only necessary to determine the time rate of the change of momentum in such direction, and similarly for the drag or force reaction along the line of motion.

At this point, however, it became necessary to make some further assumption regarding the elastic properties of the particle assumed as the element of the fluid. The picture of the fluid assumed provides in effect a stream of moving particles or little bullets, as it were, moving independently and impacting with the plane. Three assumptions are then possible:

1 Perfect elasticity as between particle and surface at the point of contact
2 Complete inelasticity as between particle and surface
3 Some intermediate condition of partial elasticity.

In the first case the particle will rebound from the plane with velocity unchanged and at an angle with the plane equal to that of approach. In modern terminology with an angle of approach or of attack = Θ, this would produce a vector change of velocity represented by turning the vector V through the angle 2Θ.

In the second case there will be no rebound and we may assume the particles to slide along the plane and leave it in the line of the plane itself. This would produce a vector change represented by turning the vector V through the angle Θ.

In the third case there will be some intermediate condition and the vector change will be represented by turning the vector V

Paper presented at the International Civil Aeronautical Conference, Washington, D. C., December 12 and 14, 1928.

through some angle intermediate between Θ and 2Θ. It is well known that Newton's assumptions give rise to the "sine square" law relating the total force to the angle of inclination—a law which persisted in textbooks and elsewhere long after experiment had shown it to be in error.

It will not be necessary to further discuss the results of these various possible assumptions. It is known that experimental research by Borda, d'Alembert, Dubuat, Hutton, Duchemin and others showed that the results of the application of this physical picture to the problem in hand indicated clearly the inaccuracy of the picture and the need of a complete revision of the physical concepts involved.

Reference in passing may, however, be made to another line of reasoning attributed to Euler which gives the first power of the sine instead of the second. While based on a questionable reasoning, this law was later shown, experimentally, to have, for small angles, a very satisfactory degree of accuracy. Still later Duchemin's empirical formula gave a still more satisfactory expression for the relation between the total force and the angle of inclination. In all this, however, there was nothing which gave any rational explanation of the development of these force reactions or of the particular physical conditions upon which they were dependent.

It thus became clear that this particular picture of the relations between a plane and a fluid in relative motion gave results obviously incomplete and imperfect. In fact, there is no reason for assuming that Newton himself considered this picture of a fluid and of its action on the plane as anything more than a trial hypothesis—the best he was able to make and use with the tools at his disposal in terms of mathematics. Furthermore, it is not easy to see what other pictures could have been treated mathematically with the means at his disposal. His own concepts of the calculus had not reached the point which made available the differential equation as an instrument permitting the study of the problem from the entirely different and more natural viewpoint furnished by the picture of a fluid as a continuous medium.

The development, during the century which followed Newton and Leibnitz, of the differential equation as a means for the study of the phenomena in nature which are assumed to involve continuous change in space and time, was an achievement the significance of which it would be hard to exaggerate; but no such means was available in Newton's day, though the germ of the entire development lay in the concept of his "fluxion" or rate.

However, as time passed it became increasingly clear that the trouble with the formulas for the force reactions between a plane and a fluid medium, the two in relative motion, was to be sought in the picture of the fluid and its relation to the plane around which it is considered to be flowing.

Finally, about a century later, with the development and provision by the differential equation of a tool fitted to the hand of the student of such natural phenomena, it became possible to approach this problem from the standpoint furnished by an entirely different concept regarding the physical constitution of a fluid.

The picture which thus developed, viewed from the standpoint of the possibility of mathematical treatment, was that of a continuous medium with infinite mobility—that is, a medium, the parts of which, however conceived of, may move past each other with no tangential or shearing resistance. This gives us the so-called "perfect" fluid of the mathematician—the fluid of viscosity zero. It is well known that in Nature there is no such fluid—that all fluids exhibit some degree of viscosity—some degree of tangential or shearing stress resisting the sliding of one portion or element of the fluid relative to another. However, the admission of this element into the picture increases the difficulties of the mathematical treatment to a degree which has thus far rendered impracticable any solution except in certain very special and restricted cases.

On the other hand, the omission of this feature of the problem, reducing the medium to the so-called perfect fluid condition, has rendered possible, through the application of various mathematical devices, a very considerable generality of treatment—such a development of the details of the physical picture, in fact, as should give full information regarding all dynamic relations involved in the problem—but only true, of course, for the "perfect" fluid.

Before speaking of this development of the picture, however, it will be well to go back for a moment to note the two forms which the general differential equations applying to this problem may take.

These two forms have been given names from Euler and Lagrange, though both trace back to Euler. In the Eulerian form, the results are calculated to give information regarding the field distribution of velocity and pressure while the Lagrangian relate to the history of a particular particle.

It is well known that the equations in the Eulerian form are much more manageable than in the Lagrangian form, and furthermore the former seem better adapted to give more immediately the information desired. It is clear that with a field knowledge of velocities, the entire field as regards paths of flow, distribution of pressure and of momentum becomes known, and most of the things with which we are concerned become immediately determinable.

For these reasons, the equations in the so-called Eulerian form have been usually employed, and have rendered chief service in building up this phase of the general treatment of the problem of fluid motion.

Granted then that we thus have means whereby, for bodies of certain forms at least, we may obtain a complete geometric and dynamic account of the field occupied by a fluid between which and the body there is a motion of translation measured by a velocity V, what further useful results may be drawn from the knowledge thus acquired? Here enters the tragedy attaching to this splendid development of mathematical science as applied to a concept of a fluid which seems, at least, to be closer to reality than the one employed by Newton.

The results, as well known, furnish no indication of any over-all force reaction between the body and the fluid, or rather they show that, with the "perfect" fluid as defined by the equations, there can be no such over-all force reaction. These results are therefore valueless so far as giving us any explanation of how a "lifting" force can be obtained upon a plane moving in a fluid medium and in an attitude oblique to its line of motion; or again as to how or why, in such case, there develops a force in the line of motion and opposed to it, or again, as to any measure of these forces.

It might well be questioned therefore whether, with this complete failure so far as any measurement of force reactions is concerned, any useful result had been accomplished through this new attack on the problem. The answer is that, though in itself this particular development was a failure as regards the furnishing of either an explanation of the origin of any such force reaction or its measure, it nevertheless did furnish a foundation and a general method, which, with the addition of certain further elements of detail in the picture, have carried us a long way toward the desired goal.

Before considering this further advance, however, some note should be taken of certain matters of detail regarding the development thus far.

In order to be able to trace stream-line paths and thus to determine the geometrical and dynamical details of the fluid field, use is found for a combination of five mathematical and physical agencies or concepts as follows:

1 The differential equation
2 The Newtonian mechanics
3 The principle of potential
4 The concept of sources and sinks
5 The method of conformal transformation.

The differential equation, as already noted, furnishes the mathematical means whereby we are able to trace the details of continuous change.

The Newtonian mechanics furnishes the tie between geometry and the dynamic details of the fluid field.

The principle of potential vastly simplifies the procedure in detail by furnishing a single expression, the vector differentiation of which gives immediately the velocity in that direction.

The concept of sources and sinks in two dimensions and in its simpler form furnishes the start for the determination of stream-line paths for certain resultant geometrical forms of cross-section of body. In its more generalized form, especially as developed by D. W. Taylor in his paper before the British Society of Naval Architects, it can be made to give the stream-line paths for flow either in two or in three dimensions and for a wide variety of forms symmetrical about an axis parallel to the direction of motion. In all such cases, however, the procedure is from an assumed distribution of sources and sinks, to the resultant stream-line form and the lines of stream flow about it. This procedure, unfortunately, is not reversible. That is, there is no direct way, having given a particular form, whereby we may determine the distribution of sources and sinks which would give such a form as a stream-line body with its accompanying field of stream-line flow. However, by a process of trial and approach, using a series of sources and sinks distributed along a line and with suitable variation of interval and strength, close approximations may be reached to any proposed form not too far removed from what are usually classed as "stream line" forms.

To Rankine in the last century must be given, perhaps, the chief credit for the application and development of this method to the production of stream line, or as he called them, "neoid" forms for the water lines of ships. The same general method was again taken up in the late years of the last century by D. W. Taylor, and generalized by the substitution of the concept of a continuous slot, so to speak, for a series of separate points. Such a slot, with continuously varying strength of flow, positive or negative, becomes, then, the final generalization of the source and sink concept, and as Taylor has shown, may be made to produce almost any form within the range of so-called stream-line forms, together with its accompanying field of stream-line flow.

The method of sources and sinks, is not, however, so readily applicable to the treatment of problems of flow about unsymmetrical forms, such for example, as the airplane wing. For the treatment of such cases, the Schwartz-Christoffel transformation (or as it is now commonly called, the method of conformal transformation) has provided us with an agency of marvelous and far reaching power. In the whole domain of the application of mathematical methods to the treatment of physical problems, there is perhaps nothing more impressive than the application of the wizardry which attaches to the imaginary $\sqrt{-1}$, to the transformation of one entire geometrical field into another of widely varying form, but with fundamental relations subsisting between the two such that we are justified in saying that if field number one represents the field of stream-line flow about a particular form of solid boundary, then will field number two represent likewise the field of flow about the transformed boundary form.

Now one of the earliest problems solved by the source and sink method was the determination of the flow about an infinite cylinder placed in a stream flowing in a direction at right angles to its axis. This means, in two-dimensional motion, the flow about a thin circular disk. Now comes in the method of conformal transformation and provides us with means for transforming the circle as a contour into airfoil shaped forms, and with it, the flow about the circle into what it would be about the foil.

Here again, however, we must accept the limitation of a "one-way street." Having given the circle and its field of flow and an assumed formula of transformation, we can find, by straightforward methods, the resulting form and field of flow. Having given the airfoil form, however, we cannot determine directly the formula of transformation which would produce such form from a circle and thus we cannot, in general, determine by direct procedure the field of flow for a given form moving in an indefinite fluid.

However, by indirect methods—by trial and approach, we may continuously so modify the formulas of transformation as to give a satisfactory approach to all ordinary forms of airfoil sections.

Joukowsky's pioneer work in this field during the second decade of the present century laid the foundation for the development of an entire series of airfoil sections named for him, and the field of flow about which could be immediately determined by these methods.

By such means, therefore, the mathematical agencies for which were developed largely during the latter half of the last century, we are now able to determine, at least with close approach, the field of flow for almost any proposed airfoil form.

It should also be noted at this point that by the use of the generalized source and sink method, as referred to above, the field of flow in three dimensions about spindle-shaped bodies may be also determined to any degree of detail necessary. In this manner the conditions of flow and the distribution of pressure about airship forms (aside from appendages) may be developed to a surprising degree of accuracy as determined by comparison with measurements on full-sized forms.

These various agencies serve, therefore, to give with reasonable accuracy the field of flow for a perfect fluid about any form of airfoil, considered as a two-dimensional flow, or about any spindle or fusiform body considered as a three-dimensional flow.

It thus results that for the case of two-dimensional flow, or what would correspond to the flow near the middle portion of an airplane of very long span, or again for any spindle-shaped body in three-dimensional flow, and assuming always a non-viscous fluid and rectilinear flow (not necessarily parallel to the axis), we are in a position to map out with a high degree of accuracy the lines of stream flow and to investigate the velocity and pressure conditions about the body. But as before indicated, while all of this resulted in a picture not far wrong, at least in many ways, it gave, nevertheless, no measure of the ultimate force reaction between the body and the stream, or rather, it indicated that such force reaction was always zero.

Confining our attention to the airplane, the problem then became, how to develop a theory or a picture which would explain, for an airfoil shaped body suitably exposed in a current of air, the lift or the force at right angles to the direction of relative motion, and the resistance or drag—the force along the line of relative motion.

The next step in the solution of the problem traces back to Helmholtz, who in the latter part of the last century, developed his theory of vortex motion and thus, quite unwittingly, laid the foundation for one of the most significant of the more recent advances in the field of theoretical aerodynamics.

The student of these problems thus became furnished with two basic modes of flow which he might use in his investigations—rectilinear flow and rotating or cyclic flow, and it was soon realized that these modes of flow might be combined in an infinite variety of ways.

In particular it was seen that assuming a combination of a

rectilinear two-dimensional flow with a simple rotating or cyclic flow, about a solid circular disk (two-dimensional body) the theory as it was already developed in the basic equations of fluid mechanics would furnish immediately the explanation and the measure of the force at right angles to the direction of relative motion.

Thus with a thin circular disk and a cyclic flow (the simplest possible case of the type of flow investigated by Helmholz) the explanation of one of the forces acting between the solid and the fluid came immediately to hand, and not only its explanation but its measure as well, and to a very satisfactory degree of accuracy when compared with the results of experiments.

Thus came into the picture the concept of "circulation"—the line integral of the velocity taken about any closed path—as a factor bearing a direct relation to the measure of the lift force. But while this was all simple enough, granting the cyclic motion, there seemed no possible way of explaining the development of any such motion in a perfect fluid. Or rather, the mathematical expression of a "perfect fluid" carried with it the impossibility of generating any such motion in a body of fluid not already endowed with it, or otherwise of destroying such motion once it be assumed to exist. But we are not, in fact, dealing with the perfect fluid of the mathematical equations; but with a medium (air) having a small though definite viscosity.

At this point Lanchester in 1907 came forward, with his remarkable physical insight, and gave a reasonable and convincing explanation of the generation of just the type of circulation about the wing which was needed to furnish the explanation of the lift force.

This was followed shortly by Kutta, who gave to the problem its expression in mathematical form and deduced the now classic formula relating the lift force to the circulation, the linear velocity and the density of the medium.

But this relation, important as it is, is not enough to deal with the problem of the actual airplane wing. The flow must here be considered in three dimensions and many secondary phenomena not present in the two-dimensional problem must be taken into account.

Here again came Lanchester and extended his vision regarding the case of circulation about an infinite wing to the vastly more complete case of the actual finite wing. Without attempting expression in mathematical terms, he developed in measurably full detail the physical picture of the complex system of vortex motion shed from the airplane wing, and which we have since come to accept as our point of departure in the detailed study of the wing, especially in combinations of two or more.

But the Lanchester picture lacked quantitative interpretation. In particular, there was needed some means for analyzing and evaluating the special distortion of the rectilinear field of flow produced by the presence of the wing—a distortion which we now express in terms of the downward component of velocity at the wing, and to which the name "downwash" is commonly given. It was seen that a given wing must be considered as acting in a field thus distorted due to its own presence, and further that in the case of two or more wings, the field in which each one acts will be subject to the distorting influence of each of the others.

At this point, Prandtl brought to the problem the resources of high mathematical skill, familiarity with the vortex theory of Helmholz and a physical picture, gained at first largely independently, but nevertheless quite in accord with that previously developed by Lanchester. In his later work, Prandtl had the advantage of familiarity with Lanchester's development of the physical picture and in public addresses has given to Lanchester generous recognition for his pioneer vision in picturing the physical conditions of this problem.

In the development of this splendid capstone to the modern aerodynamic theory of non-viscous fluids, we must give to Lanchester the credit for his pioneer work in the development of so complete and so satisfying a physical picture, while to Prandtl and his school must go the credit for translating this splendid picture into mathematical terms and for reducing the theory to the point of practical quantitative application.

One of the most interesting features of the theory of vortex motion is the perfect mathematical equivalence between a line vortex in an indefinite fluid and a conductor carrying an electric current, with reference to the so-called "induced velocity" in the fluid field on the one hand and the magnetic induction on the other. Aside from a constant factor, or in other words, aside from the arbitrary choice of the units of measure, both of these quantities have the same expression.

It follows that to the extent to which the action of a wing may be represented by a line vortex, to that extent may the action of such a wing or of any number of wings in combination (with reference to the production of the downwash velocity) be represented by an assemblage of electrical conductors with a specified current flowing in each, the magnetic induction at any point in the field representing the analogue of the downwash velocity at that point.

The development of this theory at once shed a flood of light on the general problem of the airplane wing, both with reference to the production of lift and the occurrence of one component of the drag.

As chief contributors to this result in its various details, mention should be made of the names of Prandtl, Joukowsky, Kutta, Betz, Munk, and Mises.

Thus far, then, we have a theory, satisfactory and practicable, and admitting of application under conditions as follows:

1 To the case of non-viscous fluids, or practically to fluids with viscosity small, or where, from the nature of the case, viscosity will play a relatively unimportant part.

2 To the extent to which it may be proper to replace the wing itself by a so-called "lifting line" and then the latter, mathematically, by a line vortex with its attendant system of tip and trailing edge vortices.

The theory may then be applied to:

(*a*) The explanation of lift, its measure and its relation to other conditions and phenomena involved in the problem.

(*b*) The explanation of downwash, its measure, and consequent influence on the field of flow.

(*c*) The explanation of the occurrence of a part of the drag force (induced drag) and its measure.

As noteworthy as were these achievements and as far as they seem to carry us toward a full and adequate treatment of the problem of the forces acting on the wing of an airplane, they yet fail to give any adequate treatment whatever of the drag, the force in the line of relative motion of the fluid and the wing.

It is true that the theory does give one component of such force—the induced drag. The lift force reckoned at right angles to the direction of relative motion at the wing is now no longer at right angles to the direction of movement relative to the great body of undisturbed air. The downwash u combining with the linear velocity V produces a resultant velocity at the plane inclined to the direction of V at an angle whose tangent is u/V. And, assuming horizontal flight, this has the effect of tipping the direction of flow at the plane up from the horizontal and hence of tipping the line along which we must compute the lift, back from the vertical by the same angle. This gives a component of the lift in a direction opposed to the motion and thus gives rise to a drag force to which has been given the name of "induced drag."

But this all develops out of a theory applied to a nonviscous fluid. Now we know that the induced drag does not account for

the actual drag as measured; and we know also that air is viscous and we naturally seek for the balance of the drag force in conditions which we trace back to viscosity and its influence on the phenomena of fluid motion.

Here again steps in the mathematician and obligingly furnishes general differential equations including the influence due to viscous forces. But while such equations can be written down in their general form, it is quite a different matter to effect their solution as applied to particular cases. In this matter the engineer is still waiting upon the mathematician. However, by making various special and simplifying assumptions, these equations may be made use of to give valuable indications regarding the phenomena attendant upon the movement of a body in a viscous fluid.

Historically, however, efforts had been made by Helmholz and Kirchhoff in the later years of the last century to devise some modification in the accepted ideas of fluid motion which should serve as a basis for the explanation of a force acting along the line of relative motion and opposed to it. Thus developed the concept of discontinuity which, with the aid of conformal transformation, was made to yield indications of a quantitative character in certain special cases. This concept of the conditions of fluid motion was developed, of course, without reference to the problems of present-day aeronautic engineering, and while suggestive and interesting and while supported by observation as to the broad fact of the existence of discontinuities, it was not, however, capable of giving results of any very great value in connection with these later problems.

At this point, von Karman, accepting the concept of discontinuity and at the same time including viscosity as a definite factor in the picture, together with the Helmholz theory of vortex motion, developed a picture of two series of vortices, the members of which are given off alternately from the two sides of a body past which a viscous fluid is moving, and which then pass to the rear forming between them the so-called "Karman vortex street."

Here we see, continuously passing to the rear, a series of vortices, each one of which embodies a certain amount of energy which can only be supplied from the source which is producing the movement of the body. This translated into terms of force means a resistance to the movement—a drag force, opposed to the line of motion.

To this component of the resistance the name of "form drag" has been given.

The existence of such a double set of vortices given off alternately on opposite sides of a body, especially if of bluff form (such as a cylinder), past which a fluid is flowing, had been already indicated by observation and more recent experimental research has served to show their existence quite in the manner as assumed in the theory.

The mathematical part of the problem involved the examination of the conditions which would secure the stability of such a system of vortices, as well as the development of a relation between the circumstances of the motion and the frequency and individual energy of the vortices as shed from the body.

This has all been carried out by von Karman in part by empirical formulas, thus furnishing a basis for the quantitative estimate of the rate at which energy must be supplied in order to secure the continued formation of the members of this series of vortices, and hence an estimate of the form drag. The results of comparison with experiments directed to test the formulas as thus deduced from the theory seem to give a good degree of confirmation. Further experience may indicate change in the empirical factors. In any event, it makes a definite step in advance as an attempt to supply a rational and definite means for the quantitative measure of this element of the total drag force.

Reference has thus far been made to two components of drag or resistance. There still remains a third, the existence of which is related to the formation of a blanket of eddying and turbulent fluid as the immediate envelope of a body in motion relative to the fluid. The existence of such an envelope had long been recognized as a matter of observation. Its existence, as well as that of the so-called "boundary layer," found ready explanation (as physical phenomena) in the theory of viscosity and its action as a factor in fluid motion. The continued generation of this blanket of eddying fluid which passes away downstream as formed, requires the continued expenditure of energy, and this again, as in the case of the eddies of the Karman vortex street, becomes translated into a resistance to the movement.

This gives us, finally, three components of resistance or drag: The induced drag due to the distortion of the field of flow by the presence of the wing, the profile drag due to the formation of the Karman vortices and the skin friction due to the effect of viscosity on a fluid undergoing rapid changes in velocity in the neighborhood of the boundary surface of the body.

It must be noted, however, that while the theory supplies a direct and simple measure of the induced drag, and while von Karman's analysis supplies a basis for estimating the measure of the form drag, there is as yet no adequate basis in theory for a direct measure of the frictional resistance. This item must still depend on empirical formulas for its measure.

It thus appears that existent theory furnishes a physical explanation of the development of the lift and drag forces, together with a basis for the measure of the lift and of two components of the drag. This does not imply that the theory is complete or that it is capable of taking care of all of the circumstances involved in actual engineering constructions, but rather that aside from secondary disturbing elements, it does furnish, as tested by actual experience, a reasonably satisfactory basis for the estimation of the operating characteristics of airplane wings of anything approaching conventional form and at small or moderate values of the angle of attack.

Stability and Control

While the basic problems of aerodynamics are concerned with the explanation and measure of the fundamental force reaction between a solid and a fluid in relative motion, yet the present sketch would be incomplete without some mention of the problem of stability and control. This problem, assuming the various air reaction forces on the plane as known or knowable, calls then for a complete investigation of the stability of the plane in rectilinear and curvilinear flight and for a study of the oscillatory or periodic movements which may develop under such conditions.

This problem has been investigated by Ferber, Bryan, Reissner, Bairstow and others and may be considered as in a very satisfactory state of progress. With a knowledge of the geometry of the plane, its aerodynamic characteristics, the moments of inertia about the principal axes, and the conditions of flight, the equations will serve to give a satisfactory account of matters coming under the head of stability and control under normal conditions of flight. Further extensions to conditions developing in aeronautics and especially in connection with the phenomena of spins are yet needed to make the theory satisfactorily complete in all respects.

Wind-Tunnel Research

Parallel with this development of theory, recent years have witnessed a most extended development of wind tunnel installations, wherein models of airfoil sections have been examined and measured for their aerodynamic characteristics. Literally hundreds upon hundreds of such forms have been tested and their characteristics measured with a view to their use for full scale estimate through the principles of kinematic similitude.

Such experimental examination is, in fact, a necessary element of the situation at the present time, since such measures have been needed as a check on the indications of theory, and since moreover, theory does not give a complete account of the drag force. We may, furthermore, expect that there always will be need for such laboratory research, since it can hardly be expected that theory alone will ever be able to give so complete an account of the circumstances and details of airfoil action as to eliminate the need of further experimental check and measure.

However, the use of reduced models calls for the application of the law of kinematic similitude and where the model experiments are carried on with air at atmospheric pressure, it is well known that the conditions for kinematic similitude (the same Reynolds' number) cannot be realized as between the model and the full scale body. The problem of the correcting factor thus enters—the factor for "scale effect" so-called. There is also a factor of correction for wall effect where the measures are made in a closed tunnel. Prandtl has given a seemingly satisfactory method for the estimate of the latter of these two corrections, but so far we have made little progress in the way of any development of a theory to account for the variation of results with change in Reynolds' number.

At present, the only assured method seems to be to eliminate the need for this correction by securing the conditions for kinematic similitude through the use of a wind tunnel in which the medium employed is air under high pressure, as in the installation at Langley Field, and by which means the full Reynolds' number may be realized for all ordinary operating conditions.

Along with the development of what may be called the main stem of aerodynamic theory as above briefly outlined, the last quarter century and in particular the last decade have witnessed a vast number of special studies and developments in detail; some lying outside the main line of development as here noted and others concerned with the examination of special points intended to make application of the theory in its simpler form either more broadly general, or more certain and specific in particular cases.

Much of this work constitutes what may be called the advancing fringe of aerodynamic theory and there are problems lying still further ahead which represent outlying portions of the field still awaiting investigation and study.

In any such account as the present brief sketch can attempt to give, it would be unwise to attempt to cite authors, names, or particular titles. The field is too rich and it would be well nigh impossible to know just where to stop. However, some indication of the general character and content of this field may well be attempted.

Thus we have:

The extension of airfoil theory to the case of large angles of attack.

More generally the development of some theory of accounting for the intimate phenomena attendant on the operation of airfoils at large angles of attack and including the separation of the boundary layer and the formation of reverse flow.

The explanation and quantitative estimate of the influence of the various means which have been proposed and employed for the removal of the boundary layer and including the phenomena attendant on the use of the Handley Page slot or other like devices.

The extension of theory to a more adequate account of the forces acting on control surfaces (rudder and elevator).

Further development in detail of the theory of the formation of the Karman vortex street including the periodicity, spacing, velocity and inherent energy of the individual members of the series, all as dependent on the circumstances of the body and of its motion.

Broad studies on the phenomena of turbulent flow and its relation to the other circumstances of specific cases.

The extension of studies on viscosity and its influence as a factor in the problems of aerodynamics.

Further study of the problem of skin friction with a view to the development of some form of rational relation between the body as to form and character of surface, the velocity of the relative motion and the amount of the skin resistance.

Studies on the mutual interference of airplane wings in various combinations and the development of optimum combinations in this respect.

Studies on the relations between aerodynamic conditions, laws and requirements, and the extension of airplane construction to continuously increasing dimensions.

The development of some theory adequate to account for the change in the value of the scale factor with change in Reynolds' number and to give an estimate of its value in specific cases.

The Screw Propeller

With the preceding sketch of the development of general aerodynamic theory, it will not be necessary to consider the parallel growth in the theory of the helicoidal propeller in other than broad outline. Four names may be used to mark the essential stages in the development of this theory. These are Rankine, Froude, Drzwiecki, and Prandtl.

Rankine, now some sixty years ago, took as the point of departure for his theory, consideration of the momentum change in the fluid acted on. That is, he studied the phenomena in the fluid and derived therefrom expressions for thrust (or pull) and effective work. Froude, a quarter century later, built upon the same theory and added many refinements in detail, especially the concept of inflow velocity, to which he gave the now commonly accepted value of one-half the ultimate increase in value.

Drzwiecki, early in the present century, took as his point of departure the blade of the propeller rather than the fluid medium. Considering the blade as made up of a radial series of airfoil sections, he took the aerodynamic characteristics of these sections and by a simple process of arithmetic integration was able to derive expressions for thrust, input work, and efficiency. This theory provides readily for taking account of the inflow velocity and this feature soon became incorporated as an essential part of the physical picture upon which the theory is developed.

Finally, Prandtl's vortex theory has been developed to apply to the propeller, and in such way as to round out the Drzwiecki method by supplying the resources of the vortex theory as an aid in estimating the aerodynamic characteristics of the series of elementary airfoil sections of which it is assumed that the blade is composed.

We have, therefore, at the present time, three methods of approach to the problem of the screw propeller:

The Drzwiecki method in which the aerodynamic characteristics of the sections are determined by direct model investigation in a wind tunnel.

The same general method, but using the further resources of the Prandtl's vortex theory of airfoil action.

Direct experimental research by the use of models and the law of kinematic similitude, in so far as it may seem proper to apply such law, where the conditions of similitude are not completely realized.

The literature on the subject of the screw propeller has enormously increased in recent years. A survey of aeronautic literature covering the last ten years shows some three hundred titles relating to the screw propeller, either theory or experimental research.

The advancing edge of propeller theory is concerned chiefly with problems relating to a more complete adaptation of

Prandtl's theory to the complicated phenomena presented by the operation of a screw propeller, especially as regards mutual blade interference and the periodic effect of the blade action on the inflow velocity. General advance in our knowledge of the screw propeller will require properly coordinated work along several lines as follows:

1 Extension of the general theory as above indicated.

2 Experimental investigation on model scale as a check on theory and as additions to our general store of observational material.

3 Experimental investigation on full scale as a check on model scale work and for the determination of ranges of "scale effect" factors.

4 Investigation, both theoretically and experimentally, of the mutual reaction between the propeller and the plane with which it is associated, and as affected by the circumstances of the case.

Aerodynamic theory is only one of the factors which make for advance in the general field of aeronautics, but it is one nevertheless of basic importance. It should point the way to useful and effective improvement, it should give indication of the goals toward which we may hope to carry forward our lines of progress, and it should warn where the way seems to be closed. Building upon the splendid body of aerodynamic theory which has been developed during the past two decades—a body of theory which, in its main features, has been so abundantly justified by experience, and guided always by resort to experimental test in the future as in the past, we may safely predict that the same spirit which has characterized the development thus far will carry on worthily in the future and that the aeronautic engineer and designer will not lack for adequate guidance in theory in his efforts to meet the demands of an ever-advancing use of aircraft as an agency of human progress.

Some Notes on Airplane Production

By JEROME LEDERER,[1] MOLINE, ILL.

RECENTLY a well-known automobile company decided to get into production on a two-place cabin monoplane. The company had had no previous experience in aircraft construction, but ample facilities and experience in producing good stampings, tanks, cowling, and machined parts. Plenty of floor space and a personnel trained in automobile production were available. The airplane company which they had taken over supplied one set of jigs and a small but well-trained aircraft personnel. The decision to build airplanes was made in early spring. A huge spring and summer market was immediately ahead. No time had to be lost in getting into production.

A production manager was supplied by the automobile company. His first step was to get a thoroughly complete material list. Every detail of the airplane down to the last cotter pin was listed, together with the number required, materials, etc. Orders were immediately placed for the required amounts of materials and parts. In the meantime dope rooms were being erected, dies made, jigs improved and built in multiple, an overhead conveyor system for carrying wings was installed, numerous welders were hired, tested, and the best retained, men and women were taken on and taught to do one job well.

Metal parts were stamped out by the automobile company's machine shop; wooden members for wings and fuselages were also made by the automobile company's wood shop. A few days' work in these shops produced sufficient parts to supply the airplane company weeks ahead. Difficulty was encountered with quantity production of welded parts such as fuselages and tail surfaces. Therefore, more welders were hired, more jigs built, and production increased to the desired quantity.

Welders were trained by putting them on scrap metal for a week under constant supervision of an experienced welder, then they were given odd jobs about the plant such as welding jigs and fixtures, after this they were allowed to weld on unimportant parts of the plane, and when they became good enough they were put on fuselages.

In six weeks the company was producing one plane a day; in two months, two a day; in three months, five a day. There has been no structural failure in any of these planes, although each plane is stunted to the limit before delivery.

[1] President, Aerotech, Inc. Jun. A.S.M.E.

Presented at the National Meeting of the A.S.M.E. Aeronautic Division, Wichita, Kans., September 21, 1928.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The difficulties in securing good welds and welders has turned this company's attention to the use of riveted joints, using structural members of duralumin. The advantages appear to be that a good riveter is cheaper than a good welder; a riveted joint can be inspected for strength and workmanship, whereas a good weld depends on the conscience of the welder; there is less chance of warpage; jigs are easier to build and handle; a lighter ship results. How these advantages work out in large production remains to be seen, but all indications point in their favor.

It may be reassuring to some manufacturers to know that the Germans have made numerous tests on the efficiency of welded joints made by good welders and by novices, and have found that the strength of the welds made by beginners was about 79 per cent of the strength of good welds. If this high ratio did not hold, there would be many more structural failures than now occur.

Women are generally employed for all sewing work; they are fast and efficient workers, but the invention of a special sewing machine or of some other good means of quickly attaching fabrics to airplane structures would meet with instantaneous approval by manufacturers.

Aside from production problems, manufacturers of approved types of ships have worries in connection with the requirements of the Department of Commerce. A small change in design may mean lower production cost, or increase in performance, or an improvement in the appearance of the plane, but before the change can be made, approval must be secured from the Department of Commerce. This may take several days or several weeks, depending on how busy the department is. It is suggested that a special division of the engineering branch be organized and devoted to the checking of minor changes in approved-type ships.

An example of possible damage due to delay in having a change approved is furnished by a manufacturer who was about to install a new type of landing gear on his ships, the installation to begin as soon as the department had given its approval. Rumors of the proposed change reached prospective buyers, who immediately canceled their orders and decided to wait for the improved ships.

It is apparent to many that the industry, especially the smaller companies, is in a state of great excitement. It would appear that older business heads are needed to stabilize things and provide a certain degree of soberness and experience now very much lacking. Otherwise unforeseen circumstances will force many companies to the wall.

THE ENGINEERING INDEX

(Registered United States, Great Britain and Canada)

Items From Aeronautics Classification

AIRCRAFT ENGINES

Cylinders. Improved Cast Iron Cylinder for Air-Cooled Engines, R. A. Brewer. Inco, vol. 8, no. 3, 1928. pp. 15 and 21, 1 fig. Analyzing cost of major units, cylinder stands out predominant as possible source of cost reduction; problem was to obtain uniformity of structure, eliminate weak spots and also to apply support to cylinder so that stresses were not concentrated and complicated; most satisfactory metal, contents of iron.

Diesel. Advantages of Diesel-Type Aircraft Engine Pictured From Tests, L. M. Woolson. Automotive Industries, vol. 59, no. 25, Dec. 22, 1928, pp. 892–897, 6 figs. Details of high-speed compression-ignition solid-fuel injection Packard Diesel engine developed for airplanes; ignition and carburetor troubles practically eliminated; fire danger reduced; fuel cost lower; less noise from exhaust; engine will operate satisfactorily from any position and is not affected by rain or water; elimination of radio interference; possible effect of engine on airplane design. Abstract of paper presented before Soc. Automotive Engrs.

Testing. Aircraft Engine Testing, G. H. Walker. Aeroplane (Lond.), vol. 35, no. 26, Dec. 26, 1928, pp. 1007–1008 and 1010, 7 figs. See also Flight (Lond.), vol. 20, no. 52, Dec. 27, 1928 (Aircraft Engineer), pp., 100–104, 8 figs. Requirements of British Air Ministry in testing of airplane engines; details of Froude hydraulic dynamometer and of Heenan-Fell air-brake dynamometers; description of wind tunnels purchased by Bristol Aeroplane Co. from Heenan and Froude for use in testing airplane engines; testing Bristol Jupiter engine; Heenan and Froude equipment furnished Argentine Naval Aviation Station.

Dynamometer Testing of Airplane Engines, C. E. Platzer and R. F. Johnston. Aviation Eng., vol. 1, no. 3, Dec. 1928, pp. 10–11, 3 figs. Principles of operations of electric dynamometer and its advantages as means for testing airplane engines are discussed; test of water-cooled engines; altitude chambers used in tests; load and fuel consumption curves for Wright Whirlwind J-5C and J-5CA taken on dynamometer; problem of providing air for air-cooled engines while testing on dynamometer.

AIRCRAFT MANUFACTURE

Gluing. About Glue and Gluing Practice, C. L. Ofenstein. Aviation, vol. 24, no. 27, Dec. 29, 1928, pp. 2099, 2112, 2114, 2116 and 2118, 3 figs. Glue and gluing practice among commercial aircraft factories; casein especially described; testing for adhesiveness and water resistance after glue has been mixed according to directions, some sort of mechanical mixer having two speeds is recommended; glue receptacles should be cleaned out once a day; high pressures for thick glues.

AIRPLANE ENGINES

Berlin Exhibition. New German Aero Engines, E. P. A. Heinze. Aero Digest, vol. 13, no. 6, Dec. 1928, pp. 1168, 1170 and 1172, 8 figs. New German engines exhibited at International Aircraft Show in Berlin are described; B. M. W. leading with Junkers second, and Siemens and Halske third. Details of one new water-cooled 12-cylinder and two 6-cylinder B. M. W. engines, 6-cylinder and 12-cylinder V water-cooled Junkers engines, Siemens-Halske air-cooled radial engines, Daimler-Benz 12-cylinder V water-cooled and 3-cylinder water-cooled engines, and Argus two 12-cylinder inverted V engines.

Cowling. Drag and Cooling With Various Forms of Cowling for a "Whirlwind" Engine in a Cabin Fuselage, F. E. Weick. Nat. Advisory Committee for Aeronautics—Tech. Notes, no. 301, Nov. 1928, 25 pp., 35 figs. on supp. plates. Results of investigation in 20-ft. propeller tunnel on engines entirely exposed up to completely cowled types; cooling tests made and cowling modified; drag tests; great drag in uncowled engine; effect on airplane performance; cowling entirely covering engine reduces drag 2.6 times conventional cowling; careful design for proper cooling; with cabin fuselage its use should substantially increase high speed.

The New N.A.C.A. Low Drag Cowling, F. E. Weick. Aviation, vol. 25, no. 21, Nov. 17, 1928, pp. 1556–1557, 1586, 1588 and 1590, 6 figs. Wind-tunnel tests undertaken by National Advisory Committee for Aeronautics on different designs of cowling on air-cooled engines; enormous drag due to uncowled engine; conventional cowlings covering only central portion of engine only slightly reduced drag; new cowling of N.A.C.A. design completely enclosed engine but provided for cooling; great reduction in drag in wind-tunnel and flight tests; substantial increase in high speed and all-round performance.

Efficiency. Thrust Horsepower and Engine Efficiency, J. M. Shoemaker. Aviation (Aeronautical Eng. Supp.), vol. 26, no. 3, Jan. 19, 1929, pp. 6–7, 1 fig. Maximum effective thrust per horsepower, or effective thrust available in aircraft power plant is discussed; high-speed engine with propeller driven at crankshaft speed is less efficient than slower turning propeller in same aircraft; high-speed direct-drive propeller may also suffer loss of efficiency due to excessive propeller tip speed; latest practice in regard to reduction gear ratios.

Heavy-Oil. Heavy-Oil Engines for Aircraft, D. R. Pye. Aeronautics (A.S.M.E. Trans.), vol. 50, no. 26, Sept.-Dec. 1928, pp. 45–47 and (discussion) 47–50, 2 figs. Early experimental work with single-cylinder research unit to explore possibilities of compression-ignition operation; alternative designs; results in single-cylinder experiments showing effect of maximum cylinder pressure upon brake m.e.p. and fuel consumption; fuel-valve and nozzle design; air swirl; valve mechanism; possibilities of two-stroke cycle; performance at altitude; earlier use of heavy-oil engines in airships probable.

Problems. Problems of Aircraft Engines (Flygmotorproblemet), E. Hubendick. Ingenioers Vetenskaps Akademien (Stockholm), no. 84, 1928, 34 pp., 29 figs. Account of problems of aircraft engines; J. E. Cederblom's research work on ideal aircraft engine; climatic conditions of Scandinavia call for special measures for cooling and starting; adaptation of Diesel engine for aircraft; possibilities in design conditioned by new materials, etc.

AIRPLANE PROPELLERS

Characteristics in Flight. Characteristics of Five Propellers in Flight, J. W. Crowley, Jr. and R. E. Mixson. Nat. Advisory Committee for Aeronautics—Report No. 292, 1928, 23 pp., 22 figs. Investigation to determine characteristics in flight of four propellers differing uniformly in thickness and pitch, and of fifth which was identical with one of others except for change in airfoil section; efficiencies in flight were consistently lower than in model tests; conclusion that for accurate comparisons it is necessary to know propeller pitch angles under actual operating conditions.

Design. Aircraft Propellers, C. H. Havill. Soc. Automotive Engrs.—Jl., vol. 24, no. 1, Jan. 1929, pp. 17–23, 4 figs.; see also Aviation Eng., vol. 2, no. 1, Jan. 1929, pp. 7–12, 3 figs. Nearly all Army and Navy aircraft propellers of detachable-blade type; Navy has found it necessary to make its own designs; sources of designer's information; discrepancies between model tests and wind-tunnel tests; substitute propellers; strength of propellers; empirical formulas for maximum fiber stress; whirl test for strength; necessity for use of gearing; considerations applying to variable-pitch propellers.

Vortex Theory of Airplane Propellers (Zur Wirbeltheorie der Luftschrauben), T. Troller. Zeit. fuer Angewandte Methematik und Mechanik (Berlin), vol. 8, no. 6, Dec. 1928, pp. 426–430, 8 figs. Diagrams are presented showing results of calculation of induced speeds in axial direction, based on Prandtl's approximate method; there are cases in which more exact calculation is necessary, but in most cases it is believed that Prandtl's method is sufficiently accurate.

Design of Aircraft Propellers (Calcolo delle eliche), A. Zezi. Notiziario Tecnico di Aeronautics (Rome), vol. 7, no. 11, Nov. 1928, pp. 1–80, 36 figs. Review of theoretical researches; presentation of author's original method of analysis and design; author's method compared with study by Durand and Leslie.

Influence of Fuselage on Propeller Design, T. Troller. Nat. Advisory Committee for Aeronautics—Tech. Memorandums no. 492, Dec. 1928, 11 pp., 5 figs. on supp. page. Simple method for designing propeller for given arrangement of airplane parts; inflow to propeller and efficiency of propeller affected most by fuselage; flow conditions in plane of propeller, which are affected by shape of fuselage; determined mathematically; condition for best thrust distribution; induced efficiency of propeller calculated. From Zeit. fuer Flugtecnik und Motorluftschiffahrt, July 28, 1928, previously indexed.

Propeller Problems, A. Betz. Nat. Advisory Committee for Aeronautics—Tech. Memorandums, no. 491, Dec. 1928, 13 pp., 3 figs. on supp. plate. Comprehensive survey of most important propeller problems; detached propeller considered; propeller slipstream and propeller blade theories; conditions on best thrust distribution; special care must be exercised to avoid excessive angle of attack in starting which would cause air flow to separate from blades and thus interfere with their normal functioning; reactions between propeller and vehicle are discussed.

Manufacture. Making Micarta Airplane Propellers, R. L. Knight. Machy. (N. Y.), vol. 35, no. 6, Feb. 1929, pp. 409–411, 8 figs. Manufacture of micarta propellers is described; extreme care throughout manufacturing process to assure uniform and high-grade material, perfect balance of blades, and perfect fit of blades to hub; machining to fit blade to metal hub; final balancing and setting of pitch angle.

Metal. Technical Development of the Reed Metal Propeller, S. A. Reed. Aeronautics (A.S.M.E. Trans.), vol. 50, no. 26, Sept.-Dec. 1928, pp. 55–62, 14 figs. Details of aircraft propeller with solid, thin, and almost knife-like blades of forged or rolled duralumin or other aluminum alloys of similar type; development of metal propeller; propeller and its function; types of Reed metal propellers; materials of construction; methods of manufacture.

Metal, Failure of. Preliminary Study of Fatigue Failures of Metal Propellers Caused by Engine Impulses and Vibrations. Air Corps Information Cir., vol. 7, no. 618, Aug. 15, 1928, 17 pp., 7 figs. Study of cause and prevention of breakage of certain metal propellers in bending in plane perpendicular to propeller axis; causes investigated with particular reference to phenomena of resonance; theory presented in detail; cantilever beam, dynamic load, on propeller blade due to constant acceleration of hub; mathematical analysis of vibration of propeller in plane of rotation; frequencies of similar propellers.

AIRPLANES

Ailerons, Forces Produced by. Determination of Air Forces and Moments Produced by Ailerons of Airplane (Bestimmung der durch die Querruder eines Tragfluegels erzeugten Luftkraette und Momente), C. Wieselsberger and T. Asano. Zeit. fuer Flugtechnik und Motorluftschiffahrt (Munich), vol. 19, no. 13, July 14, 1928, pp. 289–293, 10 figs. Lift distribution produced by aileron deflections for rectangular wing on straight flight previously determined on theoretical principles for certain case, and air forces and moments produced by ailerons derived; approximate values deduced from former results for use in calculating acting forces and moments for all cases; results expressed by non-dimensional coefficients represented in diagrams.

Alloys for Use in. The Use of Light Alloys in Aircraft From the Point of View of Corrosion, H. Sutton. Royal Aeronautical Soc.—Jl. (Lond.) vol. 33, no. 217, Jan. 1929, pp. 38–54 and (discussion) 54–74, 19 figs. Value of various light alloys in aircraft construction and question of corrosion are discussed; aluminum and its alloys; restrictions of commercially pure aluminum; duralumin; aluminum-copper-silicon alloys; wrought aluminum-silicon alloys; wrought aluminum-copper-nickel alloys; aluminum casting alloys; protection of aluminum and aluminum alloys; magnesium alloys assuming increasing

importance; influence of corrosion on fatigue properties.

Anti-Friction Bearings in. Anti-Friction Bearings in Aircraft Construction, W. B. Moore Aviation Eng., vol. 1, no. 3, Dec. 1928, pp. 7–9, 5 figs. Application of anti-friction bearings to airplanes from engineering and practical view is discussed; suitability of bearings of any type for service; advantages; application of tapered roller bearings to main crankshaft and rocker arms of airplane engine to carry both radial and thrust loads; load characteristics and service requirements encountered in application of anti-friction bearings to landing and tail-wheels.

Autogiro. The Autogyro, V. E. Bertrandias. Engrs. and Eng., vol. 46, no. 1, Jan. 1929, pp. 26–27 and (discussion) 27–28. Interesting points of this new windmill plane are described; autogiro plane possesses valuable qualities of stabilty at large angles of incidence and ease of landing.

The Autogiros of Cierva (L'autogire de la Cierva), M. Ducout. Aérophile (Paris), vol. 36, no. 19–20, Oct. 1928, pp. 295–298, 7 figs. Cierva autogiro has carrying surface of 11 sq. m.; total weight 1120 kg.; motor 220 hp.; theory of design; rotation of lifting screw; speed of air relative to blade and forces applied; speed of autogiro.

The Cierva Autogiro, W. H. Sayers. Aviation, vol. 25, no. 18, Oct. 27, 1928, pp. 1320–1321, 1340–1342, 1344 and 1350, 8 figs. Aerodynamic principles involved in design and operation of this craft are discussed; all autogiros so far have standard airplane fuselage, landing gear and tail unit; rotating system of supporting surfaces in place of wings; ailerons are separate organs carried on each side of fuselage; blades in addition to rotating, move up and down; speed of vane system constant; auxiliary drive being developed will allow spinning up of rotating wings directly by main engine.

Biplane, Freight. Boeing Building Mail Plane Fleet. Aviation, vol. 25, no. 27, Dec. 29, p. 2106. Few details of new biplane Model 95 for handling mail and express only; 525-hp. Hornet engine; four mail and express compartments have cargo capacity of 1600 lb.; wing span 44 ft. 3 in.; body of steel and dural construction, durat and fabric covered; wood wings.

Commercial, Design of. Commercial-Airplane Design (Der Verkehrsflugzeugbau), A. Gymnich. Luftfahrt (Berlin), vol. 32, no. 23, Dec. 7, 1928, pp. 364–368, 7 figs. Problems of design are discussed from standpoint of pilot; monoplane is favored in Germany, Holland, and United States, whereas England favors biplane and in France both types are employed to about equal extent; one cannot be called superior to other; aileron construction; steering gear.

Control. Research on the Control of Airplanes, B. M. Jones. Nat. Advisory Committee for Aeronautics—Tech. Memorandum, no. 485, Oct. 1928, 23 pp., 9 figs. on supp. plates. Controversy between theory of airplane with control organs and uncontrolled stable airplane; provision of good control qualities is more a question of proportioning airplane and adjusting its load than of new control organs; motions of stalled airplanes studied by Cambridge University Air Squadron; great influence of yawing motions on rolling couples; ailerons positive source of danger; rudder provides control difficult to use; solutions offered. From Nature (Lond.), May 12, 1928. Lecture delivered at Royal Instn.

Control, Automatic. Device for the Automatic Control of Airplanes, A. Gradenwitz. Nat. Advisory Committee for Aeronautics—Tech. Memorandums, no. 495, Jan. 1929, 6 pp., 6 figs. partly on supp. plates. Control device of Franz Drexler has three switch buttons, with which three-part automatic control can be switched on or off in whole or part, leaving controls to be operated by hand or foot; for intermediate control, purely electric transmission used; each mechanism has special contact-making device by which reversing motor is set rotating; direct current produced by windmill-driven generator; provisions for correction. From Motorwagen, March 31, 1928, pp. 204–206.

Design. The Modern Aerodynamic Theory in Design, I. H. Driggs. Aviation (Aeronautical Eng. Supp.), vol. 26, no. 3, Jan. 19, 1929, pp. 2–5, 2 figs. Discussion of Prandtl theory with formulas developed from study of subject; rational formula for drag curve of airplane over useful range developed and from that minimum drag and consequently maximum L/D and velocity at which they occur; from resulting power equation value of minimum power and speed at which it occurs is found; wing are a should be determined from speed of minimum power rather than landing speed desired; case of glider and soaring speed; minimum sinking speed for soarer.

Design Stresses. Design Stresses, C. D. Holland. Flight (Lond.), vol. 20, no. 43, Oct. 25, 1928; (Aircraft Engr.) pp. 936f-936g, 3 figs. Design stress defined as maximum stress material will be subjected to when structure is loaded to amount of load factor times normal load; determining tension, pure compression, compression for long struts, shear, bearing, Young's modulus, modulus of rigidity, and Poissons' ratio; effect of workshop processes on normal design stresses of materials; effect on design-stress value due to different types of loading.

Dope. Aircraft Dope and Finish Problems, E. G. Davis. Aviation Eng., vol. 2, no. 2, Feb. 1929, p. 10. Discussion of dope failures, and complete peeling of dope film away from fabric; this trouble was noticeable some 12 years ago, but disappeared with development of dopes after war, only to appear again now; military and naval aircraft free from these troubles; tendency of aircraft industry toward heavy, thick, smooth coatings which do not show any fabric is mechanically unsound.

Landing Gear, Caterpillar. A Caterpillar Landing Gear for Airplane, P. E. Lamarche, Jr. Aero Digest, vol. 14, no. 1, Jan. 1929, p. 88, 1 fig. Details of caterpillar tread device called "petin atterrisseur" developed by Louis Vinay, Paris; caterpillar tread is attached to landing-gear axle in such a way that it allows plane to pivot on its axis when it meets an obstacle; it can overcome obstacles on ground up to height of about 16 in. with ease; Westinghouse air brakes mounted on each caterpillar tread inside plates that form sides.

Metal Construction. Armstrong-Whitworth Metal Construction. Flight (Lond.), vol. 20, no. 52, Dec. 27, 1928, pp. 1083–1087, 28 figs. Typical Armstrong-Whitworth forms of metal construction and methods employed are described; both circular-section tubes and rolled or drawn strip used; tubular construction confined to fuselage; two types of mechanical joints; each side of fuselage built up on jigs; steel strip wing spar construction; heat treatment and rust protection.

Metal, Manufacture of. New Construction in Metal Airplanes, F. H. Colvin. Am. Mach., vol. 69, no. 26, Dec. 27, 1928, pp. 983–986, 7 figs. Advanced method of constructing airplane fuselage and way in which aluminum alloy sections are built up, drilled, and riveted for Navy planes in plant of Glenn L. Martin Co. are described; alignment of fuselage claimed difficult with construction of welded tubing; Eureka built-up section developed by engineers of Martin Co. is described; fuselages of high-strength aluminum alloy with chrome molyldenum steel fittings.

Structures of Thin Sheet Metal, Their Design and Construction. H. Wagner. Nat Advisory Committee for Aeronautics—Tech. Memorandums, no. 490, Dec. 1928, 21 pp., 32 figs. on supp. plates. Uses of sheet-metal coverings in conjunction with inner structure; special methods of construction on which author worked with Rohrbach firm, and which enables simple and cheap shop work combined with great simplicity and lightness; Junkers, Brequet, and Dornier construction; flat sheet-metal girders with very thin webs; buckling strength of flat metal sheets; curved sheet-metal girders.

Performance Testing. The Reduction of Performance Tests, H. L. Stevens. Roy Aeronautical Soc.—Jl. (Lond.), vol. 32, no. 215, Nov. 1928, pp. 934–957, 11 figs. and (discussion) 957–958. Computing work necessary between receipt of performance figures from pilots and issue of complete report; method adopted for all but supercharged engines assumes power depends on pressure only; effects of atmospheric temperature on altimeters and air-speed indicators; correction of air-speed readings for propeller-efficiency correction; density method for correcting performace tests of supercharged engines; pressure methods explained.

Speed Control. Increasing Airplane Speed-Range, H. Alfaro. Soc. Automotive Engrs.—Jl., vol. 24, no. 1, Jan. 1929, pp. 99–100. Devices for improving control at slow speed are discussed; recommendations made by Daniel Guggenheim Foundation for safety and efficiency of aircraft.

Spinning Characteristics. The Spinning of Airplane, M. Watter. Aero Digest, vol. 13 no. 5, Nov. 1928, pp. 912, 914 and 916, 2 figs. Spinning and efforts directed toward explaining it; spinning sometimes considered desirable maneuver in combat; aerodynamical and dynamical causes of spinning; mastery lies in reliable means of recovery and not in prevention; increase in size of stabilizing and controlling surfaces only temporary remedy; possibility of using automatic leading edge slots on horizontal tail surfaces; rudder action is of utmost importance in spinning and efforts should be directed to increase its efficiency by preventing its shielding; inclination of rudder axis suggested.

Wing Design. A New Method of Stress Calculation of Monoplane Wings, S. Kaneko. Tokyo Imperial Univ.—Jl. (Tokyo), vol. 17, no. 12, Oct. 1928, pp. 213–244, 22 figs. General equations for deflection and torsion of wing and expressions for stresses in its structure; actual strength of monoplane wing is widely different from results obtained by conventional method of stress calculation; it must be calculated from combined considerations of deflection and torsion of wing as whole; problems solved for special cases; comparison of numerical results obtained by present method and by conventional one. (In English.)

AIRSHIPS

Metal, Construction of. Metal Airship Construction. Engineer (Lond.), vol. 146, nos. 3803 and 3804, Nov. 30 and Dec. 7, 1928, pp. 598–599 and 622–625, 18 figs. Nov. 30: Description of Boulton and Paul's most recent practice with particular reference to work which it has carried out for Government airship R 101; materials entering into airship structure. Dec. 7: In addition to rolling and drawing of various sections in steel and in duralumin, contract involves manufacture of large number of joints, sockets, shackles, and other details.

Rigid. Airship R 101. Flight (Lond.), vol. 20, no. 47, Nov. 22, 1928, pp. 997–998. Single-line diagrams stressed by Royal Airship Works and geometry and load used by Boulton and Paul to convert line diagram into actual structure; airship is compromise between perfect aerodynamic shape and practical manufacturing possibilities; very fundamental differences between R 101 form of construction and that of Zepplin; accuracies to which manufacturers had to work; some dimensions show magnitude of task.

AER-51-5

Production Problems of the Commercial-Aircraft Manufacturer

By E. E. PORTERFIELD, JR.,[1] KANSAS CITY, MO.

The author divides the problems confronting the manufacturer of commercial airplanes into those of production and sales, and confines himself to the first of these. The problems of production include inadequate supply of motors and lack of an outstanding standard type, unreliability of supply of materials of construction, uncertainty of schedule to follow in large-scale production, difficulties arising out of the certification required by the Department of Commerce, standardization of product, methods, and materials, and the coordination of production and distribution.

THE producer of commercial aircraft has enjoyed a period of tremendous growth within the past two years. The industry has expanded amazingly during this time, thanks to the startling achievements of a score of heroic figures whose feats have crystallized general interest and created a public air-consciousness. The airplane manufacturer has been riding the wave of the industry's first great boom, so to speak. However, his initial success has not been achieved without a number of attending difficulties.

Any industry, of course, may expect to encounter circumstances in its early stages of development which only time and intelligent effort at organization can overcome. Every business goes through a formative period in which it must experience its growing pains. Of these, commercial aviation has had its share and, in fact, is still having its share. Such problems as may be considered common in the early years of every industry need not be studied at any great length here. However, the manufacturer of commercial aircraft is confronted with certain problems which are peculiar to the aircraft industry. These fall naturally into two classes: namely, the problems of distribution or sales, and the problems of production.

In our own industry, the difficulties arising in production have assumed an importance to the manufacturer which has, to date, practically excluded serious consideration of sales development. Although it is my task to consider the problems of production, I want to call particular attention to the increasing importance of sales effort in the industry. For, as we apply ourselves to the problems of building more airplanes and building them better and more economically, we shall find ourselves reaching production capacities for which sales outlets must be created. In other words, in the solution of production problems we shall be creating problems of selling.

The groundwork in our selling organizations cannot be established too soon. Probably every prominent builder has seen the necessity of devoting more and more effort to sales organization and is acting accordingly. He realizes that large-scale production will drive him to a higher pitch of selling activity.

The point I would make regards the vital importance of solidarity and reliability of the selling organization as it affects production. There can be no such thing as stable production until there exists a distributing system in which we can place dependence. How shall we estimate production for a given period unless we can gage accurately the capacity of distribution over that period? The manufacturer who creates a sales organization from which he can accurately predetermine sales potentialities has gone a long way in the matter of simplifying production problems.

Motor Problems

But perhaps of more immediate interest to every producer is a discussion of problems now affecting production. For after all, we are still in the formative period, in which we find our most serious problems in the factory. Of these, one of the most important—and by the same token, one of the most vexing—is the difficulty of powering planes.

Although there is promise of new production motors in adequate quantity, and at prices which will permit their use in the medium and lower priced plane, we are still struggling with the problems arising with present motor supply. In the first place, no single new production power plant has proved itself to be outstanding. In fact, no two or three engines have developed what might be called public preference. It has therefore been necessary for the manufacturer to diversify production to satisfy a wide range of public demand. The result is reduced production and increased production costs.

The war-surplus motor has been both an invaluable aid and a decided handicap to commercial-aircraft builders. These power plants have made it possible for aircraft companies to meet the growing demand. They have made it possible to put ships on the market at prices which make possible something approaching large-scale production and distribution. But on the other hand, they have greatly retarded the development of new motors for the simple reason that motor builders have not been able to compete with this cheaper type of power. Of course, with a very limited market for new engines, the builders could not possibly hope to reach a point in production where their motors would receive general acceptance. The day of the war-surplus motor is about over, and manufacturers are awaiting the end of the OX-5's and "Hisso's" with mixed feelings of joy and misgivings. Will it be possible to continue large production with ships powered with expensive new motors? I think the let-down will be scarcely noticeable—and then only for the few months it takes engine builders to reach large-scale production. When that point is reached we shall all look back upon the war-surplus power plant as a necessary evil which both helped and harmed the industry. In the meantime, we can only fight for standardization of the power equipment and foster the efforts of motor builders who are striving to give us the type of power we must have before commercial aviation can make substantial progress.

Problems of Materials

The motor situation is largely duplicated in much of the materials used in plane construction. The industry has actually grown so fast within the past two years that the sources of material have proved entirely inadequate. The manufacturer, unfortunately, has been entirely dependent upon independent sources for practically the entire list of materials used in plane construction. The rapid growth of the industry calls not alone, therefore, on the aircraft builders, but upon a dozen other industries as well. And in the case of most materials, the companies that are called upon to supply the aircraft builder find themselves faced with the necessity of producing this material to

[1] President, American Eagle Aircraft Co.

Presented at the National Meeting of the A.S.M.E. Aeronautic Division, Wichita, Kans., September 21, 1928.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

special specifications. As a result, it has taken time and a great deal of effort to secure anything approaching an adequate, reliable supply of aircraft production materials.

In view of the fact that there are so many different kinds and types of material involved in the production of the airplane, we must congratulate ourselves upon being able to accomplish as much as we have. Much has been done toward the solution of this problem. Whereas a year or two years ago the business of supplying airplane materials was incidental to other lines of business, we have today a group of organizations handling airplane supplies exclusively, or specializing in the materials the industry demands. Still there is much to be done in this connection. There must be greater standardization of parts and materials; there must be more definite and more rigid specifications imposed on the producers, and more thorough and painstaking inspection of supplies in instances where we are dependent upon outside sources. We have fought, and are still fighting, for better motors. We have accomplished a great deal in the matter of supplies coming from outside sources, but still find ourselves handicapped at every turn. We still, for instance, are forced to tie up a practically completed ship while it awaits the delayed delivery of a propeller, or some other part over which we have no control. But greater than either of these difficulties, perhaps, is the one arising within our own organizations.

Problems of Organization

There is the vital question, "What shall our program be this year, or this month, or a year from now?" We have found it almost impossible to gage public demand. Fortunately, so far we have underestimated it. Fortunately, I say, for such a condition leaves us financially safe for the moment. But it adds to our problem. Public demand is calling upon us early for large-scale production. Still, we find ourselves with many of our initial problems unsolved and with our policies consequently undetermined. The industry is still in its formative period, even though we may say that we are approaching the close of that stage.

As a result, we are facing the problem of constantly increasing production without being sure of the ground over which we must travel. None of us knows what the trend of public demand may take a year from now or even a month hence. We have by no means completed our engineering and research work. We are by no means satisfied with our present product and present methods, gratifying as they may be. Therefore, no manufacturer cares to invest heavily in machinery and equipment necessary to make large-scale production possible. As a result, we are faced with the alternative of forcing production through the continued use of present methods, namely, through hand work or small machine-tool work, upon materials provided through outside sources. Obviously, such a program means a high cost of production. Equally obviously, the continued success of the industry demands the use of efficient machi nery for large-scale production—the only course to reduce production costs. We are agreed, I think, that we want to move into the era of greater production, with its many obvious advantages for the manufacturer. We must reach the large-production stage soon. In fact, we are being forced toward it daily. But how soon shall that time arrive? How soon shall we be fully prepared to enter it?

Three Essential Conditions

I would say that three things are necessary in the meantime. One is beyond our control, except as we can cooperate as a group to remedy the situation now existing. Due to the fact that the Engineering Department at Washington has been so overloaded with the mass of applications piled up on it by manufacturers, we are all vitally interested in seeing some steps taken to alleviate that situation, and to speed up the part which the Department of Commerce must play in our progress. The approved type certificate is vitally necessary to the commercial builder. The mass of work thrown upon the department is seriously delaying the issuance of important approvals, and consequently seriously hampering our efforts at determining upon a definite program. We must determine among ourselves some method of reducing the demands being made upon this department; and recommend, if possible, some method of simplifying the work of the department.

Within our own organizations there are two courses of action which suggest themselves. First of these is standardization as far as possible in every phase of factory operation. It means standardization of product, of methods, and of materials. The manufacturer obviously must cease to experiment with a dozen different types of planes and motors. He cannot hope to continue, as he has in the past, a system which makes practically every ship an individual production problem. Neither can he allow such wide latitude in the installation of special equipment. He must standardize upon a given line of planes, powered with certain motors and equipped in a given manner. Such a program leaves the manufacturer with a number of engineering problems and only a limited time in which to solve them. It is simply his own responsibility to determine his program and to institute it without delay. And if he should waver too long in his decision, he will find himself trailing the leaders, who have had the foresight and initiative to fix their programs early.

Further standardization is vitally necessary to materials. I have already mentioned the necessity of demanding more reliable sources of supply, and of imposing more rigid standards of specifications and inspection. In this phase, the initiative rests with the manufacturer. When he has fixed his program of production more carefully, a certain degree of the confusion now existing regarding supplies will automatically be eliminated.

Finally with our policy of action definitely settled, we shall have a basis from which to proceed. Our only problem from that point is the coordination of production and distribution. The responsibility then passes largely to the sales department, which must establish a definite method of arriving at potential sales over a known period. Knowing sales capacity, the question of accomplishing stable production is comparatively simple.

The industry is facing an important year. It must prepare to move from its formative period to the stage of permanent development and expansion. If it would lose none of the impetus it has gained within the past two years, it must move quickly, but carefully. There are any number of problems confronting the aircraft builder, each one of them vitally important. There can be no set of rules offered for the solution of any one of these difficulties, for after all the problem is largely individual and peculiar to each manufacturer. However, there is much to be gained through cooperation within the industry. If there is any one thing I hope we shall all learn early in the game, it is that we shall learn to get together with our problems; to cooperate—for there will be much that we can accomplish together that will be impossible in any other manner.

The industry has prospered in its early years. It will prosper even more if we grasp the opportunities before us—if we devote the thought and energy necessary to carry us into the more permanent and important phases of development and expansion still ahead of us.

List of A.S.M.E. Transactions Papers Published Since January 1, 1928

BELOW is published a complete list of the papers which have appeared in the various sections of Transactions since January 1, 1928, together with references to the issues of "Mechanical Engineering" in which abstracts of them may be found.

	Issue and page of MECHANICAL ENGINEERING in which abstract was published
AERONAUTICS	
Progress in Aeronautics	June, '28, p. 496
Facilities for Research Work in Aeronautics in the United States	June, '28, p. 496

FIG. 1 T. C. AIRSHIP WITH AIRPLANE ATTACHED

Design, Construction, and Handling of Non-Rigid Airships

BY THOMAS L. BLAKEMORE,[1] LAKEHURST, N. J.; J. F. BOYLE,[2] NEW YORK, N. Y.; AND NORMAN MEADOWCROFT,[3] HAMMONDSPORT, N. Y.

FOR AIRSHIP construction the fabric must be light in weight, strong, and gas tight. The cloth used should be high-grade cotton sheeting, closely woven, and as free from imperfections as it is possible to get it in order that it will rubberize perfectly. Airship cloths were formerly made of Egyptian cotton. Now the best grade of long staple American cotton is used. Silk is unsatisfactory since it does not rubberize. There is a standard grade of balloon cloth which weighs two ounces per square yard, and has a strength of approximately 40 lb. per inch of width. All cloth received from the manufacturer is inspected carefully for dropped threads, slubs, and blemishes. All of these are combed out or the cloth is discarded. This work is preparatory to spreading rubber on the fabric.

Spreading the fabric is the process of making it gas tight. A spreader machine is about 20 ft. long and five feet wide. It has a series of steam-heated pipes over which the spread fabric travels, driving off the solvents of the rubber. At the feeding end of the spreader is a knife extending all the way across it. This knife is adjustable, up and down, and is brought down very close to the fabric which runs under it. The rubber compound, which is spread on the fabric, is a plastic mass. It is placed in front of the spreader knife on the cloth as the cloth runs through. The knife scrapes off the compound leaving a very thin film on it. Seven passes through the spreader deposit approximately one ounce of gum per square yard on the surface of the fabric.

After the various plies of cloth have been rubber coated on both sides, they are plied together into the finished fabric. This finished fabric is then vulcanized. Airships are generally made of three-ply fabric of the following construction:

Outside aluminum	0.7 oz. per sq. yd.
Outside gum	1.0 oz. per sq. yd.
Outside cloth (straight)	2.0 oz. per sq. yd.
Film (gum)	2.0 oz. per sq. yd.
Middle cloth (bias)	2.0 oz. per sq. yd.
Film (gum)	3.5 oz. per sq. yd.
Inside cloth (straight)	2.0 oz. per sq. yd.
Inside gum	0.5 oz. per sq. yd.
Total	13.7 oz. per sq. yd.
Strength warp	80 lb. per sq. yd.
Strength filler	80 lb. per sq. yd.

Maximum permeability, 15 liters per sq. m. in 24 hr.

Other fabrics used for various purposes are two-ply bias and one-ply straight. The object of a bias ply in a fabric is to prevent spreading of tears. The vulcanizing or curing of the fabric is accomplished by winding the completed fabric on a roll very tightly. The roll is wrapped in cloth and the whole placed in a steam cabinet. Steam pressure is increased to a certain point, maintained a certain time, and then gradually reduced. About an hour is required to cure a roll of fabric. This vulcanization process changes the gum from a plastic to an elastic mass. The vulcanization is not carried to completion.

The life of airship fabric depends greatly upon the cure and condition of service. Airships operated at Scott Field, Ill.,

Presented at the Third National Meeting of the A.S.M.E. Aeronautic Division, St. Louis, Mo., May 27 to 30, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

have been in constant service, under pressure, for over two years. One "TC" ship has a record of 1300 flying hours. The pressure of the gas, combined with the loads on the fabric due to the suspended weights, gradually weaken the fabric, which in turn begins leaking. Gas bags are usually replaced after two years of service.

The general practice now is to paraffin the entire inner surface of airship envelopes. Paraffining increases the life of the fabric, and decreases the permeability to gas. The process of paraffining an envelope is purely a mechanical one. The completed envelope is turned inside out, and melted paraffin mixed with hot benzol is spread on the surface with common garden sprinkling cans, and is brushed quickly over the surface with corn brooms.

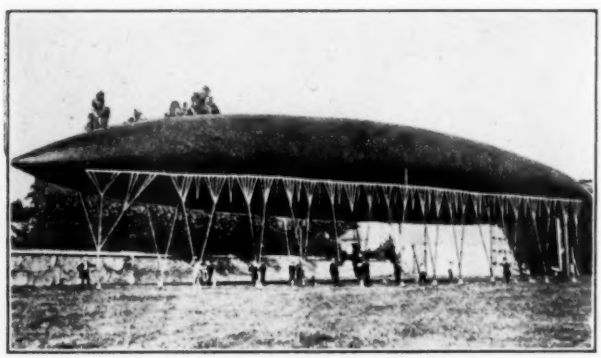

FIG. 2 EARLY NON-RIGID AIRSHIP WITH SUSPENSION GIRDLE OR BAND

The hot benzol carries the melted-paraffin solution into the gum and leaves a film of paraffin on the surface. This benzol penetrates so rapidly that it carries the paraffin clear through the entire fabric, and in some cases blooms out on the opposite side. The envelope is allowed to stand twenty-four hours until all the benzol evaporates, leaving the paraffin alone on the surface.

The red rays of the sun are the worst enemy of rubber, consequently the outer surface of the fabric is coated with aluminum. The aluminum is put on the fabric during the spreading process. It is in the form of powder, and is mixed with gum compounds in some cases, and spread on the surface. In other cases the aluminum powder is printed on to the surface by a printing machine, which consists of several rolls through which the fabric is passed, the powder being pressed into the outer surface of gum. This metallic-aluminum surface reflects the red rays of the sun.

All airship fabric is tested for diffusion and tensile strength. The diffusion must meet the specification requirements, which are very rigid. Diffusion varies considerably with the cure. Some fabrics when new have a relatively high diffusion, which drops shortly after being put into service. Other fabrics have a low diffusion when new, which rises in service. It has been found that practically all fabrics reach a common level of diffusion.

Diffusion of gas through fabric is a process of leakage or osmosis. There is a leakage of air from the outside in through the fabric. The final result is that the filling gas becomes mixed with a certain amount of air and becomes impure. In the case of hydrogen-filled balloons it is necessary to test the purity constantly, since hydrogen mixed with gas becomes an explosive mixture, and when the purity of hydrogen gas comes to a certain low point, it is necessary to purge the ship. This purging process consists simply in adding more pure hydrogen to the filling, thereby raising the purity of the entire contents. When, however, the hydrogen purity drops to a certain point it is necessary to deflate and refill. The old hydrogen is discarded.

In the case of helium-filled ships purity is checked constantly. However, when the purity of helium reaches a certain low point, the helium is removed, purified, and returned to the ship. Although the initial cost of helium filling is higher than that of hydrogen, when it is considered that helium filling can be purified and returned to the ship, the initial cost is not such an important factor.

There are no hydrogen-filled military airships operated in this country, since there is an act of congress forbidding the use of hydrogen in airships. Helium, of course, is non-inflammable and although the efficiency of a helium-filled ship is below that of a hydrogen-filled one, the increased advantage of non-inflammable helium compensates for the loss of efficiency.

FABRICATION

The process of fabricating an envelope of an airship is as follows:

The rubberized fabric is cut into panels. The largest panels in a standard training ship of the "TC" type are eight feet long

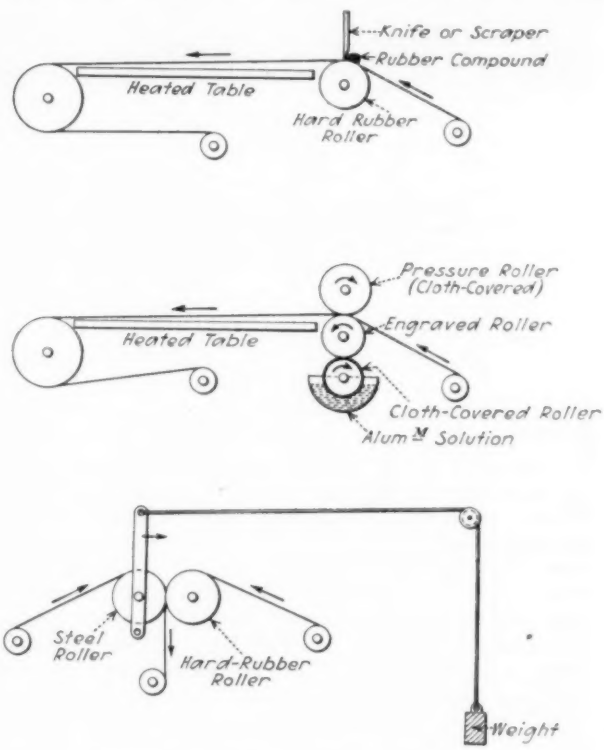

FIG. 3 OPERATIONS IN AIRSHIP FABRIC MANUFACTURE. AT TOP, SPREADING; IN CENTER, PRINTING; AT BOTTOM, DOUBLING

and the width of the fabric, which is 40 in. The panels are developed on the conic-frustrum method. The envelope being a surface of revolution, it is necessary that the panels be developed on this conic-frustrum method. The cutting of the fabric in the panels is accomplished in much the same way as the cutting of clothes is done in the tailoring industry. Cardboard patterns of individual panels are laid upon the fabric, which in turn is placed on a cutting table in several layers. Cutting is done with a cloth cutter. It is possible to cut as many as fifty layers at one cutting.

The panels of fabric are seamed together with an ordinary lap seam. The lap is three-quarters of an inch wide. The joints are made with rubber cement. It is necessary to buff the aluminum surface where a seam is made. After the cemented

seam is completed it is sewed with a double row of stitches. The stitches are covered inside and outside with rubberized-fabric tape to prevent leakage.

The rubberized cement used is a non-curing cement, although the latest cements are air curing. A three-quarter inch lap is sufficiently strong to break the fabric in a test. These tests are made before the seam is sewed. The sewing is simply an extra precaution. The seams are tested at a temperature of 115 deg. fahr., which has been found to be the maximum temperature obtained on airships in hot climates. This temperature is a superheat due to the sun's rays and to the heating of the filling gas. At this temperature the rubber cement (three-quarters of an inch seam) is capable of holding 40 lb. per in. of width.

Balloon fabric is made right-and-left bias. The bias is alternated in the balloon in gores. A "TC" ship, which has a diameter of about 45 ft., is made up of twelve gores running lengthwise of the ship. The gores are made up of individual panels. All the panels in one gore are of the same bias, and the bias in the adjacent gores are alternated. This alternation of the bias keeps the ship from twisting out of shape.

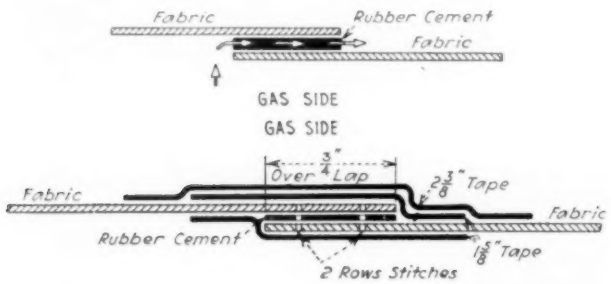

Fig. 4 At Top, Leakage of Gas Through Plain Seam. At Bottom, Typical Envelope Seam

Due to the weight of the tail surfaces the ship droops at the tail after being in service, consequently the envelopes are tailored, that is, pie-shaped pieces of fabric are cut out of the envelopes at various sections so that the envelope when new actually has a rising tail. When it has been in service awhile and has stretched, the tail pulls down level.

The internal ballonets and air lines are assembled in a similar manner to the envelope, and are attached inside the envelope. The internal ballonets are filled with air, and are used for maintaining constant pressure in the envelope.

When an airship rises the gas expands due to the decrease of atmospheric pressure, consequently when a ship leaves the ground it is inflated only partly full of gas. The remainder of the inflation is air. As the ship rises and the gas expands, it forces the air out of the ballonets; as the ship descends again air is forced back into the ballonet through air scoops which are raised and lowered in the slip stream of the propeller. In this manner a constant pressure is maintained in the bag. This pressure is recorded on pressure gages which are visible in the car of the ship.

The internal pressure of an airship is about one inch of water pressure at the center of the bag. This means about two inches of pressure at the top of the bag and one-half inch of pressure at the bottom, the pressure varying with the height of the bag. This pressure of one inch above atmospheric is sufficient to maintain a tight bag.

The airship car is suspended by cables attached to finger patches which are cemented only to the outside surface of the bag. The finger patches are built of combed-out rope cemented and attached to fabric fingers. The standard four-finger patch is capable of holding a load of 2000 lb. These patches are assembled on the ship in groups according to the load which they are to carry. The suspension lines themselves are steel cables spliced into the patches and attached to the suspension points on the car by means of cable clamps. It is necessary to adjust the suspension cables constantly at the car end.

An airship is designed usually so that it trims down three degrees at the nose. This trim down at the nose compensates for the force couple due to the line of thrust of the propeller being below the center resistance of the ship. The fins or control surfaces are suspended from the bag by patches. The various handling lines and mooring lines are attached to the bag also by suspension patches.

It is necessary to stiffen the nose of an airship to prevent its caving in at high speeds. Light-weight box-type nose battens are installed in much the same manner as umbrella ribs. The battens are lashed to small patches, which are cemented to the ship. The effect of the bow stiffeners is to reduce considerably the pressure which must be maintained inside of the envelope. It is evident that the internal pressure must be greater than the dynamic pressure against the outside of the envelope. The maintenance of this greater pressure at the nose when diving at an angle means that the fabric of the ship would be unduly stressed, and the life would be reduced greatly. The effect of bow stiffeners in non-rigid airships is completely described in Technical Memo. No. 221 of the National Advisory Committee for Aeronautics.

Airship envelopes are equipped with gas and air valves. These valves have opening and closing devices operated from the control car. The airship valves are very delicate instruments. The latest type are the result of a great deal of experimenting.

The standard form of car used on the training ship of the "TC" type is a wooden structure about 40 ft. long. The cars carry two motors on outriggers. Water-cooled motors of about 180 hp. have been used. The latest types have air-cooled motors of 200 hp. The cars usually have open cock pits.

The cars accommodate a crew of eight. The latest types of cars have enclosed cabins for the crew. Airship cars are equipped with landing pontoons which are rubber pontoons, air inflated. These take the landing shocks, and support the weight of the car at rest. An airship lands in the air, that is, it comes in at a state of equilibrium at about 100 ft. from the ground, and is hauled down to the ground by the handling ropes. There are usually no landing shocks similar to those experienced in airplane landing. Landing wheels have been experimented with, and work very satisfactorily, especially on two-motor ships. A caster-type wheel has been found to assist greatly in maneuvering the ship.

Water recovery has been installed on non-rigid airships, and has been found to increase the range greatly. The theory of water recovery is simply the condensation of the exhaust gases from the engine. This condensation is accomplished by running exhaust gases through aluminum tubing which is placed in the slip stream of the propeller. The amount of water is equal to the amount of fuel burned, and is recovered in this manner, thereby maintaining the trim of the ship. It is seldom necessary to valve gas in modern airships.

Control surfaces of airships are very large as compared with the size of airplane wings. They are built up in much the same manner as an airplane wing using wooden latticed girders, although some of the later types are made of metal. All surfaces to date are cloth covered. The control surfaces are very light, weighing but one-half pound to a square foot of area. This light surface will sustain loads of 10 lb. per sq. ft. The rudders and elevators are of the balanced type. Most airships carry, in addition to the bottom fin, rudder, and the side fins, an elevator or a top fin. It has been found that a top rudder

is very advantageous, but it is difficult to operate, in that the long control line must be brought down over the top of the ship to the car.

Rip Panels. All non-rigid airships are fitted with a device for releasing the lifting gas almost instantly in an emergency. If, for instance, a ship runs out of fuel or has complete motor breakdown, and a landing must be made in a strong wind, the rip panels are pulled, when reaching the ground, and the envelope is deflated, allowing it to fall over the ground without material damage. It may then be rolled up and removed for new inflation. The rip panel is a specially strong panel of fabric fitted over a specially reinforced hole in the top of the envelope. To one end is attached a heavy rope which passes down to the

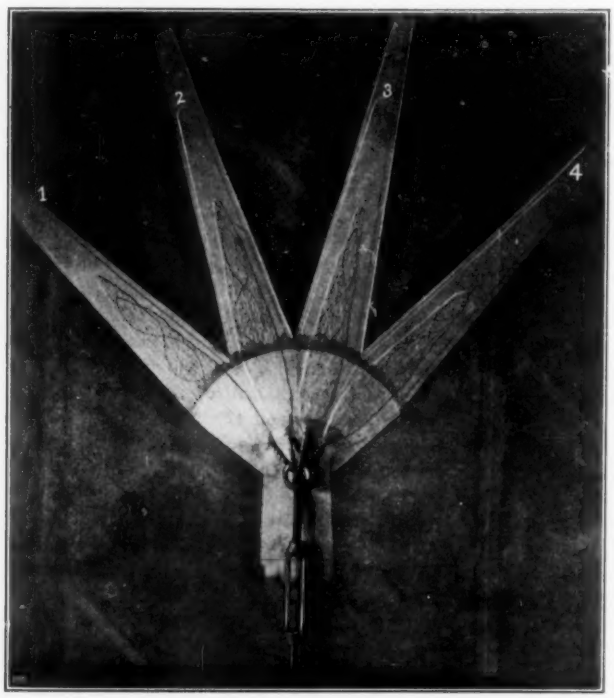

FIG. 5 FOUR-FINGER SUSPENSION PATCH

control car, and is pulled by the pilot when required. This pulling tears out the panel but does not harm the envelope. The panel may be refitted before the next inflation. For ships up to about 200,000 cu. ft., one panel is sufficient, larger ships usually having two rip panels.

Suspensions. The method of suspending the relatively short car to the long envelope of an airship is a whole problem in itself. The early pioneers used the simple net which completely surrounded the envelope, and was brought down to the car in a smaller number of larger ropes. This system had numerous disadvantages, notably excessive weight, resistance, tendency to slip over the envelope, and the difficulty of properly apportioning the loads. The next step in suspension was that of a girdle or band arranged on each side of the envelope on such a line as to allow of a tangential pull of the car ropes. The simplest form of band is that used in kite balloons where the total load to be carried by the envelope is small. This girdle consists of a doubled strip of fabric into which are sewed small wooden toggles, the complete band being then stuck or sewed to the envelope. A slot is cut in the center of the band at each toggle, and the suspension cords are passed around the toggle, and either tied or spliced securely.

Suspension girdles for larger ships are made by developing strips of heavy fabric in trajectories for each group of suspension ropes. The edge of the trajectory is reinforced by rope, formed into loops at each point, into which the actual-suspension lines are fastened. In the German "Parseval" ships suspension bands are fitted, which consist of lengths of strong webbing fastened in at each point of suspension, and passing through fabric pockets completely over the envelope to the suspension band on the other side. These bands distribute the loads over the envelope, and also add enormously to its strength.

Another form of suspension is that of individual patches for each suspension rope or each group. This type was first developed by the British Airship Service and first used on the

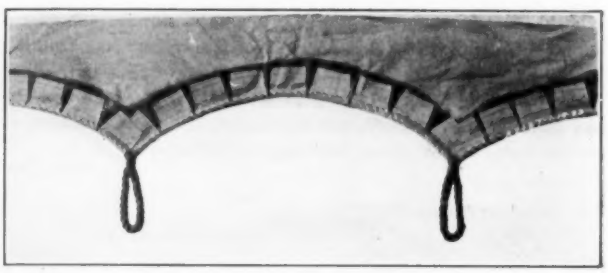

FIG. 7 SIMPLE LOOP SUSPENSION BAND FOR LIGHT LOADS

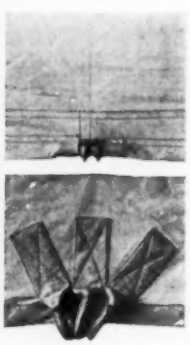

FIG. 6 AT TOP, TOGGLE SUSPENSION. AT BOTTOM, CROWS-FOOT SUSPENSION

British army airship *Eta*. The patches were afterward known as Eta patches. In this type of patch, lengths of strong webbing are passed around a tubular-steel "D" ring forming the bottom of the patch, and spread out fan-wise on to or between heavy rubberized fabric. The complete patch is about three feet overall each way, and will hold a load of about 1800 lb. when stuck with rubber cement on to the fabric envelope.

About ten years ago developments were started in this country with a modified suspension having the same features as the Eta patch, but formed by using manilla rope frayed out instead of webbing. Also, instead of using a fan-shaped patch, each strand of rope was stuck between fingers of fabric. This type is known as the Finger patch, and is now the standard type used for suspensions in U. S. airships. The regular four-finger patch will hold 2000 lb. A patch with two fingers is used for light loads, such as guy wires for stabilizers, etc., and holds about 1000 lb.

INFLATION, ASSEMBLY, AND RIGGING OF NON-RIGID SHIPS

To inflate and erect a non-rigid airship, the floor of the hangar must first be swept clear of dirt and all obstructions which would be apt to cut the envelope fabric, and the envelope is laid out flat on a clean ground cloth of duck. All air must be rolled out of the envelope, and the rip lines properly connected inside. The gas and air valves should be fitted, and the envelope left topside up, in order that it will rise from the ground straight, when the gas is allowed to flow in. A net made of soft-cotton cord is then placed over the whole envelope, and sufficient sandbags arranged along each side to take care of the total lift of the full envelope. The gas hose of heavy rubberized fabric and about 11 in. diameter is next connected to the filling sleeve near the nose of the envelope on the underside. A row of sandbags is placed across the bag just forward of the place

where the stabilizers will be fitted. This is to hold the gas in the front end until sufficient lift is obtained to carry the stabilizers. Gas is then allowed to flow into the bag, and as the lift increases, sandbags are hung on the net along each side, and more added as may be necessary. During this time the top stabilizer (if fitted) should be attached, and its guy wires fitted slackly. The side stabilizers should also be attached with their wires. Tackles should be attached to each stabilizer with ropes to the roof of the hangar in order to relieve the weight as they are lifted by the gas. Inflation is carried on with the row of sandbags in place until it is judged that there is sufficient lift to support the stabilizers. Then the bags are carefully removed, and the bag allowed to lift the surfaces, taking up on the tackles accordingly.

When the bag is full, plumb-bob lines are attached at nose, tail, and on each side at the maximum width. These are to check the trim of the envelope, and it is leveled up in both directions by moving sandbags along the inflation net as may be necessary.

When the correct conditions are obtained the car is moved into position under the bag, and the various suspension ropes or cables attached. After the position of car is checked, and the ropes at a proper tension, the inflation net may be removed by pulling it carefully over the top of the envelope to the ground. The car is held down during this process by changing the sandbags to the inside of the car or hanging them on the places provided on the outside. The stabilizer guy wires may now be adjusted, and the various control lines fitted. A blower is hooked up to one or both of the ballonets to maintain pressure by these air balloons during the changes of atmosphere. Valves and controls are tested, and the engines run, and after satisfactory trials of all parts have been made the ship is ready for flight.

Commercial Possibilities of Non-Rigid Airships

The non-rigid airship, particularly the smaller sizes, has many possible uses. Some of these are suitable for airplane operations, and others are distinctly adaptable for the airship. Among the uses of non-rigid ships are the following:

1 Survey and photographing of large areas of difficult, wooded country. This makes it suitable for use in the Forestry and Geological departments.

2 Dusting of crops or trees where large areas have to be covered. In the case of hilly country it is hazardous for a plane to operate close to the ground where the most beneficial results are obtained. The airships' ease of operation close to the ground and at slow speeds makes it ideal for this work.

3 Examination of territory by mining interests where the terrain may be examined close up and at slow speeds, and further, in difficult country where a plane could not be used safely.

4 Advertising in the air.

5 Transportation of passengers and freight.

For all of the above named fields excepting (5), a fairly small ship would be used. The design would be such as to offer the greatest ease of inflating and assembly in the open without the necessity of a hangar. Some form of small, portable mooring mast would be used, and the base of operations moved after each set area was covered. A truck or trucks would carry the portable mast, hydrogen cylinders, and working crew, and if the project was large enough, a portable hydrogen-making apparatus would be carried. Some six or seven years ago a medium-sized non-rigid ship built for the U. S. Army (the M. B.) was loaned to the Department of Agriculture for tests in dusting areas in New England infested by the Gypsy moth. Though this ship was not designed primarily for dusting, and much trouble was encountered due to lack of knowledge, this ship demonstrated the practicability of its use for dusting. In the light of present-day knowledge it is known that a small ship especially designed for the work would be of tremendous assistance in the dusting of large areas of hilly country where the Gypsy moth is a pest.

Similarly, in 1928, a small non-rigid ship was built for advertising automobiles in Detroit, and sufficient experience obtained to prove the uses of such a ship for the purpose. In this case, the ship was the smallest practical design ever used, having a gas capacity of only 22,000 cu. ft., compared with the 57,000 cu. ft. of the smallest passenger ship, the Goodyear *Pilgrim*. One of the chief features of this ship was its extreme portability, the whole ship consisting of envelope, car with engine, controls,

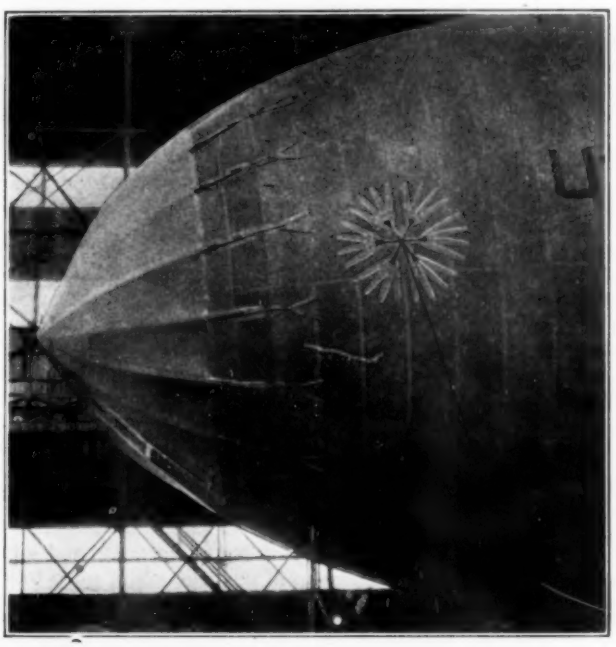

Fig. 8 Nose Stiffening of U. S. Army Semi-Rigid Ship R.S.-1

rigging, etc., being easily packed on to a small trailer, and the ship was actually transported several thousand miles in this way behind a light car. This ship was also inflated in the open several times with the same ease as the inflation of a spherical balloon, and was handled by one man when in the air. Further a ground crew of five men handled the ship for several weeks, compared with the sometimes two or three hundred used for larger ships in military use. The U. S. Army Air Corps made a technical report on this ship, and great possibilities were foreseen for the type. The small cost of a ship of this type is a notable feature. The Goodyear non-rigid ships, the *Pilgrim* and the *Puritan* of 57,000 and 85,000 cu. ft. capacity, respectively, have shown clearly the safety and reliability of airships for passenger carrying. These two ships have flown between them several thousand hours, and have carried a very large number of passengers, in addition to making many long-distance cross-country flights. The larger ship has a maximum speed of 55 m.p.h., and is, therefore, able to operate in winds of considerable velocity. Ships of this type may be used with advantage to create interest in lighter-than-air activities, and offer transport to people who cannot be appealed to by airplane passage. The satisfaction gained by the knowledge that if the motors stop functioning, the ship will still remain in the air and safe, gives it a decided advantage over the airplane, par-

ticularly a single-motor plane. Also, the passengers may be comfortably seated in a closed cabin with little trouble due to vibration or engine exhaust, and the ships ride more easily than a plane. A small airship of this type is also easily throttled down to any speed required, giving the opportunity of seeing the country at any particular time without danger.

It is foreseen that at a date not very far into the future, the non-rigid ship will be accepted as an ideal unit for passenger transportation within limited range and under limited weather conditions. It should be mentioned that a hangar will be required for the assembly and overhaul of these larger ships, but the regular operations may easily be carried on from mooring masts.

Ground Handling

There is one factor in the operation of airships that prevents the profitable operation of non-rigid as well as other types of airships. This is the handling element which includes the following operations:

(*a*) Maneuvering in and out of the hangar
(*b*) Take off and landing
(*c*) Mooring out where hangars are not available or when winds are too high for maneuvering the ship into a hangar.

The problem of handling rigid airships is receiving serious and active attention at the U. S. Naval Air Station, Lakehurst, N. J. The problem is a paramount issue, in view of the recent awarding of the contract for the construction of two, six and one-half million cubic-foot airships, and also the necessity of handling visiting-foreign airships, namely, the *Graf Zeppelin* and the British airships now nearing completion.

In consequence of this the non-rigid airship problem is practically eclipsed and will, therefore, receive little support from the government. However, the recent accident to the Navy's J-3 and J-4 ships, requiring their forced deflation at Bolling Field immediately following the presidential inauguration, has given impetus to the need for providing an adequate and safe method of mooring for an airship in the field, where entry to a hangar is impracticable or impossible.

Maneuvering In and Out of Hangar. The maneuvering crew required for non-rigid airships varies directly as the square of the wind velocity, and as the cross-sectional area of the ship. This may be expressed algebraically as follows:

$$N = K\ Vol.^{2/3}\ v^2$$

where,

N = Number of men
$Vol.$ = Volume in cubic feet
V = Velocity of wind in miles per hour
K = Factor of experience which is determined as 0.00014

Therefore,

$$N = 0.00014\ Vol.^{2/3}\ v^2$$

The various existing types of non-rigid airships would require the following sizes of maneuvering crew on the basis of the above equation when considering a ten mile an hour wind:

Type	Volume cu. ft.	No. Men
Pilgrim	57,000	15
TC and J	210,000	50
TA	130,000	36
TE	84,000	27
Puritan	85,000	27
Proposed Navy	320,000	65

This crew is split into five sections as follows:

Starboard Forward	25 per cent
Port Forward	25 per cent
Starboard Aft	15 per cent
Port Aft	15 per cent
Rudder and Car	20 per cent

The following is a brief description of the present method of maneuvering prior to a take off, and immediately on landing an airship. This is extracted from the Scott Field Airship School Manual on Airship Operation:

(*a*) The motion of the ship when in the hands of the maneuvering crew is controlled entirely by the handling guys. The function of the car party is not to move the ship but to keep the car off the ground. The car party lifts the car clear of the ground, and then the command to march forward is given.

(*b*) As soon as the handling-guy parties are clear of the hangar doors they move out at double time or walk out to the full extent of the handling guys, so that their pull is as horizontal as possible on the ship. When the ship is, at least, its own length from the hangar and nose into the wind, all the men on the after guys, except two to each guy, drop their lines and double time up to the forward guys.

(*c*) The above manner of handling the ship from the forward guys only is satisfactory for small and large ships in a mild wind, say ten miles per hour. In rough weather it is always necessary to retain enough additional men on the after guys to assist the ship in swinging into the wind. Should the wind change direction so as to strike the ship on the side, the car would tend to strike the ground due to the higher resistance of the ship when in a cross wind which produces a higher vertical component on the handling guys. Should the wind be of sufficient strength to cause the car to strike the ground, the ship would be turned broad side, in which position the ship is liable to be wrecked. But if the forward guys are held firmly and the car kept clear of the ground, the ship will swing around into the wind.

(*d*) When the ship has arrived at the point designated for taking off, it is brought to a standstill easily, the car being held clear of the ground so as to facilitate holding the ship into the wind. Assistance in this effort is rendered by the rudder man whereas the elevator man also aids in holding the ship clear of the ground. This assistance is very imperative in the case of rough gusty weather.

(*e*) In taking off, the car must be lifted waist high, then the guys are eased off and the car released.

(*f*) In landing the ship, the car party takes the position directly under the car as soon as the long forward-handling lines are in the hands of parties designated for them. The car party, obviously, prevents the car from bumping or scraping the ground. Maneuvering the ship into the hangar is similar to maneuvering it out from the hangar as far as the requirements of the maneuvering crew are concerned.

Requirements for Mechanical-Handling Equipment

From the foregoing it is apparent that the requirements for mechanical-handling equipment for non-rigid airships are fundamentally as follows:

(1) *Functional.*

(*a*) It must protect the car and surfaces from crashing into the ground.

(*b*) It should be able to keep the ship swung into the wind, as the resistance for zero inclination of the ship's axis to the wind is considerably less than when the ship's axis is at an angle to the wind. At zero degree incidence the drag is $^1/_3$ that for

20 deg. and about $^1/_6$ of the force normal to the wind (cross-wind force). These forces may be calculated on the basis of the convenient formula for resistance at zero degree angle of incidence:

$$\text{Resistance} = 0.03\ \rho\ V^2\ (Vol.)^{\,2/3}$$

Where ρ = weight in pounds of a cubic foot of air divided by g in ft. per sec. per sec., and has the numerical value of 0.00237, V is the velocity of the airship in ft. per sec., and *Vol.* is the volume of the airship in cubic feet.

(*c*) It should be provided with a weighing-off device, that is, a means for determining how much the ship is heavy or light.

(*d*) It should be quickly attachable and be provided with a master control by which it can release the ship.

(*e*) Provision for servicing the ship is desirable, such as refueling, ballasting, and gassing.

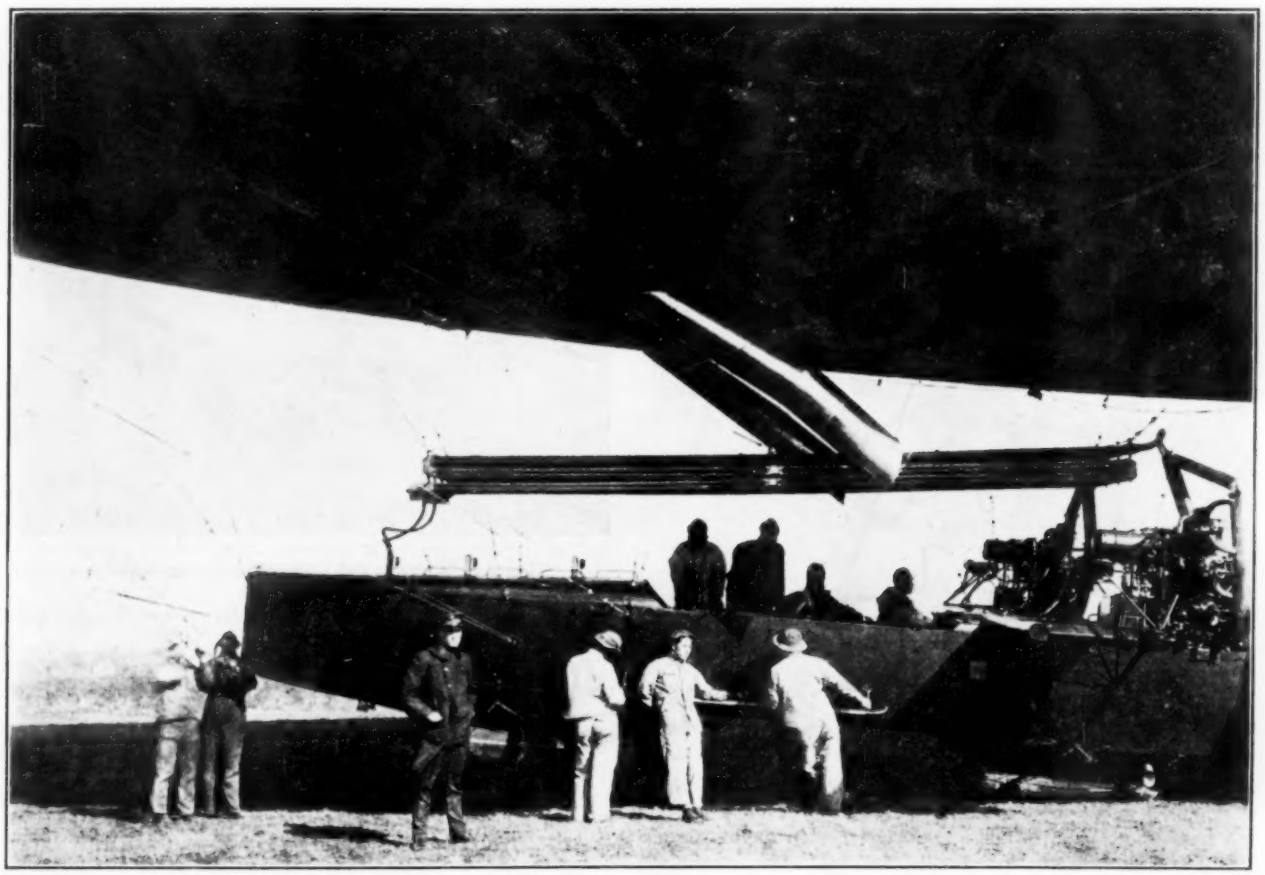

FIG. 9 WATER RECOVERY SYSTEM ON CAR OF NAVY "J" SHIP

(2) *Cost.*

(*a*) Crew required to operate should be a minimum.

(*b*) Low structural weight to reduce material and operating costs.

STATUS OF DEVELOPMENT OF MECHANICAL-HANDLING EQUIPMENT FOR NON-RIGID AIRSHIPS

Very little progress has been made in the past decade in the mooring and handling of airships of this type owing to the two retarding factors, that is, lack of funds for development, and the availability of ample manpower at a military post.

A very interesting and instructive paper prepared by Flight Lieutenant F. L. C. Butcher was read before the Royal Aeronautical Society on December 2, 1920, explaining the various methods which had been tried for both rigid and non-rigid airships in Great Britain with their advantages and disadvantages. Very little has been done in this country on non-rigids outside of verifying some of the British experience, and making some advancement in ground-mooring methods. An endeavor will be made to describe this experience.

Windscreens diverging from the sides of a hangar are a great aid to maneuvering a ship out of or into a hangar. The ship can be pivoted between the screens so as to head into the direction of the wind prevailing beyond the hangar doors.

(*a*) *Research.* Free-air tests conducted at the Bureau of Standards on models of $^1/_{20}$ scale in conjunction with wind-tunnel tests showed that a screen of the picket-fence type with the same spacing of pickets all over the screen was as good as any complicated method of perforation proposed or tried out in France or Great Britain. The most favorable spacing of pickets was found to be with $^2/_3$ of the area closed. The forces, when the ship is thus screened, are about 5 per cent of those measured without screens.

(*b*) *The method of maneuvering* an airship into a hangar equipped with windscreens is indicated diagrammatically in Fig. 10. Obviously, the maximum utility of windscreens is realized in cross-hangar winds as they minimize the danger of wrecking the airship against the doors.

For up-and-down hangar winds the danger in airship handling is caused by the eddy currents produced by the obstruction of the doors when open, and the downward pouring of the air at

the leeward end. These destructive air currents may be broken up or straightened out by opening the windward doors a distance, depending on the direction and magnitude of the wind.

(*c*) *Service Tests and Costs.* Screens have been used extensively in France and England. They have not, however, received very great support in England due partly to the fact that with large rigid airships the screens would have to be placed a great distance apart to be of any use and this would increase their cost. Furthermore, it is believed that the omission of docking-rail facilities in connection with windscreens had a great deal to do with England's decision to discontinue their use.

In this country windscreens were installed at the Fairfield,

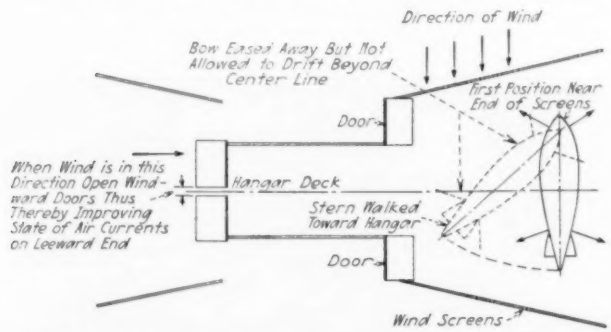

FIG. 10 METHOD OF MANEUVERING SHIP INTO HANGAR WITH WINDSCREENS

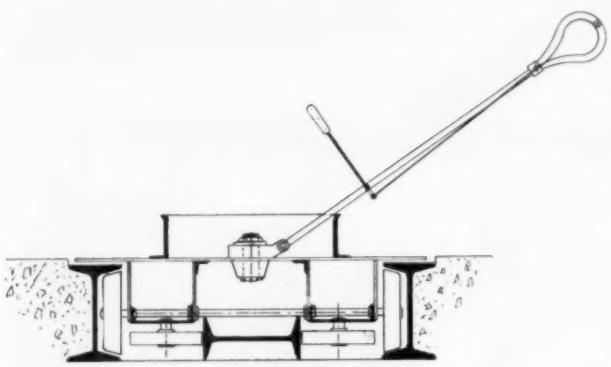

FIG. 11 OPEN-TRENCH TYPE OF DOCKING RAIL AND TROLLEY DEVELOPED IN GERMANY

Ohio, Air Intermediate Depot where a 43,500-cu. ft. airship was housed in a correspondingly small shed. As this hangar was just wide enough to house the single airship the maximum utility of the screens was hardly realized. The maximum utility of windscreens can be had only when the screens do not have to extend beyond the length of a ship, to be far enough apart to include the full length of the ship when placed broadside to the center line of the hangar.

Applying this generalization to an airship of 350,000-cu. ft. size, which is generally conceded to be the size for maximum utility, the following dimensions for hangar and screens are obtained:

Ship's length	250 feet
Ship's diameter	50 feet
Hangar height	75 feet in the clear
Hangar width	100 feet in the clear
Hangar length	275 feet in the clear

Screen diverging from 200 feet at the doors to 275 feet at the outer ends.

Here it is seen that the screens need not be longer than 250 ft., the length of the ship.

In 1926, the U. S. Army Air Corps proposed to install at Scott Field a set of moveable windscreens, as several ships had been damaged considerably in maneuvering in and out of the hangar. In order to accommodate the semi-rigid airship RS-1, then being service tested, it was decided that the dimension of each screen would be 300 ft. long and 80 ft. high. An estimate was obtained from the Wilkins and Phillipi Construction Company of St. Louis. This included figures for one screen to be mounted on 2000 ft. of trackage on one side of the hangar so that the screen could be used to protect a ship entering the hangar at either end. An estimate was also made for two screens and trackage on both sides of the hangar. In either case the cost was too high for funds then available. These figures and specifications are as follows:

COSTS AND CONSTRUCTION OF WINDSCREENS

Cost for labor and material for complete installation:

One Screen and 2000 ft. of double track $250,000
Four Screens and 4000 ft. of double track $800,000.

From this it is seen that the screens were estimated at $150,000 each and 2000 ft. of double track at $100,000.

Track to be of 100-lb. A. R. A. type-B rail bolted down to

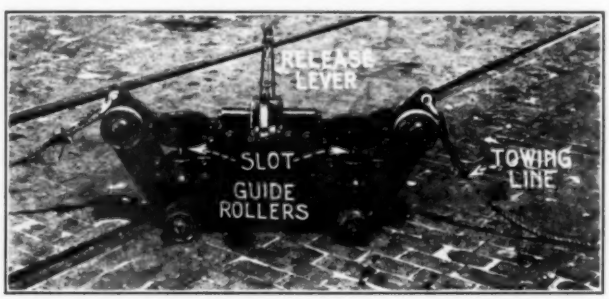

FIG. 12 TROLLEY FOR COMPOUND DOCKING RAILS

reinforced-concrete foundation with reinforced-concrete bumpers at the ends.

Screens to be constructed with structural-steel frame which was to be covered with No. 24-gage galvanized-rib metal lath wired on structural supports with copper wire. Specially designed trucks were to support these frames and air brakes and pneumatic bumpers were to be furnished for the trucks.

Motive Power. To consist of two 240-hp., two-cycle, direct-reversible, marine-type diesel engines approved by the American Board of Shipping. The engines to be equipped with clutch and to be geared to trucks to give the desired speed to the screen.

DOCKING RAILS AND TROLLEYS

An attempt has been made to reduce maneuvering personnel by the use of docking rails and trolleys. This has met with partial success. From the open-trench type developed in Germany as shown in Fig. 11, was evolved the compound-docking rail with trolley protruding through a slot (see Fig. 12). Various types of trolleys with varying degrees of success were developed to overcome difficulties experienced in operation. The principal difficulties, however, concerned the rails which being of the subsurface type required draining. During freezing weather these rails are liable to become jammed with ice and snow. In hot weather the slots will become too narrow for the passage of the trolley if the rails are set in concrete without adequate expansion joints to allow for the expansion

of the concrete. Where the trolley projects through the slots, rollers have been provided to prevent the trolley plate from scraping the sides of the slot. The size of these rollers being limited by the width of the slot, have proven too small in diameter to function as rollers. They fail to revolve under light loads, thereby producing a flat side which further prevents their action as a roller. At this stage, the roller requires replacement. It is admitted that a trolley can be developed to overcome this or any other difficulties if adequate study could be allowed for the design of a successful type.

After a study of the available data which at that time were meagre, it was decided to install the single rail and trolley as indicated in Fig. 13 for non-rigid airships. This system was installed at the Aberdeen Proving Grounds. Two parallel rails, 62 ft. apart, started inside the hangar 200 ft. from the doors, and extended straight out 400 ft. beyond the doors. This layout is similar to the German method, but the Italian method is to curve the outer ends, diverging the rails until they are at right angles to the centerline of the hangar. This latter method requires the use of one rail, obviously the one to the windward, and is based on the theory that anchorage to the leeward rail is unnecessary.

A description of the method of handling a ship with docking rails and trolleys is unnecessary as it does not differ from that of handling a ship without them, except that the guys are secured to the trolleys instead of being manned by parties. The trolleys are provided with quick-releasing gear for securing the guy lines.

Very little experience has been gained by the use of this system of handling, first because of the availability of ample manpower and second, because of the uncertainty of its success, the operating personnel being very skeptical concerning methods or devices differing from usual practice which they have found dependable and safe based on ample manpower.

Had experiments been conducted to a conclusion it is very probable that this gear would have been augmented by a cradle to receive the airship car, this cradle to be mounted on a car to run on a standard-gage railroad or to be equipped with a pneumatic-tired castor wheel such as is used with the *Los Angeles* airship at Lakehust.

Ground Cable and Snatch Blocks. Under the caption, "Emergency handling gear for small non-rigid airships" in the "Pressure-Airships" volume of the Ronald Aeronautic Library is described a method of launching an airship which is no doubt an evolution of the more-permanent docking rail and trolley system. It consists of a cable anchored a few inches above the ground on which are mounted two snatch blocks, one for each end of the ship. This gear was tested in 1918 and 1919 at the Hampton Roads Naval Air Station and at Camp Bierne, Texas and was proven practical. Later, about. 1923, it was installed at the Fairfield Air Intermediate Depot for handling the small towing airship turned over to the Army Air Corps by the Navy.

Maneuvering winches have been experimented with at Scott Field. A type designed by the McCook Field Engineering Division was originally equipped with a rope-grab mechanism located on the front end for automatically grabbing the handling rope released from the ship. This, however, proved impracticable and was replaced by the capstan and tested in the fall of 1926. The tracks of the caterpillar wheels were powered by a 60-hp. Waukesha engine. There was also a power take-off from the transmission for the capstan.

The following is quoted from a report of the test engineer W. E. Huffman for the McCook Field design of maneuvering winch. The TA airship noted therein had a volume of 135,000 cu. ft. and a length of 162 ft.

"The tests were made with a TA-type airship, using the winch on one of the forward-handling guys and the crew on the other. The first few landings were simulated ones, in which the ship came in over the winch but no attempt was made to snub it, the operator of the capstan merely taking hold of the handling guy and then releasing it after the winch had followed the ship's course some distance across the field. Due to the fact that there was little or no wind during these tests, most of the landings were quite fast, and some difficulty was experienced in keeping up with the ship.

"The first few landings proved that the best method of landing a ship is to station a man about 200 ft. ahead of the winch to grab the handling guy and pass it to the operator of the capstan. It was also found that in order to prevent running over and fouling the rope, and to enable the driver to see what is going

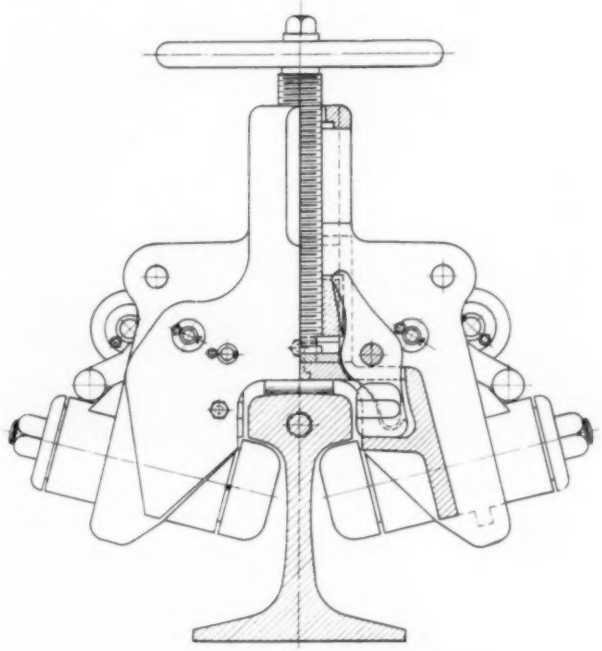

Fig. 13 Single Docking-Rail Trolley

on, it is best to head the winch toward the ship and run backward while a landing is being effected. As soon as the capstan operator is in possession of the rope, the driver reverses the winch and runs backward at the approximate speed of the ship while the capstan operator passes the rope through the hook and around the capstan. As soon as a couple of turns of the rope have been made and the slack taken up, the ship is gradually brought to a stop and then hauled in with the capstan. During these tests, handling-guy landings only were made, and of course it was necessary to use the regular crew on one guy.

"After an hour's practice a number of successful landings were made and it was found to be a very simple matter in spite of the fact that this winch is underpowered. It was proven, however, that an airship can be landed with machines of this kind without a large crew of men. The only men necessary outside of the three for each winch would be a sufficient number to handle the car upon landing. Such equipment would be especially valuable in landing ships that are very light, or the larger ships under all conditions where a great number of men are required. Using the winch to maneuver a ship across the field was successfully carried out at McCook Field.

"From the information obtained during the tests it is now possible to set forth the characteristics that a winch of this

type should possess. The first requirements are speed and maneuverability. In maneuverability the present winch is equaled by none, but its speed is not sufficient on soft ground due to lack of power. A speed of 20 m.p.h. should be possible over an ordinary flying field which is in fair condition.

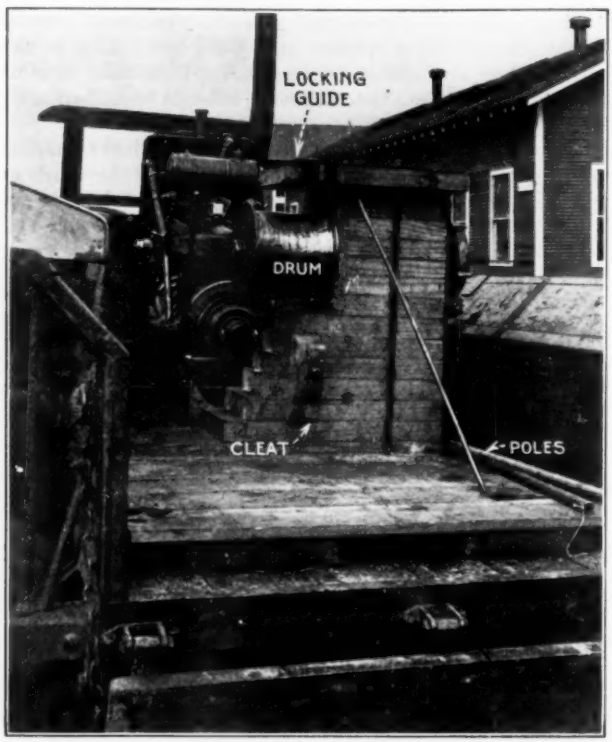

FIG. 14 MANEUVERING WINCH MOUNTED ON ARMY TRUCK

"The hook or other device through which the rope is passed before it reaches the capstan should be as near as possible to the pivot point of the winch in order to prevent jerking the ship in changing direction or in passing over rough ground.

"The capstan should be two and one-half or three feet above the floor. As it is, a man is required to stoop over while operating it, which makes it hard for him to maintain his balance when the winch is in motion. Operation of the capstan clutch should be by means of a pedal which can be reached conveniently by the driver's left foot."

In 1927 Captain H. C. Gray mounted a windlass on an army truck using miscellaneous parts from reclamation and conducted tests at Scott Field in landing both TA and TC ships. His setup is shown in Fig. 14 and was accomplished with very little funds and some ingenuity. However, definite progress along these lines can be had only by placing such equipment in service in order to obtain constructive service criticism to the end of perfecting the devices proposed.

The engine on this windlass is a small Ballot motor reclaimed from the French Zodiac non-rigid airship, of 325,000 cu. ft. capacity. The winch-driven mechanism is taken from the OB-1 airship (43,500 cu. ft.) and the radiator from the S. S. T. an English submarine-scout twin-engined airship (100,000 cu. ft.). The drum is made from a hydrogen cylinder.

The truck speed is 25 to 30 m.p.h., ample for the operator to pass the handling rope through the locking guide and wind it around the cleat thereby snubbing the ship. The poles on the floor of the car had wire hooks bent on the ends and were about eight feet long, enabling the operator to snare the rope as the truck passed by it. It was reported that a crew of two men easily landed both TA and TC ships with this device. Landings with ships light and heavy were made satisfactorily.

Captain Gray's recommendation for rigging the ship was as follows:

The ship should be rigged with the "Fixed Three-Wire Mooring System," a $^5/_8$-in. rope about 75 ft. long, being suspended from the quick release, and a $^3/_4$-in. rope 25 ft. long being attached to one front-handling rail on the car for the purpose of hauling the car down to change crews.

FIG. 15 NOSE CONE-TYPE MOORING MAST WITH TC-1 AIRSHIP

MOORING OUT EQUIPMENT

Masts. In addition to Flight Lieutenant Butcher's paper of 1921 quoted above, in which he gives a very complete history of mooring there have been rendered many papers on mast mooring, concerning tests and analyses of stresses of a ship thus moored. In the appendix of his paper on the "Development of Airship Mooring" presented to the Royal Aeronautical

Society, on March 4, 1926, and published in the Society's Journal in August of that year, Major G. H. Scott gives a brief history of mast mooring.

It appears that an Italian took out first patents on mast mooring which were allowed to lapse. Experiments with this type of mooring were started in England in 1911, continued in 1912 with non-rigids, then suspended until 1917. From 1921 to 1925 no flying was carried on in England while, however, a considerable amount of experimental work on mast mooring was carried out in this country.

In connection with rigid airships some success has been realized in this type of mooring, the initial difficulties of bringing a ship up to the mast and securing thereto having been surmounted, and the stresses on an airship thus moored determined, and structural strength being accordingly provided so as to minimize recurrence of breakaways experienced with the R-33 and the *Shenandoah*. Furthermore, servicing facilities such as waterballasting, refueling, gassing, and battery charging have been perfected. Therefore mast mooring bids well to become an established institution for large commercial airships since facilities can easily be provided for handling passengers and freight, such having been developed to meet military requirements.

Mast mooring has not however proven successful to such a degree for non-rigid airships as is evident from the following outline of the development:

Stationary types of mast were developed in the United States, patents having been taken out by V. H. Dill of the U. S. Army Air Service, the design however, having been originally conceived in England, where tests were conducted on it by the Army

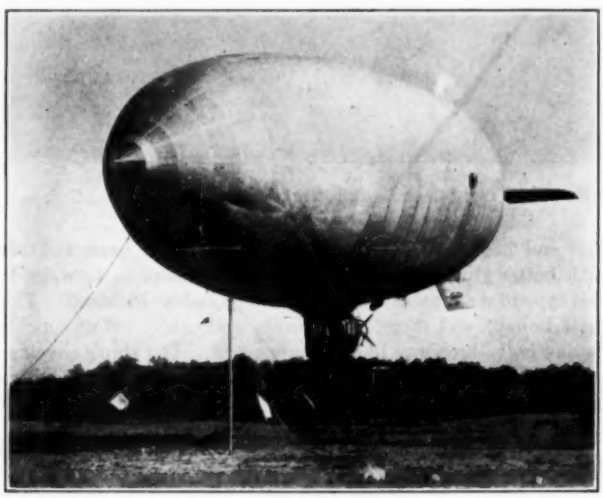

Fig. 16 Airship "Pilgrim" on Mooring Mast

in 1912 at Laffans Plain, South Farnborough with the *Beta*, an airship of about 65,000 cu. ft. capacity. Quoting Lieut. Butcher:

"This method proved satisfactory in light or steady winds, but in gusty weather when the movement of the ship was rapid a bending stress was set up in the fabric just behind the ring; this wrinkled one side of the nose and put a corresponding tension on the other, which tore the fabric after a short while.

"The reason for this was the fact that a few feet of the nose were held inside the cone and that the point of attachment of the ship was not directly above the pivot of the top of the mast.

"The cone was done away with, and a ship was moored directly to the top of the mast, but it was found that the fabric was not strong enough to stand the force of the wind on the ship. Consequently an axial spar, stayed to the after ends of the nose stiffeners, and projecting through the nose, was fitted to a ship and the spar secured to the top of the mast. This system was tried out with satisfactory results until the spar broke, and the experiments were discontinued."

Despite the British conclusions attempts were made to prove this type of mast, a number having been contracted for in 1921 for the purpose of trying out various types of cones and mast gear, and the results are rather optimistically set forth in McCook Field Serial No. 2063 prepared by V. H. Dill, July, 1922, in that the prediction is made that the deficiencies will be overcome by a suitably designed buffer.

Assuming that a buffer properly designed reduces the intensity of pressure caused by the ring type of buffer which gives

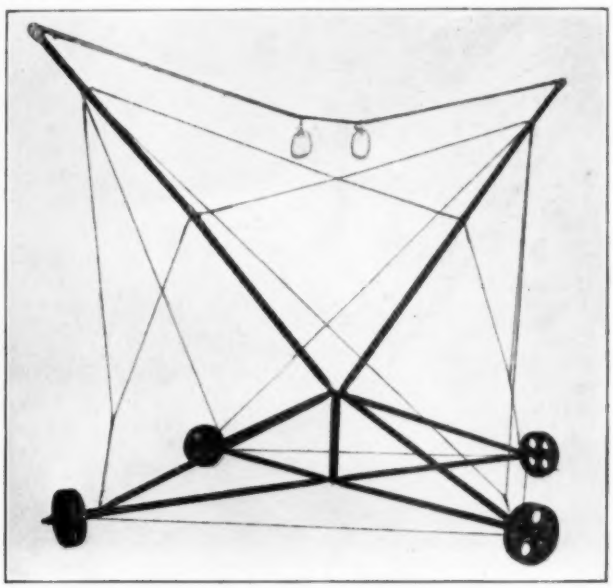

Fig. 17 Suspension-Type Mooring Mast

a line contact to the nose of the envelope, there still remains the bending stresses noted above, "the point of attachment of the ship being not directly above the pivot of the top of the mast."

Although there is no very definite data concerning the actual forces on an airship at a mooring mast, the approximation to the maximum transverse force at the bow as given in the Airship-Design Volume of the Ronald Aeronautic Library by C. P. Burgess will serve as a conservative basis for the determination of the reaction of the airship nose to the buffer, which is attempted as follows:

Given: $Vol.$ of TC airship 200,000 cu. ft. (approx.)
L of TC airship 200 ft.
Wind velocity 40 m.p.h. = 58.7 f.p.s.
$F = C\,q\,Vol^{2}/_{3}$

where F = transverse force
C = coefficient = 0.12
q = aerodynamic pressure $= \rho \dfrac{V^2}{2}$
$Vol.$ = volume of airship

Therefore:

$$F = 0.12 \times \frac{0.00236 \times 58.7^2}{2} \times 3400 = 1660 \text{ lb.}$$

FIG. 18 FIXED THREE-WIRE MOORING SYSTEM WITH J-3 AT LAKEHURST

With the nose of the airship six feet behind the pivot, and the buffer ring four feet aft of this point the vertical reaction at the buffer would be

$$\text{Reaction} = \frac{6}{10} \times 1660 = 1000 \text{ lb. approx.}$$

The component of this reaction normal to the envelope surface, assuming this surface to be 45 deg. with the reaction, would then be equal to

$$1000 \times \cos 45 \text{ deg.} = 707 \text{ lb.}$$

From this result it is difficult to conceive a buffer that would satisfactorily distribute the pressure over the nose of a non-rigid airship without stiffening the nose considerably thus introducing a prohibitive weight. This calculation further accounts for the failure of nose battens resulting from a mooring at this type of mast.

Mooring from a single point aft of the nose where the forward-handling guys are usually fitted was next attempted in England in 1918. A similar type of mast has been used by the Goodyear Tire and Rubber Company with the *Pilgrim* airship (Fig. 16) and by the Goodyear-Zeppelin Corporation with the *Puritan* airship. It is reported that the *Pilgrim* airship has moored to this mast in a 17-m.p.h. wind and the *Puritan* in a 28-m.p.h. wind. However in the latter instance one of the anchor bolts pulled loose from the ground, necessitating unhooking the ship and holding it by a ground crew. It was predicted that with better ground fastenings it would be possible to moor to this type of mast at a wind speed of probably 35 m.p.h. This mast is light and therefore portable, and can be set up quickly having only three guy lines to support it. The ship's envelope is fitted with a metal disk, and the mast is secured thereto with a ball-and-socket fitting. The British report this type of mast unsatisfactory asserting that the ship rolls badly.

From this type the Vickers Company of England evolved the crutch type shown in Fig. 19. The ends of the crutch arms are padded for fitting against ring patches attached to the envelope on opposite sides of the nose in the horizontal plane. The crutch is integral with the mast, the top part of which rides in a bearing, the housing being secured to cable guys anchored to the ground.

Cables are led through the crutch pads and secured to the envelope through ring bolts. Hand windlasses are located in the crutch arms for drawing the cables taut thereby securing the envelope rigidly to the mast crutch. Quoting Lieut. Butcher:

"Before bringing a ship to the mast it is turned so that a line drawn through the pads would be at right angles to the direction of the wind, then the ship is walked as close as possible to the mast by the handling party.

"A wire led from another small winch at the foot of the mast through a block in the bottom of the crutch is secured to the mooring point of the ship, and the ship hauled down until two

men, one stationed on each bow, are able to secure their winch wires to the ring bolts on the envelope.

"By hauling in on these winches the ring patches are brought hard against the pads on the bows, and the ship is secure. To keep the ship as nearly as possible in equilibrium chains are made fast to the car and allowed to trail on the ground. Thus when the ship becomes light extra chain is lifted, and if the reverse happens and she commences to fall, more weight of chain is supported by the ground."

In tests at Barrow-in-Furness a 70,000-cu. ft. ship was moored for eight days and rode without sustaining damage in winds of over 40 m.p.h.

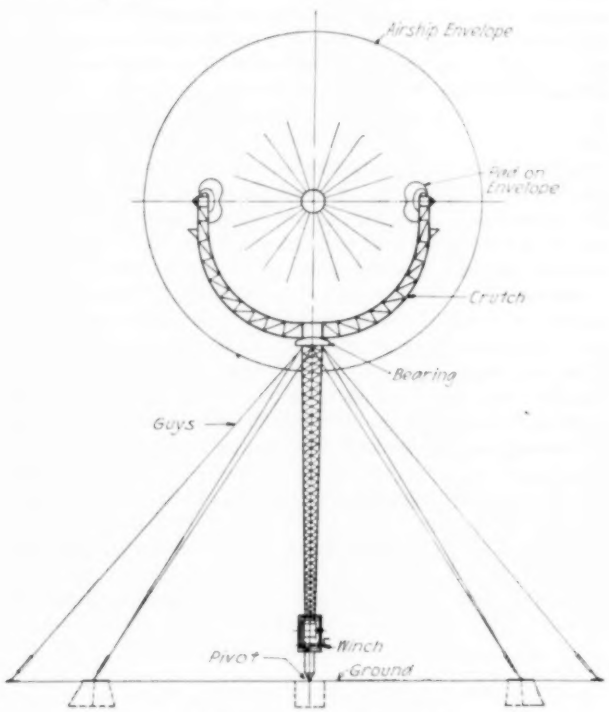

Fig. 19 Crutch-Type Mooring Mast

The disadvantages of this type of mast are:

(*a*) It is considered hazardous to have men stationed in the arms of the crutch as is required to operate the winches.

(*b*) If both sides of the ship are not attached to the mooring cables of the mast simultaneously, it is possible for the ship to swing away from the side not secured, thereby placing all the load on one patch, and subject the envelope to a tearing action.

Mobile Types

In 1922 the Air Corps initiated the development of a collapsible mooring mast with a cone top. This was designed to be mounted on a gun chassis but was found to be too heavy for transporting over flying-field terrain owing to the weight of the hoisting gear required. In fact, the mechanism was too heavy for the gun carriages then available. One of this type was constructed but owing to its excessive weight was not put through trial tests.

In Fig. 17 is shown a model of a mooring mast invented by Matt Q. Corbett, General Manager of the Aircraft Specialties, Inc., Wyandotte, Mich., which was developed and tested by the Air Corps at McCook Field in 1923. This was known as the suspension type, as the ship was attached at its bow mooring point to the cable suspended between the outer points of the upright tubular arms. The experimental units of this mast differed from the model only in that a pivot bearing was provided for anchoring the mast's position.

As the ship pivoted about the mooring point the mast would be rotated manually about its pivot point, the weight being carried by the four wheels fixed to the mast so as to travel in a circular path. It is also possible to rotate the mast automatically by securing the ship thereto with appropriately arranged yaw guys.

The advantages claimed for this type of mast were:

(*a*) Elimination of the excessive tearing strains found to exist with the nose-cone type previously described.

(*b*) Reduction of oscillations in thus mooring a ship at or near its center of resistance.

(*c*) Lessening of aerial obstruction in that it could be built closer to the ground than other types herein discussed.

During experimental tests of this mast the U.S.M.B. airship was satisfactorily moored thereto while executing its Gypsy-moth mission in the New England states in 1923. However, conclusive tests did not culminate as the urgency of mast mooring was not then realized. Consequently no further development was carried on.

Cable Mooring

From the beginning of the Air Corps' operations with non-rigid airships, the need was felt for establishing suitable anchorages at the then-existing air stations for the purpose of carrying on extensive cross-country flying. The first step in meeting this need was realized by installing anchors set below the ground surface and covered with a manhole cover.

There was also developed a snatch-block anchorage of the disappearing type, the block being mounted on a hinged plate designed to swing downward into a pit which could then be closed with a cover plate, thereby removing the obstruction from the landing field. This was known as the Terry maneuvering block, and was intended to aid the maneuvering crew in pulling the ship to the ground. The drag rope or trailing line would be reeved through the block, and manned by a party of men who would continue to haul on the line until the car was received by the car party and the handling lines by the rest of the maneuvering crew.

The next step in this development was in trying out various cable-mooring rigs such as described in Flight Lieutenant Butcher's lecture which has been previously referred to. The disadvantages of these types of moorings were early realized, being in general as follows:

(*a*) Considerable amount of cable rigging is required to be kept in working order by a ground crew.

(*b*) Ample notification would have to be given prior to making a landing in order to set up this rigging for the reception of the ship.

(*c*) The weight of such rigging made them cumbersome to handle. Ease in handling is a prime requirement for any airship-mooring rig.

(*d*) The ship was required to be moored at some distance above the ground in order to give the required kiting angle, and at the same time keep the tail clear of the ground. This led to the impracticability of servicing the ship, changing crews, etc.

In order to overcome the difficulties inherent in the existing types of cable mooring, a mooring device was conceived by the late Captain H. C. Gray of Scott Field, which was termed the "Fixed 3-Wire Mooring System." Its installation is shown in Fig. 18. The purpose of this design obviously was to reduce the weight of rigging, to facilitate installation, and to moor the ship close to the ground thereby making it accessible for servicing.

The initial service test of this device was conducted by Captain

Charles P. Clark, formerly of Langley Field, with a TC-airship. Previous experimental tests had been conducted by Captain Gray at Scott Field. In the service test which was conducted during the fall of 1926, the ship was moored at the Boston airport. Three hundred pounds of sand ballast was secured to a quick-release hook at the nose of the car. With this weight and an elevator setting of 10 deg. up, the nose of the car was kept just clear of the ground. The angle of trim of the ship averaged about 5 deg. nose down.

The wind was very gusty, ranging from 10 to 40 m.p.h. Captain Clark observed that the ship would ride the most extreme gust without the slightest danger provided elevators were used to right the ship when it surged forward or oscillated heavily after a gust. The rudder was used just sufficiently to overcome extreme yawing, but for the most part was left in neutral position.

The ground anchorage is provided with a quick-release hook, a torpedo-release hook being in the J-3-airship installation at the Naval Air Station, Lakehurst, N. J. In releasing from this anchorage the sand bags are dropped first, and the ground anchorage released immediately thereafter. This permits a quick get away in case the wind becomes too heavy for safe mooring.

The above cable-mooring gear has been used quite successfully by the U. S. Army Air Corps pilots operating out of Scott Field and Langley Field.

Summary

The salient features of the research thus far conducted may be summarized as follows:

(*a*) The present practice of handling an airship by a ground or maneuvering crew has proved inadequate, hazardous, and prohibitively costly.

(*b*) Docking rails and trolleys in conjunction with windscreens will no doubt reduce maneuvering crews, but research and experimentation conducted with this method of handling to date are not conclusive, having resulted only in the following generalizations:

Docking trolleys are considered too slow and unwieldy, rapid maneuvering being required in swinging an airship into the wind when leaving the hangar with a cross-hangar wind. A releasing and braking mechanism should be developed so that the guy lines may be reeved through at any required speed.

Wind screens have a high initial cost. Revolving hangars without screens are a logical substitute.

(*c*) Maneuvering winches have proved their utility on several occasions. It is reported that a tractor saved the R-9 from destruction when it was necessary to take it into the shed at Howden in a thirty mile cross wind. High maneuverability and a speed of 25 to 30 m.p.h. is a prime requirement of these tractors.

(*d*) Masts or towers which are proving a commercial possibility by Great Britain and the United States for rigid airships are far from being an unqualified success for non-rigid airships. This is due to the requirement, in case of the nose-cone type of a rigid nose on the airship for engaging the mast which would introduce a prohibitive weight. Masts for mooring the airship at the bow-mooring point aft of the nose have not proved entirely successful because of the excessive oscillations of the ship about this point.

(*e*) Cable Mooring. As in the case of the mast this means of mooring a ship in the field was developed to obviate the necessity of taking the ship into the hangar except for repairs or major overhauls requiring hangar equipment. The "fixed three-wire mooring system" is the latest and most approved type of such mooring, as it has saved ships from destruction on many occasions.

Conclusion

Non-rigid airship transportation is technically possible, and has certain inherent advantages over terrestrial modes of transportation. Exploitation of its commercial possibilities cannot, however, be accomplished without a satisfactory solution of the handling and mooring problems involved.

Obviously, the solution will be the one that affords the greatest number of flying hours to an airship. In this connection it may be observed that naval operations leading up to the battle of Jutland were held up by the German command because the airships were weather-bound in their sheds, otherwise the possibility of a German victory would have been greatly enhanced.

The prime requirements for a successful handling and mooring system are:

(*a*) Complete protection of the ship from the destructive elements of weather.

(*b*) Provision for determining the static lift of the ship, i.e., a weigh-off device.

(*c*) Provision for completely servicing the ship with fuel, oil, water, etc.

(*d*) Passenger facilities for embarking and disembarking.

Airports and Airport Engineering

By JOHN BONFORTE,[1] NEW YORK, N. Y.

DEVELOPMENT of efficient airports is one of the most vital problems confronting the aeronautical world today. Looking back to the war period and the years immediately following, aeronautical progress was marked by alternate spurts in the development of airplanes and airplane engines. After airplanes and airplane engines had arrived at a fair degree of efficiency, the thought of aeronautically minded men was turned to commercial air transportation. Civil air transportation was begun and carried on by the Government air services at a time when its future was uncertain. When the practicability, usefulness, and profit of air transportation had been fully demonstrated, the Government air services were replaced by private contractors.

While the Government stepped out of commercial air transportation, it continued to manifest its vital interest in American aeronautical activities by the passage of the Air Commerce Act of 1926. Since the inauguration of this Act, all commercial air activities have expanded steadily.

But, one important item is lacking in the complete air-transportation program, that is, airports which are efficient from an engineering viewpoint. Apparently, what is needed to develop good airports is specialized airport engineering. But the term "airport engineering" is so new that its meaning is apt to be somewhat loose; its application general; and its abuse by self-seekers very wide. Airport engineering is not a brand-new science or business but only a profession combining portions of the older engineering sciences in a new application.

In the absence of any accepted definition of airport engineering, the following is submitted:

Airport engineering is the profession that combines the existing knowledge of civil, mechanical, and electrical engineering, and applies them efficiently in the preparation of an area for landing field use.

The broad scope of this definition of airport engineering necessitates that the airport engineer possess the qualities of a chief engineer with the flier's knowledge of a desirable landing-field area; the city-planning expert's knowledge of city growth; the civil engineer's knowledge of surveying and topography; the soil specialist's knowledge of drainage and of sod growth; the highway engineer's knowledge of road materials and of road building; the construction engineer's knowledge of building; the electrical engineer's knowledge of the proper distribution of lighting; and the architect's knowledge of planning for present needs and future growth.

The problems confronting the airport engineer can be roughly divided into four classifications—selection, planning, construction, and lighting.

The selection of an airport site should include consideration of (1) probable users of the field, (2) geographical location of the city, (3) topography of the site and of the airways leading to the airport, (4) local weather conditions, (5) area and the shape of the airport, (6) surrounding obstructions, (7) accessibility to the site by highways and railroads, (8) availability of electricity, telephone service and water, and (9) drainage and nature of soil.

The probable users of an airport site determine largely and sometimes entirely the proper selection of an airport site. The probable users of an airport can be classified into air mail, express, and freight carriers; passenger carriers; flying-school operators; service operators; and "joy riders."

At one time joy riders constituted the bulk of the airplane passengers, and so the control lever of the airplane was called the "joy stick." Each of these users of a landing field has a different main requirement.

An airport suitable to an air-mail, express, and freight carrier should consider primarily the airway of which it is a terminal or depot. The inter-city passenger-carrier's airport should consider primarily its connection with the highway or railroad, transporting the passengers to the airport. The flying-school field should be located where ample level area is available with few surrounding obstructions and available to some nearby community by a good road. The service operators' field should be located primarily with a view to its availability to the business section of the community which it is serving. The joy-riders' field can be located anywhere that a crowd can be attracted and conveniently accommodated with parking space. And if a dance floor is provided all conveniences may be forgotten.

Local weather conditions should be given careful consideration in the location of an airport. There are sometimes small local areas in parts of the country which are frequently enveloped in fog due to the proximity of a lake, a marsh, a river, or the ocean. There are also areas in the country which are subject to peculiar local wind conditions. There may be winds that are almost blowing from one or two directions; or winds that blow incessantly and strong, or winds that fluctuate widely, causing the formation of eddy currents.

It seems superfluous to say that no airport should be selected and no airport layout should be planned without a careful study being made of the wind conditions; yet one of America's famous fliers laid out the runways for a proposed airport north and south, and east and west; when seventy-five per cent of the prevailing winds for that locality were from the southwest to northeast and from southeast to northwest, or at angles of 45 deg. to the proposed runways.

The area and shape of airports may be widely different and yet each be efficient; or the area and shape of airports may be alike and some be very good, some fair, and some very bad. The area and shape of an airport is only one of the factors entering into an airport selection, and for this reason it alone is not a criterion of the worth of an airport.

Airport drainage and the nature of the soil are two factors in airport selection which should also be given very careful attention. An airport that is excellent in summer and a marsh in spring cannot be expected to serve as an industrial center.

Airport Planning

One important consideration in airport planning is the possibility of its use for night flying. Night flying increases the safety requirements of an airport as night automobile driving increases the safety requirements of a highway. Obstructions which seem minor in the daytime may become hazardous at nighttime. The airport layout should consider in turn, the prime use of the field, the runways and landing area, the obstructions about the field, the location of the structures to be erected immediately and in the future, and the location of roads and parking space.

The location of the buildings at an airport depends upon so many other considerations that their position is frequently de-

[1] President, The Bonforte Airport Engineering Corporation, New York, N. Y. Mem. A.S.M.E.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

termined by these considerations if sufficient careful forethought is given to them. A few of these predetermining factors are: (1) The approaches to the field; (2) their availability and proximity to the highway; (3) the location of existing obstructions; and (4) the direction of the electric feeder lines. This last is an important point which is sometimes overlooked, necessitating the stringing of overhead electric lines around a border of the field, or burying them underground at considerable cost.

Construction Work and Lighting

The value of the construction work done at an airport depends largely upon the care and ability exercised in making the airport plans. Airport lighting is a new application of industrial lighting; and like it, airport lighting may enhance or impair the utility of the airport. An airport should have the usual night light equipment described by the Government, that is, a strong, distinctive beacon, field and obstruction lights, a ceiling light, and flood-lights. Flood lights are required for field and hangar illumination.

A single source of light for flood lighting is preferable to scattered sources of lights, because it is easier for the eye to accommodate itself to the uniformly graduated light from a single source than it is to accommodate itself to the uneven distribution of light from scattered sources.

At least one hangar should be illuminated by flood lighting. The same thought regarding having a single source of light, rather than a group of lights, applies to hangar illumination as well as to field illumination. Scattered goosenecks along the eaves and ridge of a building are an ineffective and insufficient means of lighting a hangar. A more efficient method is to flood light the roof by two or four flood lights mounted at short distances from opposite corners of the roof.

The term "airports" should be limited to those flying fields properly located, having a prepared surface of sufficient area to permit the safe landing and take-off of the largest airplanes, carrying their maximum loads, by day or night, in all directions of the prevailing wind currents for that locality; and having the following accommodations: (1) A maximum 30-minute traction or automobile service to the heart of the community being served, (2) a good telephone and telegraph service, (3) an ample water supply for drinking, sanitary field service, and fire-prevention use, (4) ample hangar space for the largest airplanes, containing lighting, heating, and repair equipment, (5) electric fueling service, (6) an efficient field and flood-lighting system, (7) day and night field service, (8) a weather communication office, and (9) a radio receiving and sending station.

Inefficient airports result from (1) general lack of knowledge of airport engineering, (2) widespread belief that well-known aviators are experts of everything aeronautical, including airport engineering, (3) diversified control of airports by municipal and civic bodies, who cannot profit by their early experiences, because they only control one airport, and (4) lack of experienced personnel in airport engineering.

The future remedy for the proper development of airports perhaps lies in governmental supervision. This supervision is coming very rapidly. But, instead of airport development and maintenance supervision being conducted by the Federal Government, as is the case with practically every other phase of aeronautical work, to all present indications governmental supervision of airports will apparently be conducted by state, county, and possibly municipal governments.

In an industry so widespread as aviation, such diversified control is unfortunate. However, since the Federal Government will not interest itself at the present time in airport legislation; and the states, counties, and local governments are doing so very rapidly, it is to the benefit of the entire aeronautical industry that those interested in airport legislation endeavor to make the regulatory measures as nearly uniform and helpful to the industry as possible.

Proper governmental regulation of airports should result in (1) standardization of airport planning, development, and lighting, (2) selection of air-mail airports relatively primarily to the airways of which they are a part, (3) maintenance of airports at a minimum standard, (4) increased public confidence in the security of air transportation, with a consequent increase of business for the reliable operators, and (5) an increase in the number of airports as State aid is obtained for the development of airports at strategic points in communities unable to bear the financial burden of the airport.

However, legislation at its best is only regulatory. The final solution of airport problems must lie in the hands of the airport planners and builders. Colonel Blee, Chief of the Airport Section of the Department of Commerce, summarizes the whole airport problem fully and concisely by saying: "The selection of airport sites cannot be reduced to a matter of mechanical routine; it necessitates the exercise of sound engineering and business judgment, coupled with a thorough understanding of the aeronautical problems involved."

Type Testing of Commercial Airplane Engines of Medium Power[1]

By H. K. CUMMINGS,[2] WASHINGTON, D. C.

ONE OF THE major requirements for an airworthy airplane is a reliable power plant of adequate power, suitably installed and fitted with an appropriate propeller. When a new airplane engine is built for military use, it is submitted to a type test for the purpose of determining its performance characteristics and demonstrating its reliability. The type test made by the Navy Department (aeronautical specifications E-4E) comprises (1) determination of the sea-level performance characteristics of the engine, (2) a 50-hour endurance run, (3) redetermination of the sea-level performance characteristics, and (4) a complete teardown inspection of the engine.

Under the first heading, tests are made at full throttle every 100 r.p.m. from 75 per cent to 115 per cent of rated speed. The quantities measured at each speed include brake horsepower, specific fuel consumption, friction horsepower, oil-pump capacity, oil pressure, and manifold vacuum. A series of propeller-load runs are made also, based on maximum power at the rated speed. At full throttle and rated speed, the effects on power of oil-outlet and air-inlet temperature are independently studied. The endurance test is run in five-hour periods. There are nine periods at rated power and speed followed by one period at full throttle and rated speed. Rated power is defined as 95 per cent of the maximum power developed at rated speed with the throttle wide open. The fiftieth hour of the endurance test is sometimes run at rated power but at 5 per cent above rated speed and the entire 50-hour test may be run without stops between periods. The failure of any vital part of the engine prior to the endurance test automatically rejects the engine, and any stoppage of the engine due to failure of its own mechanism terminates the test, unless such defect could be repaired while in flight. No engine is accepted for the standard type until it has passed an acceptance test (aeronautical specifications E-3E) in which it is run-in for at least five hours and then given two tests at rated speed with an inspection between. The first of these tests consists of $1^1/_2$ hours at 90 per cent rated power at rated speed followed by $^1/_2$ hour at rated speed and power. During this test the maker may make minor adjustments. The final acceptance test consists of $^1/_2$ hour at 90 per cent rated power and $^1/_2$ hour at rated power. At the conclusion of this test, the maximum power at rated speed is determined. Defective parts found on inspection and leaks developing during tests require one hour penalty runs. Not more than two such penalty runs are permitted.

The British Air Ministry prescribes a type test (Air Publication 840) as the basis for approving engines to be installed in licensed aircraft. The maker of a new type of commercial airplane engine must specify: (1) The normal speed of the engine (i.e., the maximum crankshaft speed at which it may be operated for long periods); (2) the maximum permissible speed (i.e., the maximum safe crankshaft speed for short periods of operation), which must be at least 10 per cent greater than normal speed; (3) the rated full power (i.e., the maximum power at normal speed), which must be at least $97^1/_2$ per cent of the power obtained at full throttle at normal speed; (4) the specific fuel consumption at normal speed; and (5) the specific oil consumption (maximum and minimum) at normal speed.

Prior to the type test, the maker must run a new engine in for at least two hours, tune it up on gasoline, and submit it to a standard two-hour endurance test at normal speed and 90 per cent full power. After a complete teardown inspection has been made, the engine is reassembled and given a final acceptance test for at least $^1/_2$ hour at normal speed and 90 per cent full power. (Unless otherwise specified, all test runs at 90 per cent full power end with a five-minute run at full throttle.) The type test comprises the following: (1) A power curve test, (2) a 50-hour endurance test, (3) tests of slow running and acceleration, (4) a high-speed test, (5) a high-power test, (6) a second power-curve test, and (7) a complete teardown inspection followed by a final $^1/_2$-hour test at normal speed and 90 per cent full power. The power curve is obtained by adjusting the load at full throttle to obtain successively maximum power at maximum permissible speed and at lower speeds (by 100 r.p.m. steps) down to at least 400 r.p.m. below normal speed. The engine must be run at least five minutes at each speed before the power reading is taken. The endurance test consists of five 10-hour non-stop periods at normal speed and 90 per cent full power. At least two periods are run on a torque stand and at least the fifth period is run on a dynamometer. For the final hour of this test, the load is increased to develop full rated power at normal speed and the test concludes with a five-minute run at normal speed with the throttle fully open. Fuel and oil consumptions on any 10-hour non-stop run during the endurance test must be within 20 per cent of the maker's rating. After the endurance test, while the engine is still warm, tests are made to see that the engine runs reasonably well at 90 per cent of full load when throttled down to 20 per cent of normal speed and that it accelerates to normal speed in five seconds without excessive vibration or carburetor trouble. The high-speed test consists of a one-hour continuous run at 10 per cent above the specified maximum permissible speed. For this test the load will be that recommended by the maker. The high-power test is a one-hour continuous full-throttle run at the maximum permissible speed specified by the maker. The failure of any vital part of the engine during test automatically rejects the engine, and after the replacement or rejection of any parts the government representative may require the engine to be resubmitted exactly as a new engine. The British requirements for the type testing of military engines differ only in setting maximum limits on the fuel and oil consumption and in calling for a 100-hour endurance test.

The air commerce regulations of the Department of Commerce provide that engines which have passed the regular endurance tests of the Army Air Corps or of the Navy Department will be approved for use in licensed aircraft and that all other engines submitted for approval will be tested at the Bureau of Standards. The present test requirements (Aeronautics Bulletin No. 14, pages 40–42) call for (1) a 50-hour endurance test, (2) a power-curve test, and (3) a flight test. However, the flight test is being

---

[1] Publication approved by the Director of the Bureau of Standards of the U. S. Department of Commerce.

[2] Physicist, U. S. Bureau of Standards.

Presented at the Aeronautic Division Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, Wichita, Kan., Sept. 21, 1928.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

waived in the case of engines which have a record of successful performance in the air.

The endurance test is run in ten five-hour periods. During the first period the engine is run at full throttle, the speed being at least equal to the rated speed and the power at least 10 per cent in excess of the rated power. The balance of the test is run at rated speed and power. This gives the manufacturer three options: (1) He may select as his rated power 90 per cent of full throttle power at the rated speed, in which case the first period will be run at rated speed; (2) he may select full throttle power at rated speed as the rated power, in which case the first period may have to be run at a speed 10 or 15 per cent above rated speed to obtain the 10 per cent excess power; (3) he may select as rated power 95 per cent of full throttle power at the rated speed and obtain the increased power at a speed about 3 per cent above rated speed. It will be seen that the first case corresponds approximately to the British endurance test but yields a lower power rating. The second case gives a rating equivalent to the British rating but makes the test rather more severe than the British endurance and high-power tests combined. The third case corresponds closely with the Navy endurance test but the first period is a trifle more severe than the final period required by the Navy department. This is the option usually chosen and is the most convenient one for torque stand testing since the same propeller which absorbs 110 per cent rated power at 103 per cent rated speed with the throttle wide open will also provide the proper load when the engine is throttled down to rated speed. This test is less severe than it sounds, for, contrary to both British and Navy practice, up to three forced stops are permitted. Forced stops may be required to correct fuel or oil leaks at the engine, to replace broken rocker arms or valve springs, and to clean spark plugs or repair accessories. Each forced stop becomes part of the test record and requires a two-hour penalty run at the end of the test period in which it occurred. The manufacturer's representative is also permitted to make minor repairs and replacements between test periods without penalty, provided the test schedule is not delayed thereby. The failure of a major part of the engine, such as a piston, cylinder, connecting rod, or crankshaft, automatically terminates the test, and inability to maintain rated power may necessitate a revision of the manufacturer's power rating.

The Bureau of Standards has determined with an electric dynamometer the performance characteristics of numerous water-cooled engines both under sea-level conditions and under conditions corresponding to various altitudes in its altitude chamber where temperature and pressure conditions can be regulated as desired. A 400-hp. dynamometer is available for the testing of air-cooled engines, but the air-blast required for suitably cooling radial engines of large frontal area is not yet available in the laboratory. For this reason, all tests thus far completed have been made on a torque stand located at College Park, Maryland, where the bureau's radio beacon is also located. An oversize four-blade wooden propeller is built for each engine and is adjusted until it absorbs the desired amount of power and also gives an air blast of at least 90 m.p.h. across the engine cylinders.

The torque stand is equipped with platform scales which are read to the nearest half pound, the average of three readings being taken for each $^1/_2$-hour interval. The horsepower is figured as equal to the product of the torque multiplied by the speed and divided by a constant for the torque arm. This result is increased by 5 per cent to allow for the reaction of the slipstream on the torque stand. The barometric pressure is read on a mercury barometer. Air temperatures are read on a mercury-in-glass thermometer. A stop watch is used to obtain the time required for the consumption of five pounds of fuel, weighed on a sensitive torsion balance. The oil consumption is determined by weighing at the end of each $^1/_2$-hour interval. Engine revolutions per minute are adjusted approximately by using a Navy type tachometer and are determined accurately by using a revolution counter and stop watch. The oil pressure is measured on an accurate test gage and two distance thermometers are used to indicate the oil inlet and outlet temperatures. The pressures through the fuel induction system are measured by mercury manometers. All the instruments are calibrated by the Bureau of Standards.

The curve of power versus speed is obtained by varying the load with the throttle wide open. The load is varied by adjusting a variable-pitch propeller or by cutting down a wooden propeller. At each load, the speed must be maintained approximately constant for five minutes before the torque is recorded. The test speeds range from 75 per cent to at least 110 per cent of rated speed. These full-throttle runs are normally made at the conclusion of the endurance tests. However, they may be made first for the information of the manufacturer in case his proposed power rating seems excessive.

As implied above, under existing regulations, the approval of an engine means only that it has gone through a 50-hour endurance test without a major failure and it may have escaped failure by a narrow margin. After the torque-stand tests and the final teardown inspection of the engine are completed, a report is made to the Director of Aeronautics which contains all the test data together with corrected horsepower, fuel consumption, oil consumption, cylinder temperatures, and air velocities. A detailed history of the test is given, illustrated by photographs of all parts which failed, were replaced, or showed undue wear. The design and performance of the engine are discussed and suggestions are offered as to the probable causes of any failures. Definite recommendations are made as to the approval of the engine. The fuel used during the test is stated and the engine is only approved for use with fuels of equal or higher anti-knock value. In case an engine cannot be recommended for approval, the conditions to be met by the manufacturer before a retest can be undertaken are specified. When an engine fails the test report is confidential, but the prospective user of an approved engine can and should obtain from the department information as to the actual performance of that engine under test.

Although all the engines tested thus far have been flown more or less extensively, about half of them have suffered major failures on the test stand. These failures were due in most cases to poor design, but the faults should have been discovered by the manufacturer on his own test stand. To be sure, the department requires merely that the engine submitted for test shall have been given a 25-hour bench test and that the average horsepower developed during this test shall not average less than one-half rated power, but this does not prohibit preliminary tests at rated power and speed. Difficulties with valves, valve stems, valve springs, rocker arms, rocker-arm pins, and piston rings indicate that more attention should be given these parts with respect to design and materials. In one case a poorly designed valve stem alone was responsible for a major failure. Induction, ignition, and lubrication systems have all given more or less trouble. The manufacturer furnishes whatever grade of fuel and lubricant is to be used and is permitted to have his carburetor and ignition system checked up by experts.

In conclusion, the use of a propeller which permits an approved airplane engine to run at full throttle in level flight greatly in excess of its rated speed is generally unwise and should never be permitted in licensed aircraft. An airplane engine approved for use on California aviation gasoline should never be permitted to operate at full throttle on straight Eastern domestic

aviation gasoline. The following ratings have been recommended by the Bureau of Standards:

Name	Engine description	Rating Hp.	Rating Speed	Fuel
Warner	7-cylinder (R-420)	110	1850	Domestic aviation gasoline (S. O. Indiana)
Kinner	5-cylinder (R-370)	75	1725	Red Crown aviation gasoline (S. O. Cal.)
Velie	5-cylinder (R-250)	45	1750	Esso or California aviation gasoline
Comet	7-cylinder (R-610)	115	1775	California aviation gasoline

Author's Closure

The printed airplane-engine test requirements were modified two months after the Wichita meeting in the following respects:

The paragraph specifying the endurance test was changed to read as follows:

The 50-hour endurance test shall be run in ten five-hour periods. During the first five hours the engine shall be run with the throttle wide open, the speed being at least equal to the rated speed specified by the manufacturer. A provisional power rating of the engine will be based on the average horsepower developed during the first period. During the remaining nine periods the engine shall be run at approximately 97 per cent of rated speed, and the horsepower developed should at no time be less than nine-tenths of the rated horsepower. The provisional power ratings shall remain in force for one year or until design changes or further tests justify a change.

The following new paragraph was added:

(9) No approved engine installed in a licensed airplane shall be equipped with a propeller so designed or adjusted that at full throttle the engine speed will exceed by more than 3 per cent the official rated speed in level flight at approximately sea level altitude.

The tolerance has since been increased from 3 to 5 per cent.

The effect of the first change is to eliminate the three options mentioned in the paper and to require of the manufacturer only a speed rating. The second change assures the engine manufacturer that his engine will not be permitted to operate at speeds greatly in excess of its speed rating and thus meets the point raised in the final paragraph of the paper. Under the revised regulations the power rating is determined by the horsepower developed during the first five hours instead of by the lowest horsepower developed in any five-hour period. It was possible, therefore, to raise the power ratings of the Kinner, Velie, and Comet engines by more than 10 per cent.

The present ratings of all engines which had received approved type certificates by May 15, 1929, are given herewith. In each case, the A.T.C. number is followed by the name and description of the engine and the last two figures specify the power and speed rating.

Engines Having Approved Type Certificates

1 Fairchild Caminez 447-C, 4 cyl., radial, air-cooled, 120/960
2 Warner Scarab, 7 cyl., radial, air-cooled, 110/1850
3 Kinner K-5, 5 cyl., radial, air-cooled, 90/1810
4 Velie M-5, 5 cyl., radial, air-cooled, 55/1815
5 Curtiss Challenger R-600, 6 cyl., radial, air-cooled, 170/1800
6 Curtiss Conqueror V-1550, 12 cyl., vee, water-cooled, 600/2400
7 Curtiss Conqueror GV-1570, 12 cyl., vee, water-cooled, 600/2400
8 Curtiss Chieftain H-1640, 12 cyl., radial, air-cooled, 600/2200
9 Aircraft Comet, 7 cyl., radial, air-cooled, 130/1825
10 Curtiss D-12, 12 cyl., vee, water-cooled, 435/2300
11 Dayton Bear, 4 cyl., line, air-cooled, 100/1500
12 LeBlond 60, 5 cyl., radial, air-cooled, 65/1950
13 Wright Whirlwind J-5, 9-cyl. radial, air-cooled, 220/2000
14 Pratt & Whitney Wasp, 9 cyl., radial, air-cooled, 450/2100
15 Pratt & Whitney Hornet, 9 cyl., radial, air-cooled, 525/1900
16 Axelson R-610, 7 cyl., radial, air-cooled, 115/1800
17 Wright Cyclone R-1750A, 9 cyl., radial, air-cooled, 525/1900
18 Packard 3A-1500 direct, 12 cyl., vee, water-cooled, 525/2100
19 Packard 3A-2500 direct, 12 cyl., vee, water-cooled, 800/2000
20 LeBlond 90, 7 cyl., radial, air-cooled, 90/1975
21 Wright R-975, 9 cyl., radial, air-cooled, 300/2000
22 Harris B-1, 8 cyl., vee, water-cooled, 90/1400
23 Wright R-540, 5 cyl., radial, air-cooled, 165/2000

Further work has shown that the windage correction on torque-stand measurements with a four-blade propeller may be quite large in case there is not room to use a straightening grid between propeller and engine. In such cases the corrected factor must be determined experimentally for each engine.

Development of Welded Aircraft Construction

By S. C. CLARK,[1] KANSAS CITY, MO., and W. I. GASTON,[2] NEW YORK, N. Y.

In this paper the authors point out that steel tubing is coming into common use for fuselage construction and with this there is a trend toward general use of welding. It is desirable to establish standard designs for welded joints and to this end further research is needed. Suggestions are made for improvements in welding practice that will add safety and insure uniformly well-made welds.

IN THE EARLY days of aviation it was natural that the pioneer experimenters should turn to wood as a structural material for airplanes. It was about the only suitable material available. Seamless-steel tubing was not unknown, but it is doubtful if it could be had in the extremely thin-walled variety, having the physical properties necessary to produce a very strong, light structure. High-strength alloys of aluminum were not developed until after the World War. Even if suitable steel had been available commercially, a convenient method of fabrication would have been lacking, for, at the time of the first memorable experiments of the Wright Brothers, gas welding was in about the same stage of commercial development as aviation. It is interesting to note that the development of the process is somewhat coincidental with that of aviation, having had its inception at about the same time and having received its greatest impetus during the World War.

Change From Wood to Metal

Airplane structures were, therefore, first constructed of wood. But, although wood still has its adherents, notably in foreign countries, many engineers soon began to see its shortcomings as a material for fuselage construction. In the first place wood, being a natural material, does not have the same uniformity of physical properties as metals, which are manufactured. Also, it must be remembered that a wooden fuselage is necessarily a composite structure requiring metal fittings at the joints and piercing of the wooden members, with consequent weakening of the section. It is very difficult to make such a structure function as a unit when stressed, rather than have individual members bear the brunt of the load at the point of application. Considerations of safety also favor metal construction since metal will bend while wood has a tendency to splinter leaving sharp ends. Small cracks are much more likely to exist undetected in a wooden structure than in one of metal.

However, the choice of a material for a given airplane part is largely a matter of proportion. For a part as deep as a fuselage, most of whose members function either as long columns or as tension members, according to the conditions of flight, metal is thought by the majority of engineers to produce the most economical section, considering the strength-weight ratio. On the other hand, for wings, which are of less depth and under flexural stress at all times, many feel that wood, even allowing an extra factor of safety for its lack of uniformity, produces the most economical section for wings of small or moderate size. As wing sections become deeper, metal construction becomes relatively more economical and therefore metal is being adopted rapidly for wing construction in the case of large planes. The present trend seems to be toward composite metal construction for wing structures, although some large wing structures have been fabricated entirely of welded chrome-molybdenum steel tubing. Welded steel wing beams, or spars, are being used with ribs of aluminum alloy.

Welded Steel Fuselages

For fuselage construction, mild-steel or alloy-steel tubing with welded joints is general practice. The most complicated joints or fittings can be fabricated easily from light-weight steel sheet and tubing by welding and finished fittings can be heat-treated if desired. Dies and patterns are not required, as would be the case if forged or cast fittings were used. This is especially important because of the rapidity with which airplane models change.

All forms of riveted or bolted construction will, sooner or later, loosen up to some extent at the joints. A welded fuselage is rigid and cannot develop play at the joints. Mechanical deterioration in joints is eliminated by this type of construction. A welded fuselage, if damaged, can be repaired easily, in any location, to be just as strong as it was originally.

A welded-steel fuselage, can be built, maintained and repaired economically. These considerations, in addition to the fact, that the majority of American aeronautical designers believe that the most economical strength-weight ratio is obtained through this construction, have made welded steel tube fuselages common in this country. About 90 per cent of American-made ships are being so constructed at the present time. Even when fuselages are constructed from duralumin, the highly-stressed landing gear, tail skid and motor mount are fabricated from chrome-molybdenum steel by welding and are then heat-treated.

Present Status of Aircraft Welding

The ability of welded-steel fuselages to stand the severe stresses of sustained flight with heavy loads has been amply demonstrated. All of the American planes that successfully completed trans-Atlantic and Hawaiian flights were equipped with welded-steel tubing fuselages.

Many pilots owe their lives to these crash-proof fuselages. When "crack-ups" occur the tubes bend and buckle, but the welds hold, keeping the structure largely intact. Welded aluminum gasoline tanks, which will often stand enormous impacts without even springing a leak, have also been a valuable contribution to the cause of safety. These are common equipment on the airplane of today. Fig. 1 shows the condition of a welded joint after a bad crack-up. The tubing is bent but the welds all held. Fig. 2 shows two 150-gal. gasoline tanks that survived the same crash without springing a leak.

F. F. Sisco, Chief of the Metallurgical Laboratory, Air Corps, Wright Field, Dayton, Ohio, said in a paper presented at the Tenth Annual Convention of the American Society for Steel Treating at Philadelphia:

"The art of welding, especially of thin tubular products, has progressed to the point where it is practically 100 per cent perfect.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The perfection attained is so high that at present the welded fuselage is standard in airplane construction. Other applications of welding in airplane and engine construction are too numerous and too well known to demand further consideration. Failures due to improper welding in the construction of the airplane are exceedingly rare; when they do occur they are almost always due to the welder and seldom if ever have their origin in the materials or the process."

Some of the best features of gas-welding practice have been successfully adapted to aircraft manufacture from other industries. For example, joints made by inserting a reinforcing plate in the plane of the axes of two or more tubes (in saw kerfs in the tubes) and then welding all seams are an adaptation of structural welding, this design having first been used in tubular roof trusses.

Thus it is seen that welding is at present an entirely practical and recognized process for the fabrication of aircraft fuselages and other parts. Future developments must, therefore, be in the nature of refinements.

Desirability of Further Research

J. B. Johnson, Chief, Material Division, Army Air Corps, Wright Field, Dayton, Ohio, said in a paper presented at the annual meeting of the American Welding Society in September, 1927, "There are no established rules for the design of welded joints which are directly applicable to aircraft. The Air Corps has published a few for the assistance of designers which are based on the results of tests and service requirements. A reduction of 15,000 lb. per sq. in. in the tensile strength of a chrome-

Fig. 1 Condition of Welded Joints After a Bad Crash

molybdenum steel having an ultimate strength of 95,000 lb. per sq. in. is recommended as a conservative figure for a straight butt weld. If the joint has a fish-tail form or is reinforced by gusset plates, the value may be increased and designs have been approved in which an allowable stress of 95,000 lb. per sq. in. has been used in calculation."

A new design for an airplane is checked by experts of the Aeronautics Branch of the Department of Commerce to determine whether or not it is air-worthy. Since available information on the strength and other properties of welded joints was not considered adequate by the Aeronautics Branch for checking airplane designs, the Bureau of Standards was requested to conduct an investigation of the subject, which is now nearing completion.

From these commentaries it is seen that aircraft welding in its present state may be considered a product of natural growth, which has not yet received its share of scientific research, although certain individuals have been very active in the latter field. Having achieved its remarkable success under these conditions, it is reasonable to assume that considerable further improvement can be made.

Work of the Bureau of Standards

The investigation now in progress at the Bureau of Standards includes 134 different joints of the "T" and "lattice" types. Materials used are mild steel under Army specifications No. 57–180–1, which is the same as S.A.E. No. 1025, and chrome-molybdenum steel under Army specification No. 57–180–2, which is the same as S.A.E. No. 4130 X. By systematically varying

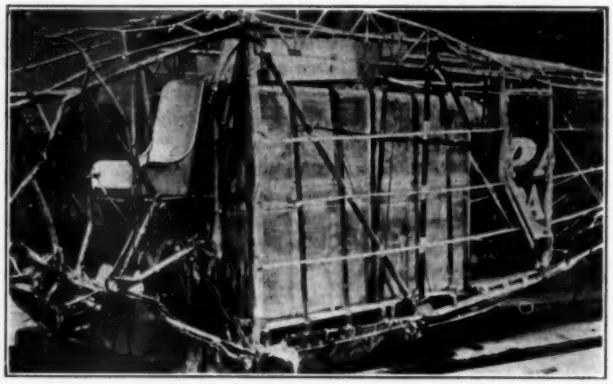

Fig. 2 Tangled Mass in Pilot Seat. There Were no Failures at Joints

the designs of the joints, including dimensions of inserted gusset plates, where used, and noting the effect on the strength, weight and cost, the most efficient types of joints will be determined. Handbook information concerning these joints will be available to all aircraft manufacturers at the conclusion of the investigation. Types of joints being tested at the Bureau of Standards are shown in Fig. 3. The ones on the right are the inserted gusset-plate type, previously mentioned.

Welding at the Bureau of Standards is being done in accordance with a "Procedure Control" drawn up by the representatives of the gas-welding industry on the sub-committee on Procedure of the American Bureau of Welding, which is the research department of the American Welding Society. A "Procedure Control" is a detailed production specification covering: (1) Check of welders' ability, (2) selection and inspection of materials, (3) design and layout of welded joints, (4) preparation for welding, (5) welding technique and (6) inspection and tests. Experience with procedure control in other fields where strength and reliability are paramount has shown that it does insure work of uniform high quality. A carefully prepared procedure control removes the human element and places the responsibility for good welding upon the designer and inspector rather than upon the welder.

Suggestions for Improvement of Present Practice

Failures of welded joints in service have been practically unknown for the following reasons: (1) Properly made welds are inherently strong. (2) In the application of Euler's formula for determining tube sizes for fuselage members, a coefficient of restraint of only 1 has been used; thus it has been assumed that the structure is pin-ended at every joint, although this is not the case. (3) The testing of new types of airplane construction has been very thorough. Nevertheless, procedure control as applied to aircraft welding has not yet been developed to the same extent as it has in other industrial fields. From the results obtained in other important fields, it is certain that by the adoption of standardized procedure control methods much can be done toward better design and execution of the weld, increase of the strength-weight ratio, and a closer approach to the ideal of a

plane that cannot be broken in the air. The procedure control prepared by The American Bureau of Welding and now being followed by the Bureau of Standards will, when finally revised, constitute an authoritative guide, available to all aircraft manufacturers, on this important subject.

Check of Welder's Ability

A standard specification that will insure the hiring of good welders has been drawn up. This includes, in detail, previous

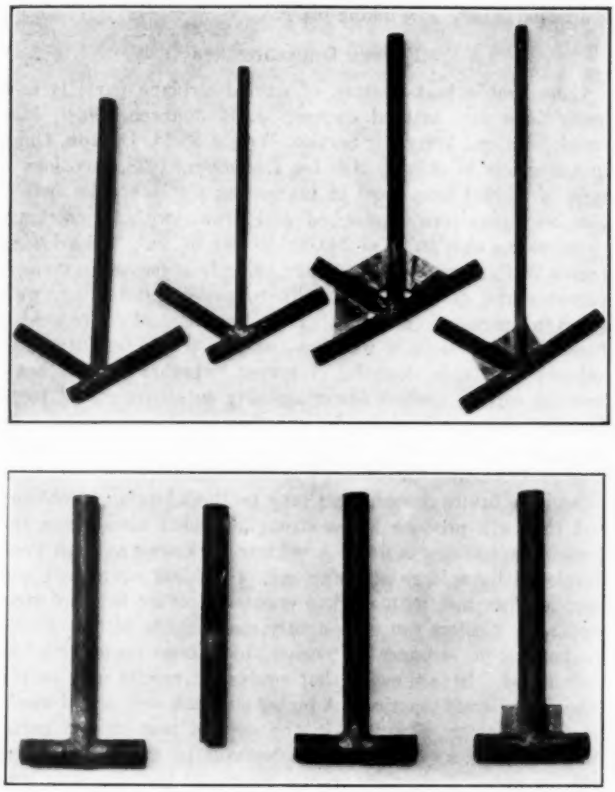

Fig. 3 Types of Welded Joints Being Tested by the Bureau of Standards

experience or training required, specimen welds to be made, observation of the manner in which the prospective welder handles the apparatus and the factors of manual skill to be looked for by the welding inspector in a preliminary qualification test. Conformity to dimension, contour of the weld, penetration and fusion are taken into consideration. If the welder satisfactorily passes this preliminary test, he is required to pass a final qualification test consisting of certain rotative and position welds, which are then examined visually and subjected to prescribed strength and ductility tests. A welder having passed these tests is certain to be capable of making satisfactory aircraft welds.

Selection and Inspection of Material

Certain grades of mild-carbon and chrome-molybdenum steel, mentioned previously, are the materials used at present. The latter has largely replaced mild-carbon steel because of its superior strength, and due to its air-hardening properties, the strength of the welded tubing approaches that of the original material. Mild steel is still used to some extent. Its modulus of elasticity is equal to that of chrome-molybdenum steel, and it is cheaper. Therefore, it is considered more economical for certain members by some manufacturers. Others have standardized on the alloy steel for all members.

The procedure control contains detailed specifications for check testing this material against mill specification for physical properties. Weldability tests are also prescribed for base metal and welding rod.

Design and Layout of Welded Joints

Design of welded joints is an extremely important consideration. While the joints used at present are very efficient, a standard design for each type of joint, which is strongest, easiest to weld, and most economical of base metal, welding rod, and gases, and consequently lightest for the required strength, is highly desirable.

Position of tack welds and sequence of welding to avoid cracking and distortion of the members joined, from the contraction of

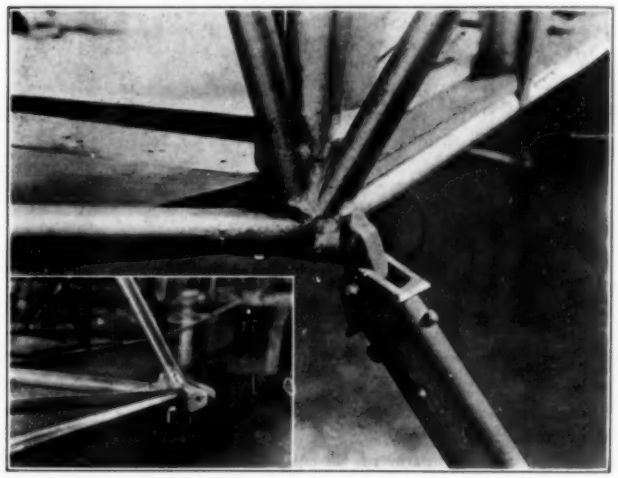

Fig. 4 Some Types of Joints With Many Members Coming Together

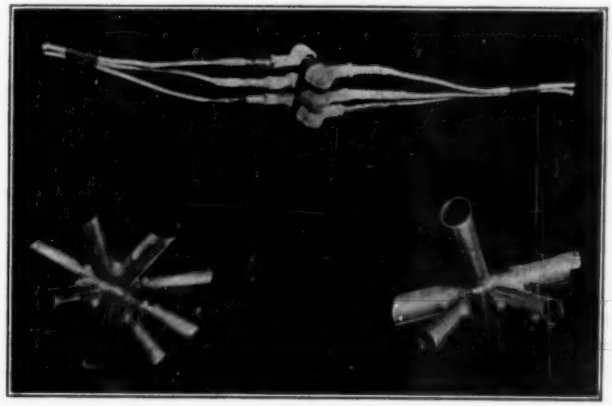

Fig. 5 Some Complicated Types of Welded Joints

the cooling weld metal, are problems yet to be thoroughly worked out. The principles of heat control are already well understood, especially for the simpler joints, but there is undoubtedly much room for improved procedure in the case of the more complicated joints containing gusset plates and fittings and where many members come together. Figs. 4 and 5 show some joints of this general type.

Preparation for Welding

The actual layout or assembly of members is usually accom-

plished by the aid of jigs, although special or experimental work may be set up largely by means of clamps. Jig design is well understood at present although this too is susceptible of improvement and standardization. A jig for interchangeable-fuselage sections for large Army bombers is shown in Fig. 6. Probably the most important problem to be worked out in preparation for welding is the arrangement of work for line production. For instance, is it more economical to have six welders working

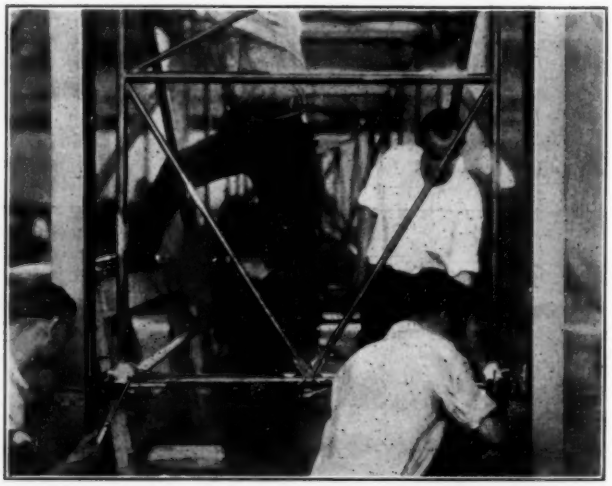

FIG. 6 TYPE OF JIG USED IN FUSELAGE CONSTRUCTION

simultaneously on one assembly or to have two welders working on each of three assemblies? Such details as this have not yet been satisfactorily determined, in most cases, due to the newness of the industry.

Actual manipulation of blowpipe and welding rod to secure a good weld needs little comment. A qualified welder, given detailed instructions, will experience no difficulty in properly executing the weld. Welding technique is, however, thoroughly covered in the procedure control.

INSPECTION AND TEST

An authoritative scheme for inspecting the work of the welder, which will insure against defective welds in the finished product, is also being worked out. Individual manufacturers have their own ideas on this subject and some of them are undoubtedly better than others. What is needed is a standard method that can be used successfully by any manufacturer. Methods of periodic testing of welders' work and test of the finished product that will apply in all cases are included in the procedure control.

Individual welders are, as has been mentioned, required to pass qualification tests before undertaking production welding. Welding inspectors should be qualified by a period of training in a good welding laboratory. By this means they will obtain a laboratory point of view and a grasp of fundamental principles, obtainable in no other way, through contact with men extremely well versed in the theory and practice of welding as well as testing methods.

Additional items covered by the procedure control are welding apparatus and gases, characteristics of flame to be used, gaging welds and weld tightness as a possible means of preventing interior corrosion.

In the foregoing an effort has been made to set forth the lines along which present aircraft-welding practice may be improved. It is not possible to offer conclusions since the process of standardization is only now taking place.

FUTURE DEVELOPMENTS

Considerable heat-treating of welded airplane parts is now being done with marked success. J. B. Johnson, Chief, Materials Section, Army Air Service, Wright Field, Dayton, Ohio, in an article in *Airway Age* for December, 1928, mentions a type of welded joint used in fabricating airplane axles, which can be satisfactorily quenched and drawn without cracking, to develop a unit stress of 200,000 lb. per sq. in. Welded wing beams 20 ft. or more in length are being heat-treated in vertical furnaces and quenched vertically to prevent distortion, with resultant increase in strength. Heat treatment of entire welded fuselages, or sections of fuselages, may be a field for future development. It is doubtful, however, whether or not heat-treating can be applied advantageously to all structural parts because, although it materially improves tensile and compressive strength, it does not increase the modulus of elasticity of the steel and therefore the efficiency of the members.

Another future development may be the adoption of welding rod that will produce higher-strength welded metal than the low-carbon rod now in use. A welding rod known as High Test, developed by a large manufacturer of welding equipment and supplies, has met with marked success in other fields of steel welding. Welders can consistently make welds with it 11,000 lb. per sq. in. stronger in tension than those made with low carbon rod. It is thought that equivalent results may be obtained in aircraft practice. A higher strength weld metal would be of particular advantage in the case of heat-treated parts. Manufacturers so far have been hesitant to adopt alloy steel welding rods because they are not convinced that the same uniformity of results can be obtained as with the type of rod now used. This matter is one that will be answered by future developments and experience. Another future possibility is the development of a new alloy steel, but the present chrome-molybdenum seems to be highly satisfactory.

The welding industry is keenly alert to the possibilities for developing further improvements in welding as applied in aircraft construction. Its engineers, metallurgists and physicists are giving serious study to all phases of the subject. They invite cooperation of aviation executives by submitting their problems, in order that the same facilities and technical guidance may be applied to aircraft welding as have been adopted with such splendid results in other industries where procedure control has proved to be the key to successful production welding.

Relative Merits of Various Types of Wing Structure in Monoplane Design

By GEORGE W. DeBELL,[1] BUFFALO, N. Y.

WITH reference to wing design, airplanes may be divided into four classes: the sport type under 2500 lb.; the small transport of about 4000 lb. for five to eight passengers; the medium-sized transport around 15,000 lb. for ten to twenty passengers; and the large transport over 20,000 lb. for more than twenty passengers. The size of the airplane has considerable influence on the type of wing structure used. For instance, in the small sport-type plane, two-spar cantilever construction may be used to advantage as the wings are so small and relatively short that torsional deflection is not a problem, and the loads are so light that two spars are sufficient to carry them to advantage. If more than two spars were used on this small airplane, they would be composed almost completely of minimum sizes and, therefore, the weights would be higher than the two-spar construction. But, if two-spar construction were applied to the large cantilever airplane weighing in the neighborhood of 20,000 lb. it would make the construction quite difficult and probably unsafe, due to the lack of torsional rigidity. Due to the tremendous sizes which would be required, when the applied loads were concentrated on only two spars, the material would be of such size as to be difficult of fabrication. Considering only cantilever construction, the following is an analysis of the types of spar structure adaptable to the different size airplanes.

In the sport type either single or two-spar construction is most efficient as the loads are concentrated and there are fewer members to fabricate. In the small transport (4000 lb.) the single-spar construction would not be adaptable as it has not sufficient torsional rigidity. Two-spar construction would probably be the most economical, particularly if the airfoil section were deep enough to give a good drag truss depth. Three-spar construction on this size airplane would again become uneconomical due to the excessive use of minimum sizes. In the medium size transport, around 15,000 lb., the two-spar construction would not be adaptable unless it was aided by a plywood or metal-wing covering as the members would become excessively heavy and the torsional rigidity would be questionable. Three-spar construction would seem the most efficient for this size airplane as any greater number than three would require minimum sizes. Two notable cases in this are the Fokker tri-motor using two-spar construction but relying for torsional stiffness on the plywood wing covering, and the Ford tri-motor using three spars of built-up channel sections and using a corrugated aluminum-alloy wing covering. In the Ford both the three-spar construction and the wing covering tend to make for torsional stiffness, while in the Fokker the plywood wing covering gives the needed torsional stiffness and also may aid in the beam forces, thus reducing the theoretical size of the members. In the large transport over 20,000 lb., multi-spar construction is practically a necessity since any fewer number of parts would require excessively large size and so would be difficult to fabricate.

The above statements apply to pure cantilever construction only. When external wing bracing of any sort is used, the number of spars required for any particular size of airplane may be diminished over the number required for the same airplane in cantilever construction. It is possible, when using deep-external bracings, to design a two-spar wing for the largest type transport and feel assured that the wing will be torsionally stiff enough to prevent flutter. There are two methods in which the wing may be externally braced. One in which the external bracing takes load in either direction, and the second in which the external bracing acts under normal flight loads and the wings act as a pure cantilever under inverted flight loads. In the second type, the front spar should be checked for rigidity as in nose dive the front spar would have inverted flight loads, while the rear spar had normal flight loads. This makes the external bracing in the plane of the rear spar act while the front spar is required to take the loads as a cantilever beam. For this reason the front spar should be rigid enough to prevent excessive washout of the wing tips.

There are two main types of drag trussing used in wing construction, the single-bay drag truss and the double-bay drag truss. The single-bay drag truss has gone more or less out of favor since the advent of the thick airfoil, although it is still used on small planes such as training planes, where cheapness of construction is one of the primary requirements. It has two disadvantages, that it does not prevent rotation of the spars, and that it does not aid in torsion. In the two-bay, or double-drag truss, where one truss connects the tops of the spars and the other truss the bottoms, the spars are held in relation to each other and rotation is prevented by the use of a trussed drag strut. It has the additional advantage of adding greatly to the torsional stiffness of the wing. In fact, the most efficient place to add weight to resist torsional flexibility is in the drag truss. This follows from the formulas of mechanics which show that in the beam of rectangular cross section the greatest torsional stress occurs in the wide face, which in the wing is represented by the drag truss, the narrow faces being the spars. In the single-bay drag system the truss is usually a pure Pratt truss with cross wires and compression struts, but in the double drag-truss system there are several types of construction used, each one being particularly adaptable to a single type of spar structure. The strut and wire, or pure Pratt type is best adaptable to two-spar construction. The Warren truss, or modified Pratt, in which the wires of the Pratt truss are replaced by tubes, is best adaptable to three-spar construction. This is particularly true if the middle spar is exactly half way between the front and rear spars, as the crossing points then occur on the middle spar and so reduce its lateral column action to half the drag bay length. In multi-spar construction where fabric wing covering is used, a drag truss must be employed to hold the spars in their relative positions. For this type of construction the drag truss is usually of the lattice type interlocking all the spars. (See Fig. 1.)

In any type of double-drag system, the drag struts should be shear braced in order to derive maximum benefit from the system in resisting torsional deflection. When a metal or plywood covering is used on the wing, the drag truss is usually omitted. However, compression ribs must still be used at intervals to replace the drag struts and hold the skin to the true contour. In

---

[1] Aeronautic Engineer, V. E. Clark, Buffalo, N. Y.

Presented at the Third National Meeting, of the A.S.M.E. Aeronautic Division, St. Louis, Mo., May 27 to 30, 1929.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

these cases the skin is assumed to take all the drag load and in the case of plywood covering the skin is, in addition, assumed to take a small amount of the beam load.

In the detail design of the spars there are several types of construction which may be used. In metal construction there are two major classes with spars made of steel and of strong-aluminum alloys. There are two main sub-divisions of the

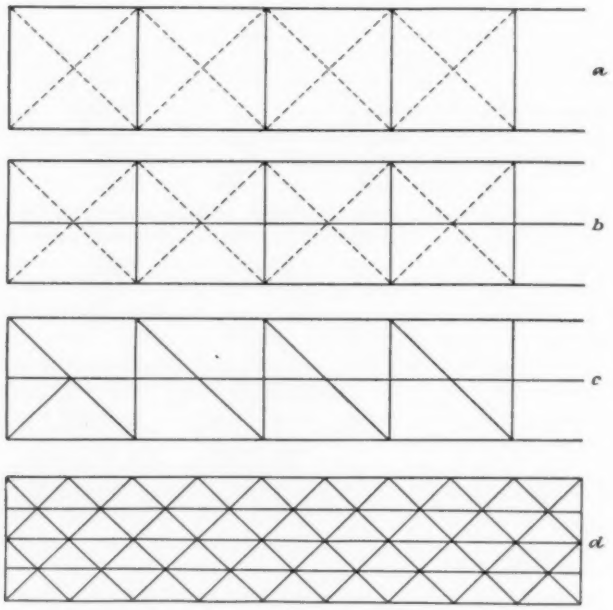

FIG. 1 TYPES OF MULTI-SPAR CONSTRUCTION: *a*, TWO-SPAR; *b*, THREE-SPAR WITH WIRES; *c*, THREE-SPAR WITH STRUTS; *d*, MULTI-SPAR LATTICE TYPE

types of metal spars; one, the continuous-web type, and the other the trussed type. There are many ramifications of the continuous-web type, several of which are used in this country.

In the trussed type there are two major methods of fabrication; one in which the parts are welded together, and the other in which they are riveted. At present the welded type is limited entirely to steel, while the riveted type may be used on either steel or aluminum alloys. The welded type does not lend itself readily to production as the welding shrinkage seriously distorts the spar and requires either considerable rework or a large percentage of rejection, with the obvious disadvantages to interchangeability. Slight distortions have even been noticed in riveted structures due to variations of the order in which the rivets are driven and of the forces used in setting them. Spar designers incorporating tubing are limited to the use of duralumin or steel. Structural, drawn, or rolled, shapes may be used in either steel, duralumin, or Alclad construction, and in many cases it is more advantageous to use some of these shapes since riveting of tubing requires long mandrels to hold, or head up the rivets on the inside of the tubing. By proper design of shapes made of flat stock, the riveting may be made external and high speed power riveters may be used to advantage. In the design of special-shaped spars, care should be taken in selecting the allowable design stresses, as very little is at present known of the form factors for various drawn or rolled shapes. The best way to determine the maximum allowable stress, or form factor, is by actual tests of samples built to the identical dimensions of the spars. In the design of spars, manufacturers differ considerably as to the amount of fixity they assume to be derived from the ribs. Most manufacturers either ignore the fixity of the ribs entirely or run actual tests to determine exactly how much fixity they derive. Designers should be warned against using rib fixity figures procured from other manufacturers as differences in detail rib construction will have considerable bearing on these fixity factors. Aside from this, rib construction has very little effect on the structural strength of the wing.

In the selection of the type of rib to be used, the main considerations should be the rib weight versus the cost of manufacturing. In large production of untapered wings, pressed- or stamped-metal ribs may be used to advantage with considerable saving in manufacturing cost. On tapered wings, unless the production becomes equivalent to that in the automobile industry, pressed or stamped ribs are out of the question as the die costs are entirely too heavy for the output. Therefore, for this type of work the most efficient type of rib construction is the trussed or built-up rib. These ribs may be fabricated either from tubing or from drawn or rolled shapes made from flat wire. The latter type usually proves to be the most economical as the material cost is lower and the riveting cost, in some cases, is less. Pressed or stamped ribs have not come into extensive use as many of the manufacturers of wood wings claim that they can manufacture wood ribs cheaper than they can purchase or make the stamped ribs. However, the moment that metal construction becomes predominant, the stamped or pressed rib will come into its own in straight wings.

In fabric covered multi-spar construction, the ribs consist merely of cap-strips with special nose formers and one or two truss members in the tail. If the multi-spar wing were untapered these nose formers could advantageously be made as stampings, but since the majority of multi-spar wings are tapered the nose formers are usually built up from structural sections. Between the nose and the tail the staggered spars of the multi-spar construction act as the rib trussing, therefore with this arrangement the ribs require no trusses of their own. In well-designed, built-up ribs of aluminum-alloy construction, strength weight ratios as high as 800 have been obtained in high incidence loading conditions, and ratios as high as 700 have been obtained in low incidence conditions.

Since torsional flexibility is so detrimental to monoplane design, the drag truss should be designed so as to be strong enough to insure torsional stiffness. In order to obtain a rigid drag truss a load factor of 2 should be used for nose-dive conditions. In cases where the aspect ratio of the wing is exceptionally high, or where the airfoil used is exceptionally thin, design requirements for the drag truss should be even more severe.

In designing the drag truss of the three-spar wing, a simple expedient may be used to prevent redundancy of the drag truss connecting all three spars. This is to assume the two outside spars to be the chords of the drag truss and the middle spar to be placed midway between the front and rear. By this means the lines of action of the drag truss members may pass directly through the center spar without putting any loads on it. At the same time, if properly designed, this method reduces the lateral column action of the middle spar to one-half the drag bay length and so lightens the most heavily loaded spar.

In three-spar construction, the drag truss can usually be built entirely of compression members more efficiently than it may be built if the standard strut and wire type is used. This, in addition to being more efficient because of fewer fittings, is, at the same time, more rigid since the allowable stresses are much lower in compression tubing than in tension wires, thereby requiring a greater area and so reducing deflection of the members. In designing the drag truss, the diagonal drag struts in the bottom truss should run from inner front to outer rear while those in the top truss should run from inner rear to outer front. By diagonal drag struts are meant those struts which replace the cross wires

in the standard type drag truss. If the diagonal struts are placed as mentioned, both tubes will be stressed in tension for torsional washout of the wing tip. In nose dive conditions, therefore, torsional deflection will not be increased due to column action bending.

In designing the spars of a three-spar wing, the best method of proportioning the load between the spars is the Burgess method of distribution. This method is explained in detail in Air Service Information Circular No. 394. This circular takes up several different methods and compares the computed results with the actual test results obtained on a three-spar test wing.

In multi-spar construction, the structure must be analyzed in three component parts instead of two (spars and drag truss), as in the two- or three-spar construction. These component parts are the spar chords, the spar trusses, and the drag truss. Each chord member is the chord of two trusses and it is for this reason that the chord must be analyzed separately from the trusses. There are two methods which may be used in computing the loads carried in the chord members. The first method neglects the center of pressure movement and assumes the resultant of the load to pass through the elastic centrum of the wing. The second method takes account of the center of pressure travel and is the one preferred in this country. The Germans in designing their original multi-spar wings used the first method. Both methods are described in an article on "Multi-Spar Wing-Design and Analysis" published in the February sixteenth issue of Aviation.

In strut-braced monoplane design, the wing, as far as analysis is concerned, is similar to the biplane wing in that the spars in the inner portion or bay are subjected to end loads. This requires the spars to be analyzed as eccentrically loaded columns or columns under initial side load. In biplane design, particularly in the smaller types of airplanes, the spars are constant in section and the "precise equation" may be used in computing the ultimate stresses, but in strut-braced monoplanes, or very large biplanes, the spars must be of varying section in order to save weight. This prevents the use of the precise equation and requires some other method of analysis to be used. There are several approximate methods mentioned in various text books but the majority of them deal only with constant-section spars. The following is a method which the author developed for analyzing beams and trusses of varying section. It is what might be termed a graphical solution of the precise equation. Its application to beams with a continuous web is quite simple. Its application to trusses is simple but rather tedious. The following is an outline of its application to the continuous-web beam. The primary moments (moments due to side load only) are computed for the beam. To these are added, the corresponding eccentric moments due to end load, if such eccentric moments exist. At any section, the eccentric moment of the end load is equal to the distance between the point of application of the end load and the neutral axis of the section multiplied by the end load itself. (See Fig. 2.)

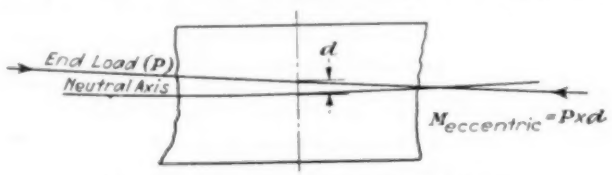

Fig. 2 Eccentric Moment of End Load

The resultant moment (primary plus eccentric) is applied to the beam and the deflection of the beam under this moment is found by the method of $\frac{M}{I}$. This deflection is the first approximate deflection and the first term of a series of which the ultimate deflection is the limit. Multiplying these deflections by the end load gives the first approximate secondary bending moment. If the deflection under this bending moment alone is computed by the same method the resulting curve will be the second term of the series, and if the ordinates of this deflection curve are multiplied by the end load, the result will be the second approximate secondary bending moment. Generally, the shape of the primary-moment curve will be entirely different from the shape of the first approximate secondary bending-moment curve.

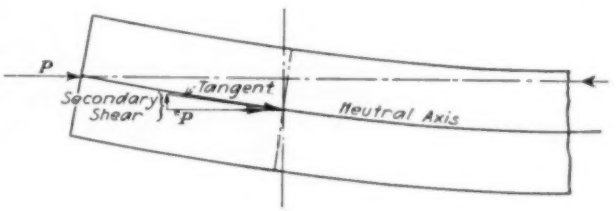

Fig. 3 Illustration of Secondary Shear

Due to beam continuity, the shape of the deflection curves will more and more closely approximate each other as each successive increment is solved. Usually it will be found that the first and second approximate deflection curves have practically the same equation, or are similar, therefore the ultimate deflection may be computed by calculating the limit of the geometric series of which these curves are the first two terms. The use of the geometric limit is reasonable, since the end load is a constant. As can readily be seen, this method is the solution of the precise equation by successive increments. In solving a truss, the same method can be applied except that the Williot diagram is used, in place of the $\frac{M}{I}$ curve, for solving the deflections.

In both types of beams, and particularly the truss type, some account should be taken of the secondary shear as this shear may in many cases be practically as great as the normal shear. By secondary shear is meant the shear component of the end load on the deflected beam. When the beam deflects, the neutral axis is given a slope and as the end load does not change in direction it must be divided into two components, parallel and perpendicular to the deflected neutral axis. The perpendicular component is the secondary shear. (See Fig. 3.) To compute the secondary shear at any section, the sine of the angle whose tangent is the slope of the deflection curve at the section should be multiplied by the end load. In designing a trussed beam, allowances for the secondary shear should be made in selecting the original tube sizes. Then, after the deflection curves have been computed, the shear truss should be checked to determine if any of the shear parts are unsafe.

From the standpoint of manufacture, the cheapest type of construction would be one in which the structure was composed entirely of flat sheets and structural shapes such as channels and angles. There is a limit to which this type of construction may be used since the flat, unsupported surfaces and free edges which form an appreciable part of the structure have a tendency to buckle at low stress values. This type of construction would require the use of very low form factors and so would produce a low strength-weight ratio. The use of curved sheet prevents the tendency to buckle and allows much higher form factors or stress values to be used. However, this type of construction requires the use of dies or rolls in the fabrication of the material, and the extent to which this die cost is warranted, depends entirely upon the anticipated production. With either flat or curved sheet, free edges are especially detrimental since they

have a tendency to buckle and so reduce the form factor of the section. There are two methods by which this effect may be overcome. The first is to place the free edges on or near the neutral axis of the piece and by this means reduce the stress to a safe value. The second method is to make the ratio of overhang length to thickness of all free edges as low as possible. By this means the material furnishes its own support and allows the use of higher-stress values. No direct formula can be given by which the manufacturer may determine the most efficient design for his particular case, as it would depend on the shop facilities, the anticipated production, and the location of the sources of supply of material.

AER-51-11

Radio Developments Applied to Aircraft

By J. H. DELLINGER[1] and H. DIAMOND,[1] WASHINGTON, D. C.

In this paper, the authors point out the need for equipment and methods, that will reduce the weather hazards of air transportation. Radio offers great possibilities as an aid to flight. Research work carried on by the Bureau of Standards has lead to developments, through which weather and landing conditions can be communicated to pilots while in flight and through course navigation, flying can be done satisfactorily regardless of fog. Many interesting applications of radio to aircraft are described.

WITH the transportation of air mail, express and passengers constituting its basic source of revenue, the success of air transportation in the United States depends in large measure upon rigorous maintenance of flying schedules by day and night. Means are at hand to cope with every limitation on flight except hazards of weather. Multiple engines assure safety, landing fields are being provided in abundance, aircraft of adequate strength and stability are available, every comfort and convenience are offered the air traveler. And yet air traffic is still halted when meteorological conditions make the pilot uncertain that he can see landmarks or landing field.

Limitations on regular commercial flight imposed by weather are, however, being overcome by the aids to air navigation being provided on the civil airways by the Department of Commerce. These aids include the lighting of the airways for night flying, special weather reporting service, and radio aids.

Possibilities of radio as an aid to flight include: (1) Communication, (2) course navigation and (3) fog landing. The most essential of these is considered by pilots to be the first, communication. The pilot is interested in receiving information while in the air on weather and landing conditions at possible destinations. A successful system of course navigation, which will permit the pilot to fly his route regardless of fog, is the second element in the conquest of weather hazards. The use of radio to enable a pilot to land in fog is not yet practicable, but promising developments are under way.

Communication

Communication between aircraft and ground is the simplest and most obvious application of radio as a navigational aid. In times of storm and low visibility the pilot can, by radio communication, be in touch with conditions along his route and learn where a landing can be made most safely. A number of problems at once arise. Shall the communication be by telegraphy or telephony? For the conditions of the U. S. Airways the answer is telephony. In some services, military, for instance, radio telegraphy is more suitable, since communication over great distances must be provided for and suitable radio-telephone equipment would be too bulky and heavy. On the U. S. Airways, however, the greater simplicity of radio telephone operation, the short distances, and the impracticability of carrying on the communications both on the aircraft and on the ground through code operators, leave no choice.

Another question is whether one-way or two-way telephony is required. Both have their place and will be used. Two-way telephony between plane and ground, and between plane and plane, permits individual handling of the problems of each pilot; this is secured at the cost of much heavier equipment and more cumbersome antenna than one-way telephony from ground to plane. The radio telephone service provided by the Government is one-way telephony from ground stations. It may be utilized by all airplanes on the airway by use of only a very simple receiving set weighing a few pounds.

Another problem of a technical-radio character is the choice of frequencies for these services. This is being gradually worked out. The beacon and telephone broadcast service are on frequencies between 285 and 350 kilocycles, and the tendency is for the two-way telephone service to be handled on frequencies between 1600 and 6500 kilocycles.

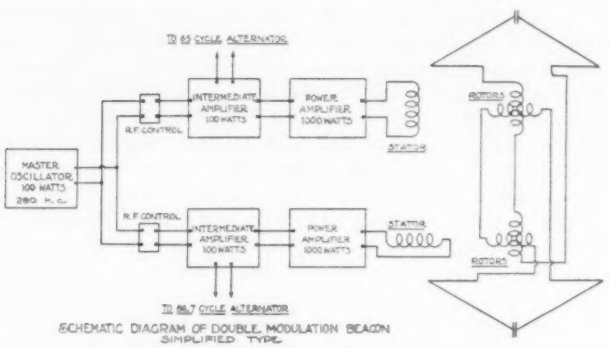
Low-Frequency Telephone Broadcast Service—A definite system of weather reports and radio-telephone communications to aircraft has been inaugurated by the Department of Commerce. Before departing, the pilot is advised as to weather conditions at his destination. After departure, the pilot is advised by radio telephone broadcasts, at least once an hour, regarding landing and weather conditions along his route, and, if landing at the chosen destination appears hazardous, he is told of alternate landing fields where a safe landing may be made. Pertinent information, such as ceiling heights, barometric pressure at the ground, elevation of the landing field, arrangements made for transportation of mail, express and passengers, and orders from the transport company, are given the pilot enroute.

With a view to making this information most effective, the Department has begun the use of an automatic telegraph typewriter system for instantaneous communication between the radio stations at landing fields along the route, weather stations, and operations offices. Timely and accurate information is thus made available to be broadcast to the pilots.

Three radio-telephone weather-broadcast stations have been installed and twelve more are under construction on the transcontinental air route. By June 30 it was hoped to have thirty of these stations in operation on the airways. The frequency band, 315 to 350 kilocycles has been allocated to this service.

High-Frequency, Two-Way Telephony—While the above system provides for the broadcasting of such information as is necessary to the safe operation of aircraft, it does not provide the complete facilities for the dispatching of aircraft, essential to the most efficient operation of a transportation service. The air-transport operators are themselves planning to satisfy this need by the establishment of high-frequency radio-telephone two-way communication between aircraft and ground. Sixty-four channels have been reserved for this purpose by the Federal Radio Commission in the 1600–6500 kilocycle band. Radio-telephone transmitting stations on the assigned frequencies will be constructed at the principal airports of certain airways, and the airplanes will be equipped with a high-frequency receiving and transmitting set in addition to the low-frequency receiving set required in connection with the government-operated radio aids. The operations office of each route will maintain a watch on the frequency or frequencies assigned to its aircraft, while the Commerce Department will also maintain a watch on a standard calling frequency. A frequency in the neighborhood of 4000 kilocycles will be used for this purpose. This constitutes a service which admirably supplements the telephone broadcast service provided by the Government on 315–350 kilocycles, and should measurably increase the safety of operations.

---



[1] Bureau of Standards, Department of Commerce, Washington, D. C.

Presented at the Third National Meeting of the A.S.M.E. Aeronautic Division, St. Louis, Mo., May 27 to 30, 1929.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Suppose, for example, that the weather information is being broadcast from a low-frequency station, and an airplane gets into difficulties and communicates on its assigned high frequency requesting specific information. The air-transport station will receive that message and will reply on its assigned high frequency, without interrupting the weather broadcast which may be absolutely essential to other airplanes in the air. In the event that the air-transport station does not receive the message, the pilot may communicate on the standard high-frequency calling wave, on which the Department of Commerce maintains a watch. This message will then be communicated over the telegraph-typewriter system to the proper operations office for reply; or, if particularly urgent, the weather broadcast on the low frequency may be interrupted or extended in order to transmit the desired information.

Furthermore, in the case of a breakdown of the low-frequency station, the high-frequency station may be employed for disseminating the weather information. Finally, the two-way communication between aircraft and ground may well be used as an auxiliary to landing operations under adverse weather conditions.

SCHEMATIC DIAGRAM OF DOUBLE MODULATION BEACON SIMPLIFIED TYPE

FIG. 1 SCHEMATIC DIAGRAM OF DOUBLE MODULATION BEACON—SIMPLIFIED TYPE

COURSE NAVIGATION ON FIXED AIRWAYS

Requirements.—Consideration of the relative usefulness of possible radio systems for guiding aircraft divides naturally into two parts: (1) aids for aircraft flying the established airways; (2) aids for aircraft flying over independent routes. The first is the more important in the United States. All commercial-transport airplanes use fixed airways. The Government's aids to air navigation are being provided with the primary view of serving aircraft flying these airways.

The fundamental requirement of a radio system for guiding airplanes traveling the fixed airways is, that it shall give the pilot information to enable him to continue along a given airway, when no landmarks or sky are visible. If he leaves the course, it should tell him how far off he is, and to which side, should show him the way back to the course, and should inform him when he arrives at his destination. Guidance along the airway means guidance along the route regularly flown, with its emergency fields, lights, and other facilities. Thus the airways guidance system is sharply marked off from direction finding and other systems which are mere homing devices, and with which the pilot can unwittingly be driven off the desired course by side winds. The guidance system must be entirely free from errors of wind drift, since one of its purposes is to prevent collisions, both between airplanes and with the sides of mountain passes, etc. The system must provide service to all airplanes flying the course, and must be adaptable to the complex conditions on the busiest airways.

In addition to these requirements, there are a number of additional desiderata which are not strict necessities. The identity of the portion of the airway traversed should be indicated by the radio signals utilized. The service should be continuous rather than intermittent. The pilot should receive the service by a mere glance at an instrument, being free from any necessity of using ear phones, or adjusting anything, or correlating with other instruments, or changing the course of the airplane. The radio frequencies, power, type of emission, and location of transmitting stations should be so chosen as to serve the needs with maximum efficiency and conservation of the limited radio channels. The radio equipment on the airplane should be simple and inexpensive.

All of these requirements and desiderata are fulfilled by the radio-beacon system adopted. This system has been worked out to be applicable under the actual flying conditions encountered on the U. S. airways.

Simplified Visual Radio Beacon—The radio-beacon system employs a special transmitting station on the ground, known as a radio beacon. This is usually located at an airport, just off the landing field. Instead of having a single antenna like an ordinary radio station, it has two loop antennas at right angles with each other. Each of these emits a set of waves which is directive, i.e., it is stronger in one direction than others. When an airplane flies along the line, exactly equidistant from the two beams of radio waves, it receives signals of equal intensity from the two. If the airplane gets off this line, it receives a stronger signal from one than the other.

The current in the two antennas is of exactly the same radio frequency, but is modulated at a different low frequency in each, i.e., the current in one antenna has a tone of 65 cycles impressed on it, and the current in the other antenna has a tone of 86.7 cycles impressed on it.

On the airplane, a visual-indicating instrument is used, consisting of two vibrating steel reeds, mechanically tuned to the two beacon modulation frequencies (65 and 86.7 cycles). This instrument is mounted on the instrument board of the airplane and is connected to the output of the receiving set. When the beacon signals are received, the two reeds vibrate, and, since they are tuned to the two modulation frequencies used at the beacon, serve as a device for indicating equality of received signals from the two antennas. The tips of the reeds are white against a dark background, so that when vibrating they appear as vertical white lines. When the two lines are equal in length the airplane is on its course. A deviation from the course to the left serves to increase the relative deflection of the left reed, and the reverse is true if the airplane deviates to the right. To return to the course, the pilot turns in the direction of the shorter reed deflection.

The radio beacon used in this system is known as the double-modulation beacon. A detailed description was published a year ago.[2] The transmitting apparatus has since been considerably simplified. Fig. 1 is a schematic circuit diagram of the beacon-transmitting station in its simplified form. A 100-watt master oscillator supplies power at 290 kilocycles to two 100-watt intermediate amplifiers which in turn supply power to two 1000-watt power amplifiers. These feed separately into two loop antennas crossed at an angle of 90 deg. to each other. Each intermediate amplifier is modulated to a selected low frequency, 65 cycles being chosen as one modulation frequency and 86.7 cycles as the second. One loop antenna therefore radiates a 290-kilocycle wave modulated to 65 cycles while the other emits a 290-kilocycle wave modulated to 86.7 cycles. Owing to the directive properties of the loop antennas, the intensity of the waves is a maximum in the directions of the planes of the antennas, transmitting them, and zero in the directions perpendicular

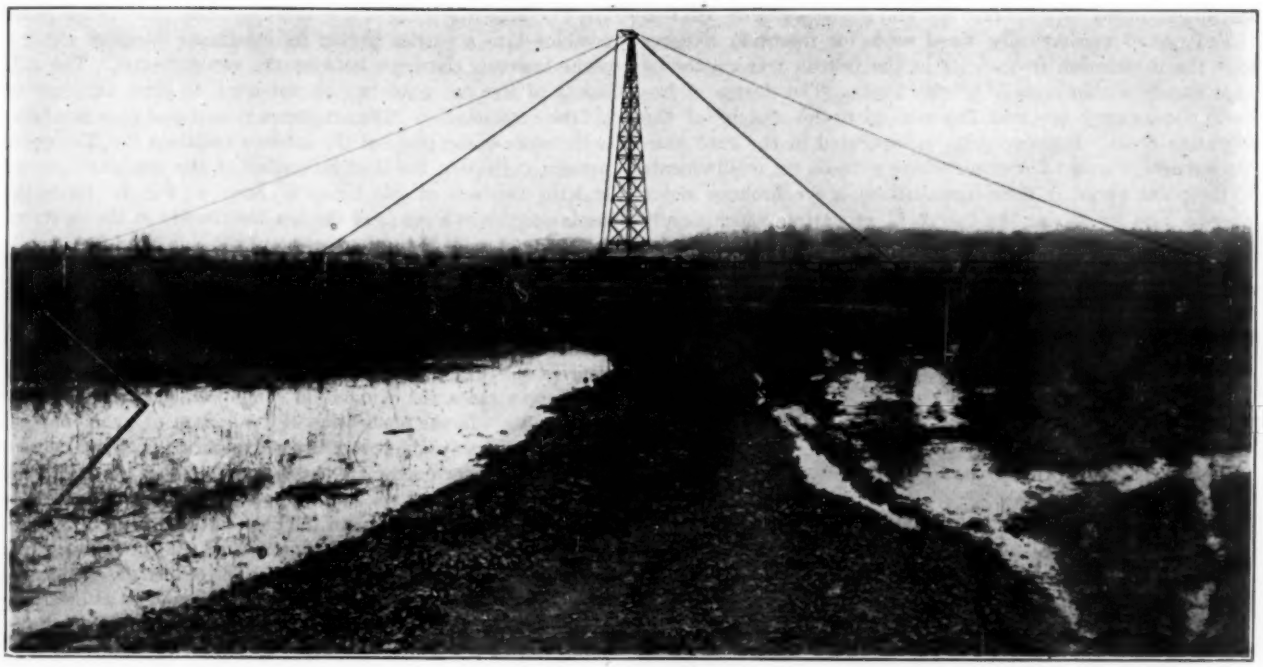

FIG. 2 CROSSED LOOP ANTENNA SYSTEM USED WITH DIRECTIVE RADIO BEACON. EXPERIMENTAL STATION OF BUREAU OF STANDARDS AT COLLEGE PARK, MD.

to these planes. Equality of received signal thus indicates a fixed line or "course" in space, and provides a means for guiding aircraft along that course. For the purpose of orienting the course in any given direction, a four-coil goniometer, consisting of two stator coils crossed at an angle of 90 deg. with each other and two rotor coils also crossed at 90 deg., are employed. The stator coils are connected to the plates of the power amplifiers, while the rotor coils are connected, each in series with one antenna. The currents in the antennas due to the driving voltage of each stator coil, create a resultant field in a direction such as would be produced by an imaginary or phantom antenna, rotatable with the goniometer rotor. Since there are two stator coils, there are two such phantom antennas rotatable as the two rotor coils rotate together, allowing the equisignal zone or "course" in space to be oriented in any direction.

FIG. 4 GONIOMETER USED IN BEACON STATION TO ORIENT BEACON COURSE IN ANY DESIRED DIRECTION

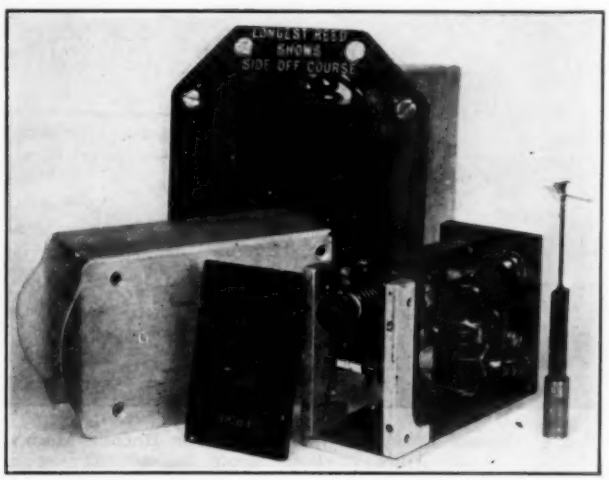

FIG. 5 VISUAL BEACON COURSE INDICATOR

A photograph of the crossed-coil antenna system is shown in Fig. 2. The beacon-transmitting equipment is shown in Fig. 3 and the goniometer used for orienting the course in Fig. 4. A photograph of the vibrating-reed course indicator showing the working parts and also the shockproof holder for mounting on the airplane is given in Fig. 5. Fig. 6 shows an airplane

instrument board with the reed box and holder suitably located.

The use of mechanically tuned reeds for reception requires that the modulation frequencies in the beacon transmitter be kept steady within certain definite limits. The degree of frequency constancy required depends upon the design[3] of the vibrating reeds. Improvements incorporated in the reed indicator during the past few months have reduced the requirements to the point where, in many installations, a synchronous motor may be used for driving the two A. C. generators which supply the modulation frequencies. At locations where the variation of

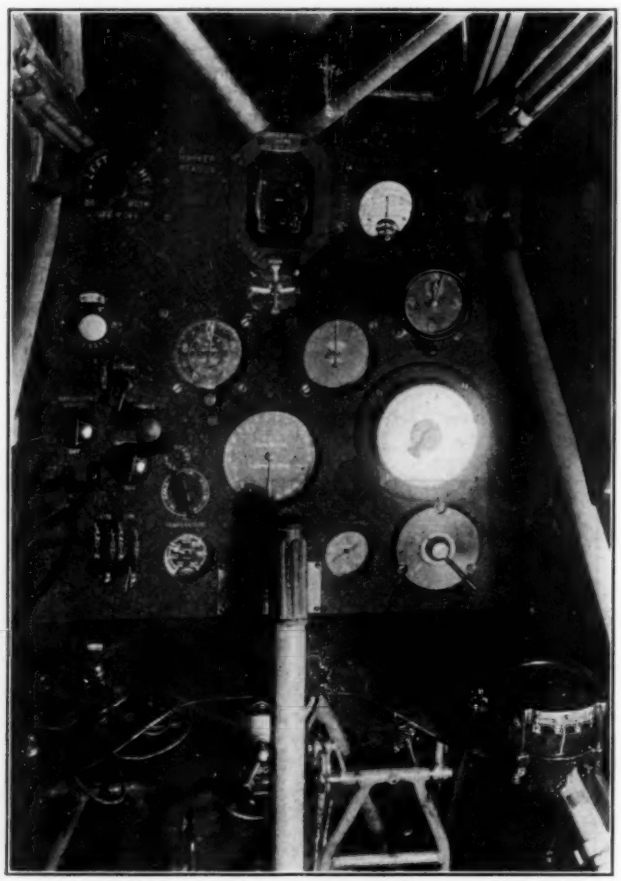

FIG. 6 COURSE INDICATOR AND SHOCKPROOF HOLDER MOUNTED ON AIRPLANE INSTRUMENT BOARD

the power-supply frequency exceeds 0.2 cycle, it is necessary to employ a motor other than of the synchronous type with provisions for controlling its speed within the desired limit of accuracy. A constant-speed unit having the requisite characteristics has been in satisfactory operation at College Park for the past few months. The speed of this unit is controlled by means of a vacuum tube driven tuning fork.

Adaptation of Beacon to Four Independent Courses—It is desirable, at this point, to study the polar pattern of the field radiated by the double-modulation beacon described. One loop antenna radiates a 290-kilocycle wave modulated to 65 cycles, while the other loop antenna radiates a 290-kilocycle wave modulated to 86.7 cycles. The wave due to each antenna, may be resolved into a carrier and two side bands. The carriers in the two loop antennas being of the same frequency and in time phase combine into a carrier having its maximum intensity along a plane bisecting the angle between the two antennas. The side bands of the two antennas do not combine since they are of different frequencies. The maximum intensity of each side band is therefore in the plane of the antenna radiating it. The space pattern indicating the field intensities of the combined carrier and the two sets of side bands is shown in Fig. 7. Since the reeds operate as a result of the low frequencies in the receiving set output produced by the beating of the side band frequencies with the carrier, they respond to a space pattern characteristic as indicated in Fig. 8. This assumes a square law detector. It will be noted that but two courses are produced, practically no signal being radiated in the directions at right angles to these courses.

In many cases, the elimination of the two right-angle courses is desirable. In the application of the beacon to course navigation on the airways, however, airports requiring only two courses 180 deg. from each other are the exception rather than the rule. At those airports where two courses are sufficient, these are usually at an angle other than 180 deg. At many airports, more than two radiating courses are necessary, the number varying anywhere from 3 to 8 or even more. The beacon described may be easily modified to permit the use of four courses at arbitrary angles. By a suitable coupling arrangement to the master oscillator, one of the carrier-frequency currents can be advanced in phase 90 deg. ahead of the other. Since the two loop antennas are in 90 deg. space phase and their carrier currents in 90 deg. time phase relationship, a revolving field is set up in space, so that the carrier space pattern becomes circular. See Fig. 9. The polar pattern as received by the reeds is that indicated in Fig. 11, four courses being obtained.

A second method, perhaps preferable from a practical standpoint, is to excite one antenna at a time. The carrier waves radiated by the two loop antennas, therefore, cannot combine since they are never sent out simultaneously. The space pattern for the carrier wave due to each antenna is then the same as for the corresponding side bands, the maximum power being radiated in the plane of the antenna considered. See Fig. 10. The polar diagram as received by the reeds is shown in Fig. 12. Again four courses are obtained, these courses being somewhat sharper than above. The switching of the power so that but one antenna is excited at a time may be accomplished electrically at high speed. Owing to mechanical inertia, the reeds maintain their vibration amplitude without interruption or flutter.

The four beacon courses obtained may be shifted considerably from their 90-deg. relationship in order to make them coincide with the airways radiating from a given airport. Two adjustments at the beacon are possible, the first and simplest being illustrated in Fig. 13. A, B, C, and D are the courses with the beacon normally adjusted. If the figure-of-eight due to antenna 1 is reduced, by reducing the voltage supply from the master oscillator to the amplifier branch feeding antenna 1, courses A′, B′, C′ and D′ are obtained. It will be observed that courses A′ and C′ are still at 180 deg., also courses B′ and D′, but that the two sets are no longer at 90 deg. with each other. To shift either set of 180 deg. courses (say B′ and D′) from their 180 deg. relationship, the method illustrated by Fig. 15 is adopted. A non-directional carrier, of proper phase value, is radiated in addition to the ordinary beacon radiation. A vertical wire, extending along the beacon tower and coupled to the beacon set, is used for obtaining this additional radiation. The resultant space pattern is indicated by the heavy lines in Fig. 15. It will be observed that courses B′ and D′ are no longer at 180 deg.

Applying these principles, the Airways Division, in cooperation with the Bureau of Standards, has succeeded in fitting the aural

beacons at Bellefonte, Pa., and Hadley Field, N. J., to the airways. At Bellefonte, two courses at an angle of 165 deg. are used, while at Hadley the three courses leading to Hartford, Conn., Bellefonte, Pa., and Washington, D. C., are served simultaneously.

With the visual beacon system, shifting the courses at the beacon is not entirely necessary. A slight change in the receiving equipment aboard the airplane makes it possible for the pilot to choose his own course, so long as he is within about 20 deg. on either side of an equisignal zone. This is accomplished by shunting a suitable resistance across the coil actuating one of the two reeds, thereby reducing the sensitivity of that reed. The course, as determined by equality of reed deflections, is therefore shifted from the true equisignal zone in the direction of the shunted reed. The same effect is thus accomplished as by shifting the courses at the beacon. The shunt resistance may be made variable and calibrated in terms of degrees off the true equisignal zone, to give additional flexibility to the system.

Multidirectional Beacon (12 Courses)—To render the beacon system still more flexible and thus make it suitable for use at cities located at the junction of a large number of airways, a new beacon has been developed capable of serving twelve courses simultaneously. The increase in apparatus over the beacon described above is not great. The same crossed-coil antenna system and the same circuit arrangements are employed (see Fig. 16) except that three amplifier branches, modulated to three different frequencies, are necessary. The modulation frequencies used are 65, 86.7 and 108.3 cycles, respectively. A special goniometer is also required. The rotor system of this goniometer is the same as before; three stator coils are, however, required, one stator coil being connected to each power-amplifier tube. The stator coils are disposed at 120 deg. to each other; these angles may be deviated from in any manner to obtain certain desired conditions.

Since the stator coils are not at right angles to each other, it is essential that but one stator be excited at any given time in order that coupling between stators be avoided. A high-speed electrical switching arrangement has been provided in the grid circuits of the intermediate amplifier tubes for accomplishing this purpose.

Referring to Fig. 16, it will be observed that one stator carries a 290-kilocycle current modulated to 65 cycles, the second stator a 290-kilocycle current modulated to 86.7 cycles, and the third stator a 290-kilocycle current modulated to 108.3 cycles. Each stator, acting in conjunction with the two crossed rotor coils and the two crossed loop antennas, sets up a system which is electrically equivalent to a single loop antenna. The plane of this phantom antenna coincides with the plane of the stator coil considered. The space pattern is therefore a figure-of-eight with its axis in the plane of the stator coil. Since but one stator is excited at a given time, the combined space pattern consists of three figures-of-eight with their axes crossed at the same angles as the stator coils. See Fig. 14.

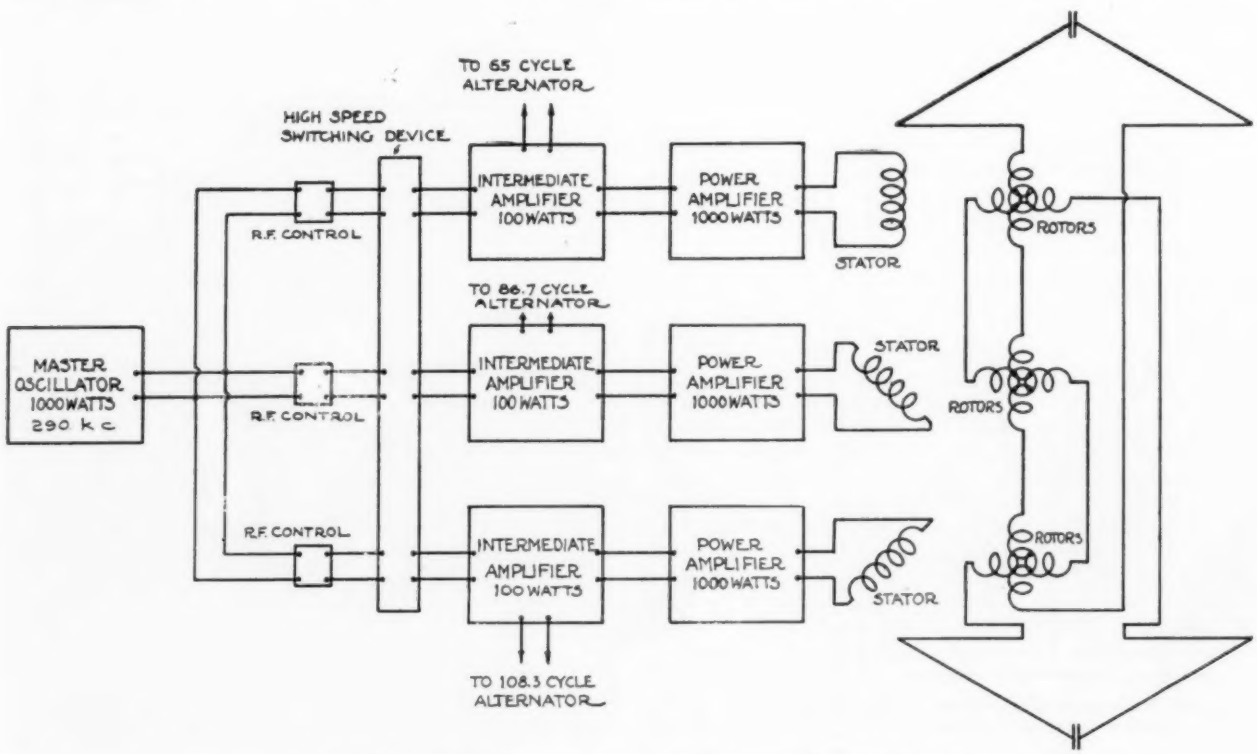

FIG. 16 SCHEMATIC CIRCUIT DIAGRAM OF MULTIDIRECTIONAL BEACON

Now assume that a pilot is equipped with three reed boxes, the first tuned to 65 and 86.7 cycles, the second to 86.7 and 108.3 cycles, and the third to 108.3 and 65 cycles, respectively. Using the first reed box, he will find two sharp courses at M and N and two broad courses at O and P. With the second reed box, two sharp courses will be obtained at Q and R and two broad courses at S and T. Similarly with the third reed box there will be two sharp courses at W and X and two broad courses at Y and Z. The sharp courses have an equisignal zone of 1 to 1.5 deg. while the equisignal zone for the broad courses is from 3 to 4 deg. wide. There are thus twelve useful courses provided, any two adjacent courses being separated by 30 deg.

Some routes, radiating from an airport may, however, be at angles differing from 30 deg. This difficulty is not insurmountable, since the angles between stators may be so adjusted as to fit the courses to those airways.

A 12-course beacon of the type described has been installed at

College Park, Md., and is giving satisfactory results. A photograph of the transmitting set used is shown in Fig. 17 and of the special three-stator goniometer required in Fig. 18. A special course indicator containing three reeds has been designed which makes it possible to receive any of the twelve courses radiated by a beacon of this type without confusion. The dimensions of this indicator are the same as of the two-reed indicator, the two types being therefore interchangeable on the airplane, which is of great convenience.

Marker Beacons—The directive radio beacon will successfully guide a pilot along a given course but does not directly indicate his exact location along that course. Where it is desirable that this indication be given, for example at the intersection of two beacon courses or at a dangerous portion of the airway, it can be obtained by the installation of a small non-directive marker beacon, which is of very low power (a few watts) and emits a characteristic coded signal. This signal operates a 120-cycle reed indicator mounted at a suitable location on the airplane instrument board, and is received for two or three minutes as the airplane passes over the marker. The pilot can thus locate his exact

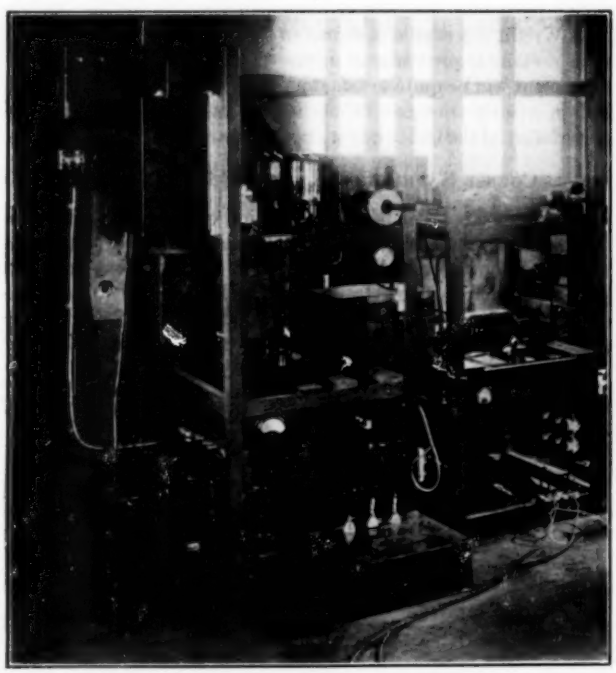

FIG. 17 EXPERIMENTAL TRANSMITTING APPARATUS FOR MULTIDIRECTIONAL BEACON INSTALLED AT COLLEGE PARK, MD.

position on the airway. The coded signal of the marker beacon can have the same characteristics as the light beacon if there is one there.

A photograph of the marker beacon transmitting equipment is given in Fig. 19. When located at the intersection of two main beacon courses, an arrangement must be provided on the marker beacon to permit the emission of its characteristic signal on the two radio frequencies used by the main beacons. A satisfactory switching device for accomplishing this purpose has been developed.

Airplane Receiving Sets—The beacon system can be used with any receiving set which operates at the frequencies employed, merely replacing the telephone receivers by the simple reed indicator unit. There are, however, a number of special conditions involved in receiving on an airplane, and the Bureau has developed special receiving sets[4] in order to use the beacon system under the most advantageous conditions.

The receiving set designed weighs less than 15 lb., the auxiliary batteries weighing an additional 10 lb. The receiving set operates in the frequency range from 285 to 350 kilocycles and is used

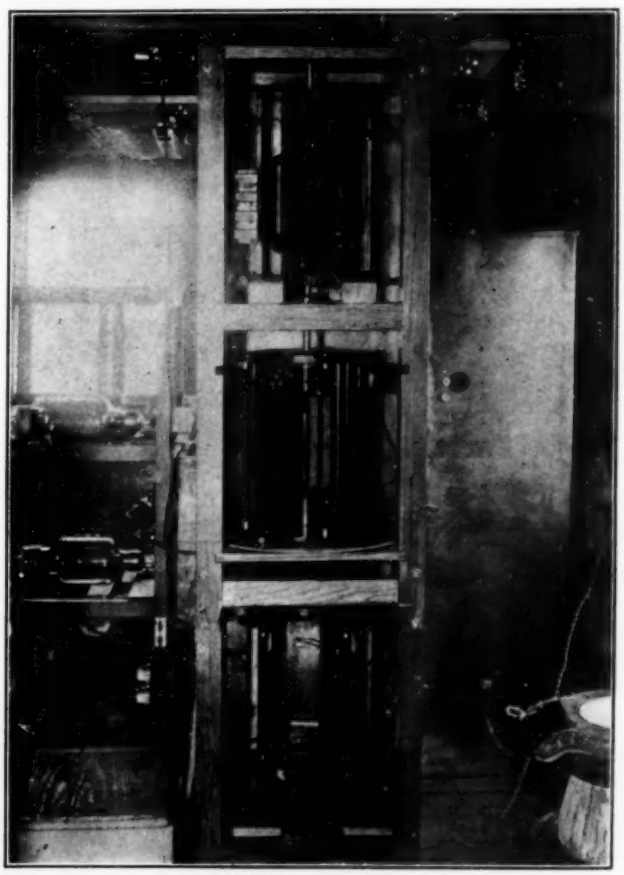

FIG. 18 SPECIAL GONIOMETER USED WITH MULTIDIRECTIONAL BEACON

FIG. 19 MARKER BEACON TRANSMITTING APPARATUS

to receive either the beacon signals or radio-telephone weather messages at will. It is highly selective as well as sensitive and is provided with interstage shielding as well as shielding against

[4] Receiving sets for aircraft beacon and telephony. H. Pratt and H. Diamond. *Bureau of Standards Journal of Research*, 1, p. 543, Oct., 1928. Research Paper No. 19.

direct extraneous interference. The audio-frequency amplifier is specially designed to be efficient at the low modulation frequencies used in the beacon. The selectivity of the set is supplemented by the selectivity of the vibrating reeds, which help greatly in reducing interference. Nevertheless, it is important that a good degree of set selectivity be provided in order to make the most efficient use of the frequency channels provided for this service and also to make the receiving set suitable for the reception of

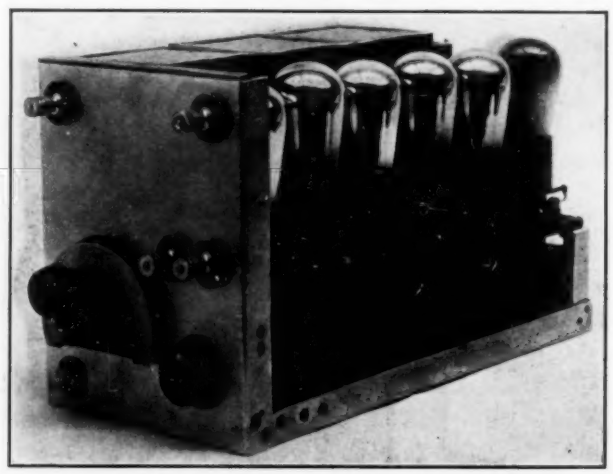

FIG. 20 UNICONTROL AIRCRAFT RECEIVING SET

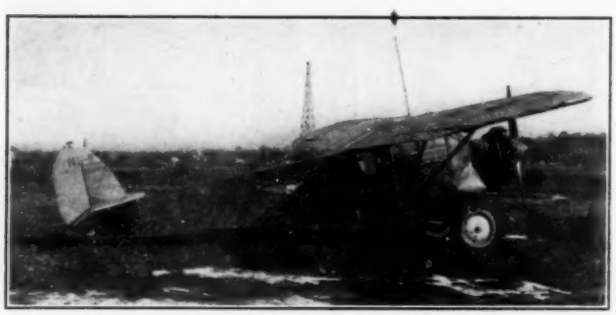

FIG. 21 AIRPLANE SHOWING VERTICAL POLE ANTENNA

weather telephone messages. The set has remote control arrangements for tuning and volume, so that it may be mounted in any location on the airplane. Fig. 20 is a photograph of this receiving set with the outside casing removed.

The Bureau has interested several manufacturing companies in building receiving sets of suitable specifications. One model, already available commercially, has proved very satisfactory; this model, with all auxiliary batteries necessary, weighs approximately 20 lb. Two more sets will become available within a short time. These will incorporate several features not included in the present receivers.

Airplane Antenna—The development of receiving sets having the necessary sensitivity made possible the use of an antenna system on the airplane, consisting of a metal pole extending vertically from the fuselage, the total length of this pole being but 8 ft.

The use of a trailing-wire antenna with its attendant inconvenience and possible danger was thus eliminated. A great advantage of the vertical pole antenna is that it is entirely nondirective. As a consequence, spurious direction variations in the beacon course, which have previously been observed at night, are practically eliminated. In addition, since this type of antenna is not affected by horizontal components of the electric field radiated by the beacon, a region of zero signal strength is met with directly above the beacon tower (where no vertical field exists). This serves quite effectively as a field localizer locating the landing field within 1000 to 2000 ft. A view of the Bureau's experimental airplane showing the vertical pole antenna is given in Fig. 21.

Ignition Shielding—The use of a sensitive receiving set together with the short vertical antenna, located near the airplane engine ignition system, makes necessary a considerably more rigorous shielding of the ignition system than is ordinarily required to prevent ignition interference. Merely shielding the high- and-low tension wires is not sufficient. The spark plugs and the magneto-distributor blocks must also be shielded.

The Bureau has been in active cooperation with airplane engine, magneto, spark plug and cable manufacturers in an effort to develop a safe method for effecting this shielding and to make the necessary equipment available commercially. The problem in ignition shielding is chiefly a mechanical one, it being much more difficult to arrive at an arrangement which will not disturb the airplane-engine ignition system than to obtain complete freedom from ignition interference for the radio equipment on board the airplane.

One particular shielding arrangement suitable for installation on a Wright J-5 engine is shown in Fig. 22. It is believed that with certain improvements in the mechanical design, this arrangement will be quite satisfactory from an operating viewpoint. Full provisions are made for mechanical sturdiness, freedom from disturbance of the ignition system, and water-proofing of all parts.

COURSE NAVIGATION ON INDEPENDENT ROUTES

As may be apparent in the description of the multidirectional beacon, an airplane receives beacon indications at all points and not merely on the established airways. It thus gives guidance service to any one flying to or from the beacon, even though he fly an independent route. There are, however, a variety of other possible radio-navigational systems for the independent flyer.

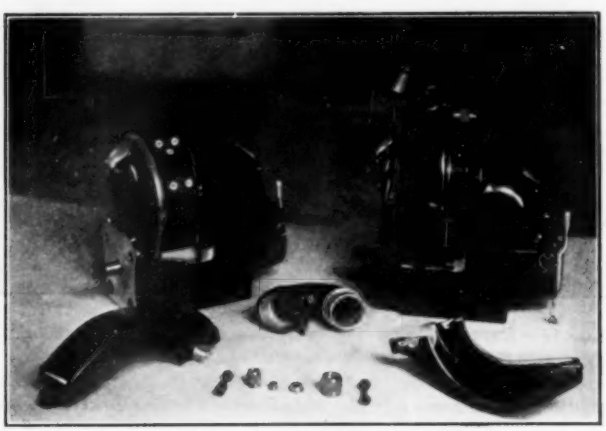

FIG. 22 IGNITION SHIELDING ASSEMBLY FOR WRIGHT J-5 AIRPLANE ENGINE

Direction Finder on Ground—This is the system used on the airways of Europe. Radio direction-finding stations are maintained by the Governments at various airports, and each airplane carries both a transmitting and a receiving set. Upon request by radio from an airplane, two or more of the direction-finding stations determine the direction of travel of radio waves from the airplane; combining their determinations, they calculate the airplane's position and send this information by radio to the airplane. This system has had a little application in the United States during the past year. On the airways, it may receive

some development, in conjunction with the system of high-frequency telephony between airplane and ground, as an alternative or auxiliary to the radio-beacon system.

Direction Finder on Airplane—A second means of radio navigation for the independent flyer is the use of a radio direction finder on the airplane. By steering a course in the indicated direction of a radio station on the ground, the airplane can be certain of reaching that point, the accuracy of the indicated direction increasing as the objective is approached. Direction finders are used extensively as a navigational instrument on marine vessels and on lighter-than-air craft. On airplanes it is considerably more difficult to protect them from error and disturbances caused by the engine ignition and other sources. They have been used successfully to some extent, and their use will doubtless increase; they do, however, require expert handling. This method of navigation has the inherent limitation that it does not prevent wind-drift from shifting the airplane off its course; the method does, eventually, bring the airplane to its destination, although by a circuitous route if there is a side wind.

Rotating Directive Beacon—A third method of furnishing navigational aid to the independent flyer is the rotating radio beacon. This is a radio transmitting station, located at an airport, which has a directive antenna rotating at a constant speed of one revolution per minute. A figure-of-eight pattern is thus rotated in space. A special signal indicates when the figure-of-eight minimum passes through north and also when it passes through east. A pilot listening for the beacon signal with his receiving set can start a stop watch when the north signal is received and stop it when the figure-of-eight minimum reaches him. The number of seconds multiplied by 6 gives him his true direction in degrees from north. The stop watch may be calibrated directly in degrees, so that the position of the second hand when the minimum signal is received gives the bearing directly. This system thus serves any course within its range. It has, however, the disadvantages of slowness of operation and also of being difficult to use during conditions of severe atmospheric disturbances or interference from outside sources, besides the common disadvantage of all these methods, the use of headphones.

Fog Landing

By the use of the radio aids being installed on the U. S. airways, it will become entirely feasible to fly between any two points along a given airway and to arrive within a few thousand feet of the desired destination regardless of weather conditions. The problem of effecting a safe landing during fog and extremely low visibility is not yet, however, an assured accomplishment.

Recent tests indicate that fog-penetrating lights are not yet available. The dissipation of fog by mechanical means has been the subject of considerable laboratory experimentation, the general result being that it is not economically possible on a useful scale.

The most feasible method of attack at the present time appears to be in the application of radio. When attacked from this angle, the problem of fog landing resolves itself into two separate problems; namely, field localizing, and the development of a suitable altimeter.

Field Localizers—Practically all previous experimentation in this field has been in the use of "leader cables." The principal installations are those of the British Government at Farnborough and of the French Government at Chartres. The British installation uses a complete circuit around the landing field with a visual indicator in the airplane instrument board. The French installation uses straight cables. The Loth Company of Paris has also conducted experimental work using straight cables.

The ground equipment at Farnborough consists of an oval loop of cable about 5 × 2 miles, buried 2 ft. in the ground. One of the straight sides of this oval loop passes through the airdrome. Near this straight side and surrounding the portion of the airdrome free from obstructions is a second smaller oval loop. A pilot circles around the major loop coming lower and lower.

Once each revolution, he receives a signal from the smaller loop indicating that he is directly over the airdrome. When he is at a sufficiently low altitude and over the airdrome a safe landing may be effected. An obvious disadvantage of the leader cable method of field localizing is its great cost.

The success obtained with the directive radio beacon in its application to point-to-point flying, suggests its possibilities as a field localizer. With the main beacon used for guiding an airplane to a given landing field, a low-power beacon with small loop antennas may be employed for marking out the major, or most desirable axis, or runway of the landing field. This can be done

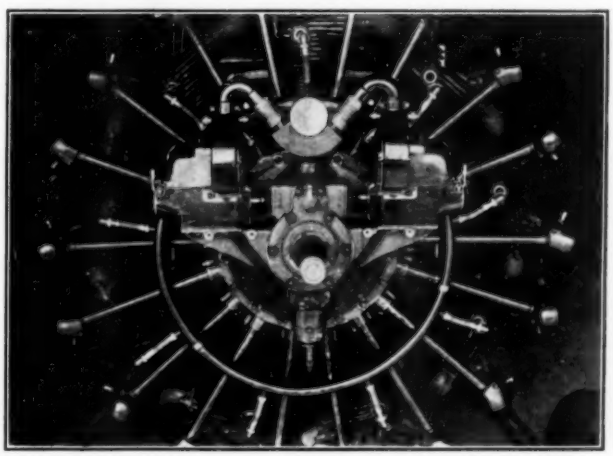

Fig. 23 Engine With Shielding Equipment

quite as effectively as with leader cables. For example, consider a class A field having the required dimensions of 2500 × 2500 ft. with two perpendicular runways at least 300 ft. wide. The equisignal zone of the two-course radio beacon is at a maximum 5 deg. wide. (The use of the two-course beacon is here assumed because of the obvious advantages of eliminating the 90 deg. courses.) If, then, a course is oriented along a particular runway, with the beacon at one end of the field, a pilot can locate the axis of this runway at the other end of the field within 100 ft. He is thus certain to land on the runway.

The complete details for effecting a safe landing have not yet been worked out, but several arrangements appear practicable. An installation is now being made at College Park, Md., to test their practicability.

Altimeters—A desirable adjunct to any method of field localizing is the development of an instrument to show accurately the height of an airplane above the ground, allowing an error of but a few feet. The barometric instruments now in general use are not accurate enough for the purpose, particularly since they measure height above sea level and not height above the earth.

Experiments are being undertaken by a number of investigators looking toward the development by several means of suitable sensitive altimeters. One is the development of a sonic altimeter. This is an instrument on the airplane, which measures the time taken by a sound wave emitted from the airplane to reach the ground and return to the airplane by reflection. Knowing the velocity of sound, the height of the airplane above the ground is determined.

Another device is the capacity altimeter which measures the distance from the ground by detecting the change in the elec-

trical capacity between two plates on the airplane, as the airplane approaches the ground. A definite limit to the possibilities of this type of instrument arises from the fact that the change in capacity becomes infinitesimal at altitudes exceeding 100 ft.

A third method is by the use of direct reflection with radio waves. The most recent work on this type of altimeter is reported by Dr. E. F. W. Alexanderson.[5] With the development of an accurate altimeter and field localizing system the last obstacle in the battle with fog will be overcome.

Recent Demonstrations

The practicability of the visual beacon system described may be illustrated by several typical tests.

1 On a day of low visibility, a pilot, unfamiliar with the route, took the air in Philadelphia for Washington with no maps or instructions as to landmarks; he was told to proceed to Washington (a distance of 120 miles) and land at College Park Field solely in accordance with the guidance given by the beacon indicator on his instrument board. He not only flew in a straight line to Washington, but when over College Park field, the location of which he did not know, the sudden drop in the reed deflections told him he was at his journey's end, whereupon he landed.

2 The remarkable selectivity of the reed indicator has been demonstrated in several test flights from College Park, Md. to Hadley Field, N. J., with the double-modulation type College Park beacon and the aural-type Hadley beacon, both operating on the same radio frequency and with approximately the same power. With the particular type of receiving set employed, the interference of the Hadley-Field beacon does not interfere with the operation of the reeds until the airplane is approximately 140 miles from College Park and only 50 miles from Hadley. This is an interference-to-signal ratio of about 8 to 1.

3 An additional test also demonstrating the degree of freedom from interference of the reed indicator was made on an unshielded airplane at Hadley Field, using a different type receiving set. The College-Park beacon signals were used, the reeds functioning perfectly at all engine speeds, even though the ignition interference present was sufficient to render a signal from a nearby radiotelephone set unintelligible.

AER-51-12

Airplane Fuel and Lubricants

By C. K. FRANCIS,[1] TULSA, OKLAHOMA

GASOLINE is the product which distils from petroleum at the lower temperatures. The desirable product of the refiner in the early days of the industry was kerosene, separated from the crude after the gasoline fraction at a higher temperature. It was necessary to set the gasoline produced aside; a very inflammable, troublesome product of no commercial value. Its combustible nature and the fact that it would ignite at normal temperatures, furnished characteristics which enabled the operator to identify it. The inflammable property was the characteristic which formed the basis for the first specification for gasoline.

The methods which were devised for the determination of the temperatures at which the illuminating oil would flash and fire were employed for the purpose of showing when a separation of the gasoline from the kerosene had been made. Some refiners did not succeed in getting all of the gasoline out of the kerosene, and the volatile nature of the gasoline caused many explosions of lamps. Numerous laws were enacted stipulating the minimum flashing temperature of commercial illuminating oils.

For many years, the petroleum refiner continued to find gasoline a source of annoyance. It was the readily combustible nature of gasoline which encouraged the original students of the internal-combustion type. With the perfection of the automobile engine, which functioned because of the explosive mixture of gasoline and air, the foundation was laid for a market which was to consume more of this troublesome product than any refiner could have imagined would be possible.

Then it was found that gravity could be used to classify gasolines, and it was thought that the higher the gravity, the better the gasoline. This explains the origin of the term "high test." Since that day, progress has been rapid. Distillation has served to indicate volatility. Sulphur, gum, and corrosive specifications have appeared. A recent development has shown that many gasolines cause knocking in the motor, consequently, there is now an endeavor to classify gasolines for this property. It appears that a condition is rapidly approaching where the chemical composition of gasolines must be known to understand their real worth.

The value of gasoline consists in its performance as a motor fuel, but our physical and chemical methods of investigation have not advanced far enough to enable us to predetermine with certainty just how a specific gasoline will function in a motor. If we are to have complete appreciation of the characteristics of a gasoline, more definite knowledge concerning the influence of molecular structure will have to be known together with the permissible limits, which may be established by means of physical tests.

There are numerous physical tests which are used in determining the characteristics of gasoline. A few chemical tests are required. The gravity, color, and odor are determined; the quantity of gum and sulphur, antiknock rating, and volatility range comply with standard specifications. Water must be absent from aeroplane gasoline.

There appears to be considerable difference in the consumption of gasoline by aeroplanes. A good performance is reported to be 0.5 lb. per hp-hr. A single motor developing 140 hp. at maximum speed would ordinarily require about 60 lb. per hr. Single motor planes use around one gallon to each 10 to 12 miles. The large ships, with three motors which carry up to 16 persons, and travel at the rate of 100 m.p.h., consume approximately 60 gal. an hour.

The problems surrounding the development of the aero engine have included similar ones to those encountered in the perfection of the automobile engine. These have been faulty lubrication and poor lubricants. The short life of many of the first ships was due to poor mechanical conditions for handling the lubricating oil. In the early types of rotary engines, the inlet valve for the petroleum-air mixture was in the center of the piston, and this valve soon became choked with deposits. In one engine, there was only one piston ring which, aside from seldom fitting, furnished a straight opening where the two ends were supposed to meet. This part of the ring was soon decomposed by the action of the slightest trace of acid in the oil used for lubrication. As soon as the corners of the ring became rounded, the ring no longer prevented the explosion gases from passing the piston, and the cylinder became overheated.

When the lubricating oil is fed to the oil pump through an elevated tank, it is necessary to use oil with a very low cold test, and to preheat the oil before a flight; this is especially advisable during the cold months.

The great majority of aero engines are now of the radial type. The oil is kept warm in the engine and circulates under pressure, consequently pure mineral oils may usually function with entire satisfaction. Some authorities advise the addition of about 10 per cent of fixed oil, such as neatsfoot oil, to reduce the danger of seizure. Castor oil can also be used in such mixtures, but only in the presence of some animal oil. An admixture of 5 per cent castor oil and 5 per cent lard or neatsfoot makes an excellent mixture. If more castor oil is desired, as much as 20 per cent can be mixed with 74 per cent paraffin free mineral oil, and 6 per cent lard oil.

The early hours, that is the breaking in period, of a new aero motor constitute the period when such oils as castor oil and castor blends are important because of the tendency of the aluminum pistons to cut and freeze owing to the initial growth of the aluminum. When the engine is running at maximum power, the piston clearance is reduced to proper working value, but when the engines are running at reduced speed, the lower temperature of the piston brings about larger piston clearances, which explains why under these conditions aero engines may have a high oil consumption.

Excessive oil consumption follows excessive oil pressure as illustrated by the following:

Oil pressure lb. per sq. in.	Oil consumption, gals. per hr.
70	1.5
50	0.9
30	0.5

Airplane motors must have superior quality oil which has been thoroughly refined. An oil that is free-flowing, at the same time maintains its body or viscosity under high pressure, high temperature, changes in atmospheric conditions, etc. Airplane motors are operated much nearer their maximum speed than automobile motors. Paraffin-base oils have proved to be much better lubricants for airplane motors than asphalt-base oils on account of the ability to resist heat.

---

[1] Chief Technologist, Skelly Oil Co., Tulsa, Oklahoma.

Presented at the Third National Meeting of the A.S.M.E. Aeronautic Division, Wichita, Kansas, Sept. 21, 1928.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and are not those of the Society.

Following are representative specifications:

Oil	Grav. A.P.I.	Flash F°	Fire F°	Pour point F°	Viscosity at 100° F	Viscosity at 210° F	Carbon
1	23–24	460–470	535–545	20–25		115–125	0.968
2	23.6	520	600	24	1408	114	1.67
3	23.7	490	570	0		125	1.92

Castor oil is insoluble in gasoline, and the fact that it does not decompose under high pressure and temperature makes it a good lubricant for certain types of motors. The fact that it is soluble when compounded with some other substances has caused large quantities to be used in the preparation of artificial leather, in the manufacture of linoleum, in the dye industry, and for the fabrication of rubber goods. Some high-grade typewriter inks contain castor oil. It is used in the varnish industry, and for making flypaper.

Prior to the war, India furnished 95 per cent of the world's castor-bean supply; with the rise in the economic position of the bean, however, this figure is gradually declining. While the eastern hemisphere looks to India and China to support its laurels, Brazil cultivates the largest acreage in the western hemisphere. It is ready to increase its production as needed. The crop grown in the Argentine is estimated at between 7000 and 10,000 acres, and in addition to these the Central American countries, including Mexico, are well adapted for cultivation of the bean. So well are they adapted, in fact, that it is said they could supply the United States' need without difficulty, should anything happen to the Indian crop.

The very high rating of castor oil as a lubricant is quite widely recognized. It is used for the lubrication of bearings, especially of the heavy-duty type, and is extensively used for lubricating the rotary-airplane engines to which service it is especially adapted. The chief objection to the use of castor oil as a lubricant appears to be its tendency to form sticky and gummy substances through oxidation. When decomposition sets in acids are produced. These facts are the cause of some corrosion and the sticking of connecting rods, etc.

Castor oil has a Saybolt viscosity over 1000 at 100 and above 90 at 210 deg. fahr. A sample tested as follows: Gravity, 15.5 A.P.I.; flash, closed cup 485 deg. fahr.; flash, open cup, 505 deg. fahr.; Saybolt viscosity at 100 deg. fahr., 1485; Saybolt viscosity at 210 deg. fahr., 110; pour, 14 deg. fahr.

This oil does not blend readily with mineral oil, but is freely soluble in rosin oil; it becomes soluble in mineral lubricating oils in the presence of rape-seed oil, lard oil, and tallow. When heated under pressure for several hours it becomes more soluble in the mineral oils. There is one peculiar difficulty that may develop when castor oil is used to cool bearings, and its use is not recommended in a circulation system; that is the formation of deposits.

After a bearing has become accustomed to castor oil it is not always easy to return to the original conditions. This appears to be due to rapid loosening of the deposits which cause trouble. When a change is to be made from castor oil to a mineral oil there should be a gradual dilution of the castor oil with a good grade of lubricating oil.

The Society of Automotive Engineers has classified lubricating oils by numbers, known as S.A.E. numbers. The table indicates how these numbers correspond with viscosities.

S.A.E. Visc. number	Viscosity range At 100 deg. fahr.	At 130 deg. fahr.	At 210 deg. fahr.
10	135–200	90–115	
20	220–330	120–150	
30	410–500	185–220	
40	600–630	255–	–70
50	635–1000		75–95
60	1300–1800		105–120

On the tag attached to each new Wright aeroplane engine is the following warning: "This engine is designed to use only high-test aviation gasoline as fuel. The use of other fuels is apt to lead to unsatisfactory operation and serious damage to the engine. The manufacturer will assume no responsibility for the engine's performance when other fuels are used. In the event, high-test gasoline is not available, always operate at reduced throttle with the mixture control in the full-rich position. Use benzol gas, ethyl gas, or high-test automobile gasoline if available. Gasoline from California base crude is much superior to gas from Mid-Continent and eastern crudes."

The weight of gasoline for airplane use is important. A plane was fueled for the Pacific flight with 500 gallons of selected Mid-Continent, 76.9 gravity gasoline, which weighed 2826 lb. or 5.652 lb. to the gallon as compared with California, 58.5 gravity gasoline weighing 6.2 lb. per gallon. This is a saving of 0.548 lb. for each gallon, or a total saving in weight of 274 lb. The consumption of the lighter gasoline has been reported to be from one gallon to a gallon and half per hour less than the heavier product in the Wright radial motor when the normal consumption was 12 gal. per hr.

The light gasoline has been tested in numerous types of airplane motors at all altitudes from sea level to above 16,000 ft., and at temperatures from below freezing to 105 deg. fahr. These tests demonstrated that the light gasoline produced an increase of 125 r.p.m. above the speed obtained with ordinary gasoline. The travel speed was increased from 5 to 11 m.p.h. With this greater speed there was a lower motor temperature of 5 deg. Flight tests with five planes showed a saving in the fuel of 1.4 to 3.25 gal. per hr.

The Skelly Oil Company has made a test with this special gasoline in a Spartan plane from Tulsa to El Dorado, Kansas, and return, a distance of 260 miles. The plane with two persons flew the distance each way in an hour and 45 minutes. Eighteen gallons of the gasoline were used, which means that a little over 14 miles to the gallon were made.

Preliminary tests had indicated that best results were obtained in the airplane motor with straight natural gasoline when jet 110 was used in the carburetor. With U. S. motor gasoline the best setting was 120. In the tests jet 115 was used as an average of the two.

Natural gasoline Gr. 74.2			Domestic aviation Gr. 64.6		
	5%	85			
	10	94	10%	136	
	20	112	20	168	
	30	130	30	192	
	40	152	40	216	
I.B.P.	50	170	50	236	I.B.P.
68	60	188	60	254	86
	70	204	70	274	
	80	224	80	298	
	90	256	90	326	
	96	316	98	368	

Dr. Brown of the University of Michigan has investigated gasoline of this type and says: "Although it seems unnecessary to use more than 50 per cent of natural gasoline in a blend with motor fuel to obtain the best engine performance for motor cars, the exacting conditions demanded from airplane engines, particularly in obtaining the maximum number of revolutions per minute possible, give natural gasoline a peculiar advantage in aviation work. Natural gasoline not only gives the maximum speed and power, but also, being of higher A.P.I. gravity, gives the plane a wider cruising for the same weight of fuel carried. It is interesting to compare the European specifications for aviation gasoline with the distillation curves of grade A natural. The specifications of aviation gasoline used in Europe are 50 per cent over at 212 deg. fahr. and an end point of 302 deg. fahr. Ap-

parently these rigid specifications for aviation gasoline for use on the Continent can best be met by natural gasoline, which appears to be an ideal airplane fuel."

Records of actual flight mileage of the various component phases of aviation in the United States are not available except in the form of estimates, mostly of an unofficial nature. The only available government statistics over any period of time are those for the air-mail service, which show a decrease over the period of 1920–23 inclusive, and from thence forward a decidedly progressive increase until it is estimated that there will be 8,250,000 miles flown with the air mail in 1928. Since all of the mail is now carried by contract operators, air transport will also show a commensurate increase for 1928. Aerial-transport service is the phase of civil aviation by which the greatest amount of flying is done, and the Department of Commerce estimates that this branch flew 18,746,640 miles in 1926. While government figures are not yet available for 1927, it is estimated that aerial-service operators flew about 20,000,000 miles in that year and will fly more than 80,000,000 miles during 1928. The latter estimate includes private, itinerant, and all other classes of flying.

Including both civil and Government aviation, probably 80,000,000 miles will be flown in the United States during 1928, or a daily average of approximately 219,000 miles. This represents an increase over 1927 of over 50 per cent.

The gasoline consumed by aviation flying these 80,000,000 air miles will approximate 530,000 barrels, while about 27,210 barrels of motor oils will be used. The process of arriving at the average number of miles flown per gallon of gasoline and oil resulted in an approximation of 4 miles per gallon of gasoline and 70 miles per gallon of oil consumed. Flight figures over the past ten years have shown that the actual operating consumption of fuel ranged from 2 flight miles per gallon of gasoline to 12 flight miles per gallon.

In October, 1918, the Post Office Department flew 12,671 miles and in doing so used 2293 gallons of gasoline, or an average of 5.52 miles per gallon at an average speed of 69 miles per hour. From May 15, 1918, to June 30, 1919, the Post Office Department flew 184,034 miles on the New York to Washington route at an average speed of 73 m.p.h., and at the rate of 4.08 miles per gallon of gasoline consumed. The official figures of the operation of the U. S. Army Model Airway for the years 1923–26 inclusive, covering the operations of all types of planes, gives a total of 1,201,370 flight miles at an average speed of 81 miles per hour. A total of 332,011 gallons of gasoline and 20,524 gallons of oil were used over the four-year period, or an average of 3.62 flight miles per gallon of gasoline and 58.52 miles per gallon of oil.

Figures on notable long distance and other record flights do not give a correct impression as to the average quantity of gasoline consumed under commercial conditions. This is due to the fact that huge quantities of gasoline are consumed in cleaning motors and testing same, which must be included in total consumption figures when cost is to be accounted for. On Lindbergh's flight to Paris of 3610 miles, 381 gallons of gasoline were consumed, which gives an average of 9.48 miles per gallon. On Art Goebel's recent West-East flight, he was in the air 18 hours and 51 minutes and traveled at an approximate average speed of 150 m.p.h.; 360 gallons of gasoline and 20 gallons of oil were consumed, which approximates an average of 8 miles per gallon of gasoline and 130 miles per gallon of oil.

The above comparisons show that the actual gasoline consumption of the average plane under all conditions, and over a long period of time will approximate one gallon for every four flight miles. This is further substantiated by operating figures furnished by two large air-transport companies who utilize various types of planes in their service of several hundred thousand miles per year on regular schedule. Both companies report an average mileage of 4.0 to 4.5 miles per gallon of gasoline consumed. One company reports oil consumed at the rate of 70.5 flight miles per gallon with one type of motor, and 108.5 miles per gallon with another type of motor, but estimates an average consumption of 70 miles per gallon of oil for all types of motors used in air transport.

Discussion

HERBERT K. CUMMINGS.[2] The Bureau of Standards receives many letters from filling-station and air-port operators, inquiring what they should stock in the way of gasolines. For obvious reasons, particular brands of gasoline cannot be recommended by a government bureau and the reply that "the gasoline should have suitable volatility, and be free from excessive tendency to knock" usually requires some further explanation. However, assuming that the gasolines under consideration do not contain sufficient unstable compounds to cause valve sticking, nor sufficient sulphur to cause corrosion, volatility and anti-knock value are the two points to consider in selecting an automobile- or aircraft-engine fuel.

High-compression engines require fuels of higher anti-knock value than low-compression engines. The tag used on the Wright engines recognizes this, and every aircraft engine might well wear a tag to indicate its fuel requirements. However, the writer objects to the term "high-test gasoline" because there is an unfortunate tendency in this country to use it as a synonym for premium gasoline. Gasolines may command a premium either because they are extra volatile, or because they are unlikely to knock, and there should be a distinction, keeping the term "high test" for the volatility factor, and using the term "high compression" for gasolines that have a high anti-knock value.

The federal specifications for aviation gasoline tie down the distillation curve which the author has been talking about by requiring that certain temperatures shall not be exceeded at 5 per cent, 50 per cent, 90 per cent, and 96 per cent distilled, and at the dry point. The Bureau's work on fuel volatility has shown that the portion of the distillation curve from 5 to 25 per cent distilled defines the relative starting performance of different gasolines. To ensure good starting performance it is specified that the temperature at 5 per cent distilled shall not exceed 167 deg. fahr. for domestic aviation gasoline and 149 deg. fahr. for the fighting grade. The specifications also provide that the temperature at 5 per cent distilled shall not be less than 122 deg. fahr. for either grade. This requirement was intended to prevent the excessive gas formation mentioned by the author. When too much air and natural gasoline are dissolved in a fuel, "gassing" is likely to occur in the fuel lines or in the carburetor at high temperatures or low pressures. Vapor lock due to this rapid evolution of gas is probably a not infrequent cause of engine trouble. It is not often reported as such because the same effect could be caused by dirt in the gasoline clogging the line. Since gassing is not by any means confined to gasolines having 5 per cent points below 122 deg. fahr., a further investigation of vapor lock in aircraft fuel systems is now in progress.

The upper end of the distillation curve is of interest in connection with the amount of heating necessary to vaporize the gasoline completely. Recent work at the Bureau of Standards on the dew points of gasolines has shown that the minimum temperature for the complete vaporization of gasoline mixed with air can be computed from the 90 per cent point. There appears to be no relation between the dry point in the A.S.T.M. distillation test, and the dew point, although the former is the sole distillation

[2] Bureau of Standards, Washington, D. C.

temperature mentioned in many commercial-gasoline quotations. The maximum temperatures specified at 90 per cent distilled are 311 deg. fahr. for domestic aviation gasoline and 257 deg. fahr. for the fighting grade. These correspond to dew points of 91 deg. fahr. and 52 deg. fahr. for air-gasoline mixtures containing twelve parts of air to one of gasoline by weight. For motor gasoline having a 90 per cent point of 392 deg. fahr. the dew point of a 12:1 air-gasoline mixture is 149 deg. fahr.

Unfortunately, there is as yet no entirely satisfactory way of determining or specifying just how good a gasoline is with respect to detonation. Nothing but a trial in the engine itself will determine with certainty how readily a given gasoline will knock in that particular engine. All present knock ratings are based on the assumption (plausible but unproved) that, if fuel A knocks more violently than fuel B in a given engine under given operating conditions, fuel A will have more tendency to knock than fuel B in other engines, and under other operating conditions.

Experience indicates in general that straight-run California gasolines are less likely to knock than straight-run eastern gasolines, and that some mid-continent straight-run gasolines are almost as good as the best California gasolines in this respect while others are nearly as bad as the worst eastern gasolines. There are some cracked gasolines, particularly from mid-continent crudes, which equal or exceed straight-run California gasolines in anti-knock value, but it is impossible to predict how much better one gasoline will be than another without actual engine tests. A large-scale attempt to market a fuel of constant anti-knock value is found in the case of gasolines containing lead, since by contract those licensed to sell ethyl gasoline in bulk are required to use sufficient lead to match under specified conditions an arbitrary standard fuel which approaches straight-run California gasoline in anti-knock value.

The domestic aviation gasoline (D.A.G.) that the government buys on the east coast under specifications knocks about as readily as any gasoline which the Bureau of Standards has occasion to test, although some of the straight-run eastern motor gasolines are even lower in anti-knock value. The navy seaplanes along the Atlantic coast use this eastern D.A.G. treated with lead, while the army uses a benzol blend of the same eastern D.A.G. The fuels used in type-testing commercial-aircraft engines are supplied by the engine manufacturers, but these fuels are compared with the Bureau's current supply of eastern D.A.G., and each engine which passes is approved for use with a certain grade of fuel, or better. No engine has yet been approved for use with straight-eastern D.A.G.

At the present time the average aircraft engine will find many volatile gasolines which are unsatisfactory for use at full throttle at the ground without treatment with benzol or lead. There are, however, a great many gasolines which are satisfactory, and the difficulty is to pick out those that can be used safely in a given engine. Knocking is objectionable in a motor-car engine, but in the aircraft engine where weight is cut down to a minimum it may actually be hazardous, resulting in mechanical damage as well as lower power, and increased heat dissipation.

Cooperative work by representative laboratories on the problem of developing a standard method for determining and expressing anti-knock value is in progress, and it is hoped that it will not be long before a definite knock test can be included in specifications for aviation gasoline.

In concluding, there is just one point that the writer wishes to make regarding lubrication. The aviation engine has a great advantage over the automobile engine, because with aviation gasoline there is practically no loss in viscosity due to progressive dilution of the crankcase oil with unburned fuel.

AER-51-13

Air-Mail and Express Traffic

By R. W. IRELAND,[1] CHICAGO, ILL.

The organization of most of the air-transport lines of the country is patterned somewhat after the organization of the railroads, as it is only a newer and faster method of moving persons or things. The number of air-transport lines is increasing with each year. The twenty-five existing lines are supported by private capital. An average of 42,000 miles is flown over these lines every 24 hours. The Department of Commerce has completed the lighting on over 9000 miles of the 20,000 miles of airways now in operation.

SELLING service is the real function of the traffic department of an air-transport company. It bears the same relation to the organization as does the traffic department of a railroad. While the actual selling does not begin until the line is operating, the work of the traffic department, or at least the traffic work of the company, should come into action as one of the first activities in connection with the organization of a line. The probable amount of traffic should be given primary consideration in the selection of the route to be flown, because if the route is not laid out properly from a traffic point of view, it will never mean anything financially. Planes may fly on time, but if they have nothing to carry, that is, if they have no traffic, the line will not continue long in existence. Therefore, before the line is actually laid out, the proposed route should be surveyed carefully from a traffic point of view.

Consideration must be given to the distance between points to be served by the proposed route and its connections. In order to offer a salable advantage to the public, an air-transport line, either in itself or in combination with connecting routes, must save time in comparison with other existing means of transportation. This requires that the distance between points to be served be great enough so that the airplane will be in the air a sufficient number of hours to effect a real saving in delivery to destination. What this distance must be depends upon the other forms of transportation with which the airplane competes. Obviously if this competitor is water transportation with a speed of only 15 or 20 miles an hour, the length of the route will not have to be as great, in order to gain time, as in a case where the air route is competing with fast trains averaging 40 or 50 miles an hour. In general, the distance between points to be served by an air route, even if flown at night, must be greater than can be traveled overnight by other means of transportation, because, ordinarily, overnight delivery is all that is needed from any form of mail or express transportation.

In some unusual cases, the airplane will save time in delivery between cities a short distanee apart, 100 or 150 miles or even less. This is true where mail or express matter can be picked up late in the forenoon at point of origin and carried to its destination in time for delivery to the consignee the same day and where such delivery is not possible with other means of transportation.

The desirability of night operation of an air line is obvious. When this is possible, the movement takes place without any loss of business time. An outstanding example of this is the overnight line between Chicago and New York. Mail or express leaves either end of this route after the close of the business day and is delivered at the other end prior to the opening of business on the next day.

Night flying, of course, depends upon the existence of a lighted airway. The Department of Commerce is proceeding with the lighting of these airways as rapidly as possible, and has completed this work on between nine and ten thousand of the 20,000 miles of airways now in operation. In many instances the installation of these lights and the inauguration of night flying has been the means of greatly increasing the cargoes carried on air-mail and express lines. A case in point is the Southwestern route operated by National Air Transport between Chicago and Dallas, Texas. Originally this line could be flown only during daylight hours on account of the absence of lights. While the plane made the thousand-mile trip from Chicago to Dallas in 12 hours elapsed time, including stops, as compared with a minimum of 26 or 27 by rail, the fact that the flight was made in the daytime during business hours destroyed its advantage so far as service between Chicago and Dallas was concerned, and while it did offer a saving between the Southwest and New York through connection made at Chicago with the Chicago–New York overnight route, it offered the man who wanted to send mail and express between Chicago and Dallas next to nothing so far as time saving was concerned. Mail posted Monday evening in Chicago was not started on its flight until Tuesday morning and did not reach Dallas until Tuesday evening, too late for delivery to the addressee before Wednesday morning. Practically this same service was available by rail. Hence very little Chicago–Dallas mail was carried. This situation was entirely changed by the installation of lights. Monday's air mail and express now leaves Chicago at 8 p.m. Monday and arrives at Dallas the next morning, saving an additional day as compared with the day flight. The improved service has been reflected by a substantial increase in cargo.

The question that must be answered in determining if a proposed air line will offer a service that the public will buy is whether the line will deliver air mail or express far enough in advance of other methods to make the saving of time valuable to those who use the service. Sound business considerations must govern the establishment of an air line, as well as any other form of business, and unless the people to be served can be offered something better than they already have, the results will be disappointing.

Obviously, careful thought must be given to the potential air-mail and express cargo in the territory to be served. A city or group of cities whose business is entirely local or is confined to points only a few miles beyond its limits will mean little to the prospective air-transport operator.

The character of population has considerable bearing on the use that will be made of a proposed air line. This is particularly true with reference to use of air mail for social or personal correspondence as distinguished from business uses. Certain classes of population will adopt new methods more readily than will others. Comparatively new communities, the population of which comes largely from other distant parts of the country, may be expected to make liberal use of air mail, as well as of all other classes of mail, on account of connections back home.

A basis for estimating the potential air-mail or air-express traffic that may be expected from a given locality may be obtained by a count of the ordinary mail and express moving by rail from that locality to points far enough distant so that a substantial saving of time may be offered by the use of air transportation. Such

---

[1] General Traffic Manager, National Air Transport, Inc.

Presented at the Third National Meeting of the A.S.M.E. Aeronautic Division, St. Louis, Mo., May 27 to 30, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

figures, while not giving accurate information as to the amount of air cargo that may be expected, at least give some basis for a more or less intelligent estimate. The percentage of air mail that may be expected from a given quantity of ordinary mail varies considerably, in some cases running as high as 15 or 20 per cent. Generally, however, the percentage is smaller.

Because of the great public interest in aviation and air transportation, and because of the desire of most cities to secure for themselves places on air-transport lines, chambers of commerce are quite often willing to institute surveys to determine the potential business which may be expected if a line is placed in operation. The common method of securing this is for the chamber of commerce to send questionnaires to the leading business firms telling them what the service will offer and asking them to indicate approximately the extent to which they would use it.

In some localities, chambers of commerce have even gone to the extent of securing guarantees of traffic, that is, to ask the leading business men to guarantee to send a certain quantity of mail or express by air for a period of a year or so, in order to help the line in its early stages. Such a guarantee as a general rule, however, amounts to little more than a good-will gesture, because it cannot be expected that the public will make permanent use of the service unless it does offer an advantage sufficient to compensate for the increased cost as compared with the cost of other means of transportation or communication. Such guarantees do have considerable value in getting a given community into the habit of using air transport and thus finding out what such a service accomplishes. These guarantees, however, contain an element of danger unless the company recognizes the traffic which comes from such a source. If this is not done, a false impression will be gained of the business to be expected and after the period of the guarantees expire, the traffic is likely to take a disconcerting drop. Taking them as a whole, I believe they are undesirable but they do offer a tempting source of revenue to a new company, particularly to one with limited financial backing and which cannot operate for a very long period of time at a loss.

In estimating the potential business which may come to a proposed line, there must be considered not only the business originating in the cities touched by the line but also business which may come into the route cities from the surrounding territory, from other air lines or from rail lines. Many times, by a combination of air and rail, as much time can be saved as in the case of an all-air route, and sometimes even more.

One matter of importance in estimating probable air-mail and express cargoes is the scheduled departure time of the plane. If this can be made late in the afternoon or in the evening, it will be much easier to induce business houses to use the service than if the plane leaves so early that a special effort must be made in order to get mail out before the normal mailing time at the close of the business day.

To function properly, a proposed air line must tie into the air-transport system of the country. The transcontinental line from New York to San Francisco forms the backbone of the system as it exists today and practically all of the other lines function as feeders to this transcontinental route.

Obviously it is an advantage to have an air-transport line follow a straight line as nearly as possible, in order that the time gained by the speed of the airplane may not be lost by following a circuitous route. However, in some cases, it may be wise to deviate slightly from a direct route when by doing so the plane may follow the route of a railroad going in the same direction as the air route. The reason for this is that, in the present stage of aviation, bad weather offers an obstacle to airplane operation, which sometimes makes it necessary to land and forward the cargo by ground transportation. When this is necessary, if the landing can be made along the route of fast rail service, delivery of the cargo to its destination will be greatly expedited as compared with the situation where a considerable period of time is required to transfer the cargo from the plane to the railroad after a forced landing.

The same consideration leads to a limitation of the number of stops to be made by the plane, because, with too many stops, a substantial portion of the time gained by the speed of the airplane will be lost on account of the time required to land and take off.

The probable amount of traffic obviously must be given careful thought in determining bids made on air-mail contracts. With the exception of some foreign routes, payment to an air-mail contractor is based directly upon the amount of mail that he carries, which in turn depends upon the amount of mail on which the people served by him are willing to pay air-mail postage. It is therefore of first importance that the bidder have some idea of the cargo that he may expect to secure before he makes his proposal.

Under the law, air-mail contracts are awarded on a competitive basis, with the limitation that the law does not permit the Postmaster General to consider a bid in excess of $3 per pound. Contracts now in existence vary considerably as regards rates, ranging from the maximum of $3 to a minimum of around 75 cents. In the earlier contracts, competition was not especially severe, but within the last year or year and a half this situation has changed, and any contracts now thrown open to bids may be expected to go at a rather low rate due to the large number of people interested in engaging in such service. This condition may lead to a bad situation, inasmuch as many contractors in order to secure a line may bid much lower than the prospective business warrants, with the result that on account of the small amount of business secured and the low rate received, the contractor will not be able to purchase the most efficient equipment nor to develop his line in the way he should.

Eventually it is felt that the method of payment to air-mail contractors will be changed to something similar to the system in force with reference to rail-mail contracts where the operator is paid on a space basis regardless of day-to-day variation in cargo.

The second and the permanent phase of the traffic work of an air-transport operator is the sale of his service to the public after the line has been laid out and operations started.

Selling air transportation, particularly air-mail and express service, is one of the most agreeable and at the same time one of the most unsatisfactory forms of selling of which I know. It is agreeable because of the general attitude of the public toward aviation. Probably 999 out of every 1000 people in the United States are interested in aviation and like to hear about it. This makes it easy for the air-traffic solicitor to gain an audience. Because of this great public interest, chambers of commerce and other civic bodies will go to great lengths to assist the air-transport company in obtaining business. I have never yet visited a city not located on an air line that was not anxious to have a place on one. In many cases, municipalities will spend large sums of money in buying and improving landing fields and constructing hangars and other facilities to secure a place on an air line, when by no stretch of the imagination can they be expected to secure any financial return proportionate to the investment required. This varies in inverse proportion to the size of the city involved. The larger cities of the country very seldom get excited about an air line, while the smaller communities (and by smaller, I mean cities of a half-million or under) will go to great lengths to become stations on such lines.

The unsatisfactory phase of air-transport traffic promotion, and this again is particularly true in the case of air-mail and express traffic, lies in the fact that the business solicitor very seldom knows definitely that he has made a sale. Air mail and air express do not come direct to the carrier, but are received through the post

offices and express agents. The mail comes to the plane already pouched, so the carrier does not know definitely who is using his service. An automobile salesman or a real estate salesman knows when he has made a sale, but the air-mail and express salesman does not except as may be reflected in the aggregate by the increased loads which his company carries.

The successful and permanent sale of air-transport service depends upon three things. First, the service must be made easy to use. Second, the public must be told of its existence and how to use it. Third, a satisfactory service must be delivered. The most important of the things that have been done by the Post Office Department to make the air-mail service easy to use is the establishment of a uniform postage rate. Originally the air-mail rate was very complicated, the rate depending upon distance flown and zones and routes traversed. Since August 1, 1928, however, a uniform rate of 5 cents for the first ounce and 10 cents for each additional ounce has been in force, which carries air mail between any points in the United States, Canada, and Mexico regardless of distance.

When the service was first inaugurated, it was necessary for air mail to be deposited in special air-mail boxes. Now it may be deposited in any mail box regardless of location, and most all boxes and chutes have been marked with the air-mail pick-up time. In addition the department permits the use of any ordinary postage stamps and any envelopes so long as the letter or package is marked plainly to indicate that it is to go by air. These things, all of which have been done to eliminate complications in the use of air mail, undoubtedly have contributed much to the increased use of this method of communication.

Air express has at its command all of the facilities of the Railway Express Agency, including pick-up, delivery, insurance, etc. The express company in many instances makes special delivery of air-express packages.

The second phase of the air-transport sales effort is largely an educational one. The public must be told that the service is available and must be instructed in the method of using it. Changing habits is not an easy task, but it is one that must be accomplished before the use of air mail and air express will become general in a community. The American business man has been accustomed to putting a two-cent stamp on a letter and to sending packages by ordinary express at the cost of only a few cents a pound. He must be given a good reason for doing something that costs him more money. He must be told about this, not once, but many times in order that air transport may become a routine business tool that is used as a matter of course. This is the principal and continuing work of the traffic department. Such a department consists ordinarily of a general traffic manager having headquarters at the home offices of the company, with division traffic managers distributed through the territory served by the line.

Publicity forms one of the most important traffic activities and is ordinarily in charge of an experienced newspaper man operating as a part of the traffic department of the company. Public interest in aviation has been and still is of such a high degree that the press welcomes legitimate items of news regarding air-transport activities. Most of the larger newspapers of the country have even gone to the extent of inaugurating aviation sections or columns, in some cases designating aviation editors who devote all of their time to this class of news. Many papers have adopted the development of aviation as a definite part of their editorial programs. There is no doubt that this liberal attitude of the press has been one of the most potent factors in building up air-mindedness in America. More columns of newspaper space were devoted to Colonel Lindbergh's flight than to any other event in history. This flight, with its attendant publicity, was of immeasurable value to the development of all branches of aviation including air transportation. Trade journals and national publications have generally adopted a progressive attitude toward aviation.

Supplementing the publicity departments of the various air-transport companies, the American Air Transport Association, made up of the principal operators of the country, maintains an office in Chicago for the dissemination of information regarding air transportation in general. The direct sales work of the air-transport company is carried on by the division traffic managers previously mentioned. One of these men is ordinarily stationed in each of the subdivisions of the territory served by the company, and is responsible for the company's sales efforts in his community. His sales assignment includes not only cities on the air line but all surrounding territory. This man is the company's contact with the public and to be successful he must combine the qualifications of a salesman with those of a diplomat. He must have a good general knowledge of business, so that he may be able to determine how any type of business may use air transport to advantage. This knowledge is ordinarily acquired by visiting one or more representative members of a given class of business and determining all the specific applications of air mail and air express for that group. The knowledge thus gained is used in solicitation of other members of the same industry, either by personal solicitation, advertising, publicity through trade journals and the press, or by other methods.

The cooperation of the Post Office Department has been invaluable in publicizing and advertising the air-mail service. The sales efforts of the Railway Express Agency (formerly American Railway Express Company) have included advertising of air express. The routine of air-transport sales activities includes many other forms of advertising and publicity, such as air-mail and express window displays, talks before civic bodies and clubs and over the radio, direct mail advertising, distribution of printed matter, educational motion pictures, etc.

Many ways have been found by which American business can use to advantage the speed of air transport. Saving, as it does in most cases, a business day, in some cases two days, air transport performs a valuable economic function. Time is our most valuable commodity. The airplane, by cutting to a half or a third the number of hours required for transportation of mail and express, enables the saving of this commodity. In effect, it enables the completion of a given task in one-half or one-third of the time ordinarily required, so far as transportation or communication is involved.

The records of the traffic department of any air-transport company will show many interesting applications of air mail and express to business. Banks derive much profit from the use of air mail and express for clearings. Clearing a day earlier than is possible by other methods means the saving of a day's interest on the amount involved. Many large banks save several thousand dollars a month by using this service. This service is used extensively for shipment of stocks, bonds, and other financial papers where an earlier delivery will mean the saving of interest.

Where schedules permit, air mail is quite often used as a substitute for night telegrams. Merchants often use this service for rush shipments of goods. Many cases are on record where air mail or express has saved the closing down of manufacturing plants by quick delivery of parts needed to keep disabled machines in operation. Air mail and express are used daily for shipment of motion picture negatives and films, especially news reels. Pictures filmed in Chicago on one afternoon may be shown on the screen in Houston, 1300 miles away, on the next day by using this method of fast transportation.

Insurance companies use the service for re-insurance, securing home-office approval of loans and for all classes of correspondence where speed is an object. Social correspondence forms a sub-

stantial portion of the mail carried in the closely packed pouches traveling by air through all hours of the day and night. The time is not far off when good form will call for the use of air mail in all personal correspondence going to distant points.

The value of this service to the American people is best evidenced by its increasing use. In 1926, 810,000 lb. of air mail were carried on all lines of the country; in 1927, this had increased to 1,650,000 lb.; and in 1928, to 4,060,000 lb. At the present rate 1929 will show a total of over 6,000,000 lb.

The final phase in the sale of air transport is not a sales problem at all but an operating one and involves delivery of service after the customer has decided to use it. This is hardly within the scope of this discussion so I shall touch on it only very briefly. Maintenance of service involves a proper flying and ground organization. Accurate weather reports must be available. Satisfactory radio or other communication service must be had.

Planes and motors must be checked and overhauled carefully at periodic intervals. Probably 99 per cent of delays in air-transport flying result from bad weather. Continuous progress is being made in overcoming this handicap. The radio directional beacon, radio ground to plane communication, and improved navigating instruments are expected to do much in this direction.

From the economic viewpoint I think it may be fairly said that air transport is making satisfactory progress. The number of air-transport lines is showing a healthy increase each year. Three and a half years ago there were but two air-mail lines in operation, the transcontinental and New York–Chicago overnight routes, both operated by the Post Office Department. Now both of these routes, as well as twenty-three others, are operated by private capital. An average of 42,000 miles is flown over these lines each twenty-four hours. Practically all of these lines are carrying substantial cargoes and are earning a fair profit. The airplane is proving itself to be a useful peace-time economic tool and one that can sustain itself financially as well as aerodynamically.

Discussion

AMELIA EARHART.[2] Women should be included in a traffic selling program. Women's organizations offer an excellent opportunity for air-mail campaigns, and one which is often neglected.

Social mail will go by air, and a very good selling point is the little added distinction which the air-mail stamp still bears. Guarantees of use similar to those from chambers of commerce can be wrung cheerfully from women's clubs with the same benefit to the operating company as from the other source.

Not only must women be sold on aviation for themselves, but for the influence they have on men. So I urge that important feminine names be added to the list of prospects to be visited by (the handsomest) traffic representatives.

[2] Aviation Editor, Hearst's International, New York, N. Y.

AUTHOR'S CLOSURE

The author agrees heartily with Miss Earhart's suggestion that air-mail traffic sales should include women as well as men. While no special point of that is made in the paper, nevertheless the work of all operators has included efforts along this line. For example, in National Air Transport, some of the things done to encourage the use of air mail for social correspondence have included talks before women's clubs, and in cooperation with Post Office department, posters have been placed on mail trucks and printed matter is distributed through mail carriers. Moving pictures are given before women's clubs and talks over the radio. Essay contests have been inagurated in schools. Air-mail stickers have been placed on mail boxes and mail chutes, including those in hotels and some apartment buildings. General publicity is featured in newspapers and magazines, and a limited amount of general advertising is done in newspapers. Air-mail literature is distributed with gas bills, telephone bills, etc., a large percentage of which reach women.

In the early days of the air-mail service perhaps the sales efforts of many of the air-mail contractors were pretty generally confined to business houses, which was quite natural in view of the fact that business houses are much smaller in number than prospective social users, and are much more easily reached by the air-mail solicitor. But as the service has progressed, everybody in the business has recognized the importance of urging the use of air mail for social correspondence, and considerable effort and money have been expended in reaching this class of mail. In an effort to determine the relative percentage of business and social correspondence which is being carried by air mail, a survey has been made recently of the air mail in certain cities served by National Air Transport lines and it was found that of the total air mail originating in each of these cities, the percentages of social correspondence were as follows:

Chicago, Ill.	19.4	Brooklyn, N. Y.	65.6
New York City	24	Newark, N. J.	35
St. Joseph, Mo.	40	Kansas City, Mo.	30
Wichita, Kansas	40	Ponca City	59
Tulsa, Okla.	43.4	Okla. City	30.8
Fort Worth, Texas	37.8	Dallas, Texas	22.3

The use of air mail as a medium for social correspondence, and the attention getting value of this class of mail was recently recognized by Miss Emily Post who is perhaps the world's foremost authority on etiquette and social usage. In an article in Collier's, Miss Post stated, in part: "As letters arrive, they are opened and laid flat on a special desk and held in place by a heavy book. Air mail and special delivery letters are put on the blotter of my writing table; these are answered the day they are received, the others are answered as I find time, in turn."

Landing Speed of Airplanes

By JOHN G. LEE,[1] FARMINGDALE, N. Y.

Results of a large number of wind-tunnel and flight tests on the maximum lift of wings are presented, analyzed, and compared. Curves are given showing the relationship between the shape and lift of wings and for the landing speeds obtained with different wing loadings and lift coefficients. The subjects of sinking speeds, landing impacts, and the effect of flaps and slots are discussed in relation to landing speed and the general problem of easy landing.

THERE is no item of airplane performance as universally misrepresented as the landing speed. It has become common practice to advertise landing speeds much lower than they really are. Reliable flight tests are scarce. Wind-tunnel tests are plentiful, but differ greatly among themselves, even for the same wing. In addition, many pilots feel that a low landing speed is only one of several qualities required by an easy-landing airplane.

The first problem is to get some sort of correlation between the wind-tunnel tests and flight tests. The maximum lift obtained in a wind tunnel is influenced greatly by the turbulence of the tunnel, so that tests in different tunnels which agree in other respects usually do not agree in maximum lift, particularly with the high-lift wings. In addition, accurate flight tests are quite rare, and are available on only a few wings.

It is equally desirable to establish a relationship between the maximum lift and the shape of the wing. By this means the lift of a wing can be predicted from flight tests on similar wings. It has been established rather generally that the lift of a wing increases with the mean camber and that of two wings having the same mean camber the thicker will have the higher lift.

Attempts to plot the maximum lift of several wings against the mean camber or the thickness gave fairly uniform results. Much better results were obtained, however, by plotting the lift against the maximum camber of the upper surface. This latter really takes into consideration both of the other variables, since increasing either the mean camber or the thickness automatically increases the upper camber. Moreover, the maximum lift occurs when the flow over the upper surface breaks down, which lends a physical significance to the upper surface of the wing.

The maximum upper camber is measured perpendicular to the common chord line for all wing sections as shown in Fig. 1, and is expressed in per cent of that chord. It will be noted that the common chord line is taken as the line joining the extreme leading and trailing edges, and in general does not coincide with the usual chord or baseline from which the wing profile is layed out, since that is located in different places on different wings.

Fig. 2 shows the maximum-lift coefficient plotted against upper camber for wings tested on the 7½-ft. tunnel of the Massachusetts Institute of Technology. This represents a considerable body of data, 28 wings, all tested under identical conditions and covering the entire range of types. The variations from the straight line are generally small, and the three or four exceptions may be explained easily as turbulence effects. The maximum-lift coefficients are in engineering units.

In Fig. 3, similar data are plotted for wings tested in the N.A.C.A. high-density wind tunnel, at 20 atmospheres pressure. A total of 28 different wings are again shown, of which about one-fourth are duplicates of those tested at M.I.T. The lift coefficients are in absolute units. It is apparent at once that while the agreement is excellent for low-lift wings, the high-lift wings diverge largely, and the question of whether this is a turbulence effect dependent upon the tunnel or whether it is actually a characteristic of the wings themselves still remains.

In Fig. 4, the maximum lift is plotted against upper camber for wings tested in flight. In this case, only 15 different wing sections are available, but the plotted points represent tests on 47 different airplanes and certain of the points are the average of tests on many planes of different types, all having the same wing section. It will be noted that the agreement of the points with the curve is quite as good as with the wind-tunnel tests, which is remarkable when it is realized that a flight test includes not only the lift on the wings in landing, but the lift on the fuselage as well, and the down load on the tail—both of which are indeterminate variables.

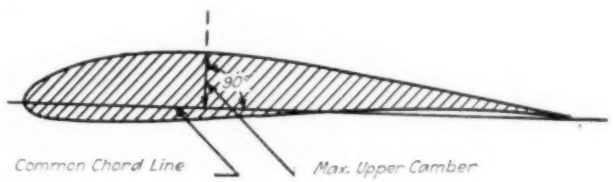

FIG. 1 THE MAXIMUM UPPER CAMBER IS MEASURED PERPENDICULAR TO THE COMMON CHORD LINE

The original data from which this plot was obtained are summarized in Table 1, together with the maximum lifts obtained in the M.I.T. and N.A.C.A. wind tunnels. The maximum thickness, mean camber, and upper camber are also given by way of general information. In this table will be found the maximum lifts of most of the generally used wings. The maximum lift may be found for other wings by determining the upper camber graphically and referring to Fig. 4.

Several of these flight tests have not yet been published, which, together with the scarcity of reliable data on the subject, makes them of sufficient interest to give in detail in Table 2. The author wishes to thank ex-Secretary Warner for the Navy data and Major C. W. Howard for most of the Army data, as well as the Curtiss, Keystone, and Fairchild companies for their contribution. All of the wind-tunnel tests, together with the

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

N.A.C.A. and several of the Army flight tests, have been published as N.A.C.A. reports or Air Service Information circulars, and are generally available.

Two different methods have been employed to obtain data. The first consists of calibrating the air-speed meter by flying over a course at various speeds and then reading the air speed at the moment of landing. Generally the average of several landings is taken. This is the most usual method. The second method consists of attaching an electric recording instrument to the landing wheels which records their rate of revolution graphically. Knowing the circumference of the wheel, the virtual landing speed is obtained which must be corrected by the velocity of the wind taken simultaneously by an observer on the ground. Both of these methods are open to certain inaccuracies, but are probably accurate within 5 per cent. In any case, it is necessary to make a careful three-point landing without stalling or dropping the machine. A test on an uncalibrated air-speed meter is very unreliable, since the position of the air-speed head on a given airplane often introduces an error of 20 per cent at slow speeds (usually too low). This explains many of the advertised slow landing speeds.

The curves from Figs. 2, 3, and 4 have been plotted in Fig. 5 using the same coefficients. The N.A.C.A. curve gives landing speeds approximately 1 per cent too low, and the M.I.T. curve 6 per cent too high relative to the flight tests, which is an excellent agreement. Unfortunately, this agreement is of academic interest only since it deals with averages. Comparisons of individual wings show great variations and inconsistencies and have led to great confusion in calculating landing speeds.

The formula for the landing speed of an airplane is given in any aeronautical textbook in one of the three following forms:

$$V = \sqrt{1/L_e}\,\sqrt{W/A} \text{ engineering units (M.I.T.)} \quad [1]$$

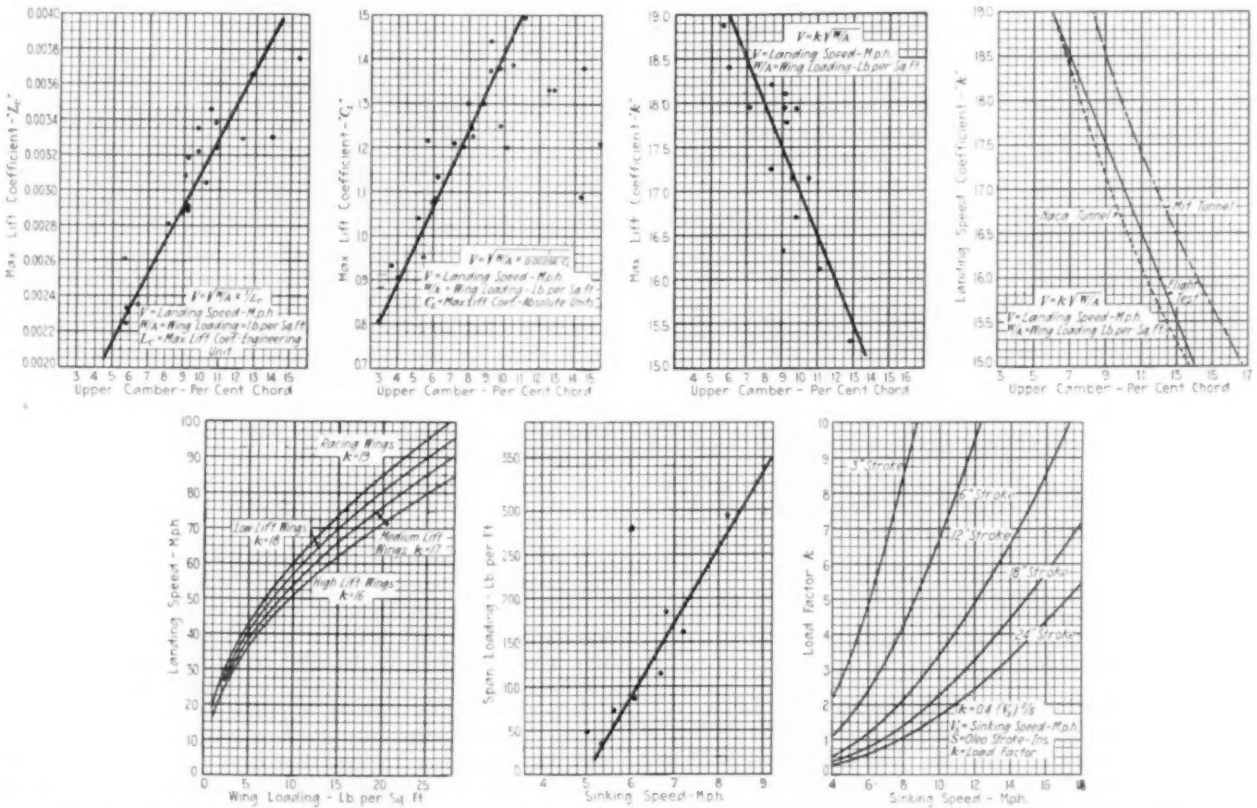
$$V = 19.75\,\sqrt{1/C_L}\,\sqrt{W/A} \text{ absolute units (N.A.C.A.)} \quad [2]$$

$$V = K\,\sqrt{W/A} \text{ as in Fig. 4} \quad [3]$$

where V = landing speed in m.p.h.
W/A = wing loading in lb. per sq. ft.
L_e = max. lift coefficient (engineering units)
C_L = max. lift coefficient (absolute units)
$K = \sqrt{1/L_e}$

The formula for converting absolute units into engineering units is $L_e = 0.002558\,C_L$.

Of the three forms, the third is the simplest, and has given rise to a series of handy formulas for estimating landing speed roughly, wherein a definite value is assigned to K for all wings. The coefficient K may well be called a "landing-speed coefficient."



Returning to Fig. 4, the "landing-speed coefficient," K varies between the values 16 for high-lift wings and 19 for very low-lift or racing wings. This makes it possible to plot landing speed against wing loading, obtaining a family of curves for different values of K, as has been done in Fig. 6. Given the wing loading of any airplane, the landing speed can be determined from Fig. 6, the only judgment required being to decide whether the wings are of the high-, low-, or medium-lift type. To take some examples, our heavily-loaded transport monoplanes with a wing loading of 17 to 18 lb. per sq. ft. land at upwards of 70 m.p.h. The usual run of cabin planes with wing loadings of 12 lb. per sq. ft. land at speeds between 55 and 60 m.p.h. For a plane to land at 40 m.p.h. the wing loading would have to be less than 6 lb. per sq. ft., and to land at 30 m.p.h. it could not be more than 3.

While a landing speed of between 35 and 40 m.p.h. is extremely desirable (although practically never obtained) for instruction and for the inexpert private owner, our present landing speeds are not excessive for competent commercial pilots. The point is to recognize our landing speeds for what they are. There is no use fooling ourselves or falsifying our advertising. It simply reflects back upon the manufacturers and throws the whole subject of airplane performance into disrepute.

The most important characteristics which make an easy landing airplane may be placed in this order: (1) adequate control at slow speeds; (2) low vertical velocity or sinking speed; (3) easy-acting and non-rebounding landing gear.

An excessive sinking speed will make a hard landing no matter how slow the horizontal speed may be. Also, the faster the sinking speed, the quicker the pilot must be. On the other hand, a plane having unusually low sinking speed will take the whole flying field after levelling out before it touches the ground and is usually known as a "floater." There is practically no test data available on this subject. A theoretical investigation is therefore of interest.

determine the total drag at any air speed. Substituting this drag back into Equation [4] and writing gross weight in place of lift, we have the sinking speed corresponding to any horizontal speed of flight. The minimum sinking speed generally corresponds to a speed of flight near the landing speed of most airplanes and no great error is introduced by taking the sinking speed which corresponds to the landing speed as the actual minimum.

Top Row Left to Right: Fig. 2 Maximum-Lift Coefficients From M.I.T. Wind-Tunnel Tests. 36 In. × 6 In. Models Used. 40 M.p.h. 7½ Ft. Tunnel. Fig. 3 Maximum-Lift Coefficients From N.A.C.A. Wind-Tunnel Tests. Fig. 4 Maximum-Lift Coefficients From Flight Tests. Fig. 5 Comparison of Landing-Speed Coefficients From Wind-Tunnel and Flight Tests

Bottom Row Left to Right; Fig. 6 Landing Speed Vs. Wing Loading for Various Lift Coefficients. Fig. 7 Theoretical Sinking Speed for Typical Airplane. Fig. 8 Load Factors in Landing

The sinking speed is easily calculated by the formula:

$$V_s = V/(L/D) \quad \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

where V_s = sinking speed in m.p.h.
V = speed of horizontal flight in m.p.h.
L/D = lift/drag ratio of the airplane.

The derivation is quite obvious when it is remembered that $1/(L/D)$ is the tangent of the angle of descent in a glide.

Generally the L/D of an airplane under flight conditions is not known, but may be estimated using Driggs method of simplified performance calculation, where the drag is taken as the sum of the induced drag and the parasite drag. The parasite-drag coefficient is assumed constant for all air speeds.

Knowing the power and high speed of the airplane, the total drag at high speed can be determined by assuming a value for the propeller efficiency, usually 75 per cent. If the induced drag is calculated and subtracted from the total, the remainder is the parasite from which the parasite-drag coefficient can be computed. Since this coefficient is assumed constant, we can

In Table 3, the minimum theoretical sinking speed has been calculated in this way for a number of typical airplanes, using the published high speed and rated power. Since the induced drag is the most important resistance factor in slow-speed flight, and since it depends directly on the span loading, the theoretical sinking speed has been plotted against span loading in Fig. 7. The sinking speeds vary between 5 and 8 m.p.h. This is obviously too slow. Any one who has landed without levelling out will bear witness to the fact that he hit harder than 8 m.p.h.

There are two probable reasons for these low theoretical values. First, the parasite drag has been assumed constant, which is correct over the usual flying range. However, the profile drag of the wing increases very rapidly at maximum lift, and hence the parasite drag is increased. Second, the drag of an idling propeller is a very large factor. The result of both of these drags is to reduce the L/D and increase the sinking speed. Taking one of the planes from Table 3 with a theoretical sinking speed of 6 m.p.h. and making approximate allowance for the above factors, the sinking speed would be increased to roughly 17 m.p.h., a much more reasonable figure.

It therefore appears that this theory is scarcely adequate, and in the absence of flight test data, we are largely ignorant of one of the important phases of landing, the value of the sinking speed.

When an airplane strikes the ground with a vertical velocity or sinking speed, the shock absorbers resist with a nearly constant force (the modern oleo type) and the load factor K imposed upon the airplane is given by the equation:

$$K = v^2/2gs \quad \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

In other words, the load factor in landing is equal to the square of the vertical velocity divided by $2g$ and divided by the stroke of the oleo. The actual weight of the airplane does not enter in. The larger the stroke, the smaller the load factor and the easier the landing. We are apt to forget the fact that a long stroke is just as important on a small airplane as on a big one.

TABLE 3 THEORETICAL SINKING SPEEDS OF TYPICAL AIRPLANES

Airplane	Type	Sinking speed, m.p.h.	Span loading, lb. per ft.
Dornier "Superwal"	2000 hp. Flying Boat	7.98	295
Fokker F-10	1275 hp. Tri-Motor	7.20	162
Boeing 80 Transport	Biplane Tri-Motor	6.82	185*
Fairchild 71 (loaded)	425 hp. Cabin Type	6.69	115
Fairchild 71 (light)		5.43	73
Fairchild FC-2	200 hp. Cabin Type	6.12	86
Monocoupe	60 hp. Cabin Type	5.35	39
D.H. "Gypsy Moth"	90 hp. Open Biplane	5.07	48.5*

* Biplanes are figured with equivalent monoplane span.

The above equation is in the usual foot-pound-second units of theoretical mechanics. Substituting for g its value 32.17, and converting v into m.p.h. and s into inches, we obtain:

$$K = 0.4(V_s)^2/s$$

where V_s = sinking speed, m.p.h.
K = load factor obtained in landing
s = travel of oleo, in.

The value 0.4 is in reality 0.4012, the conversion factor.

In Fig. 8, the load factor is plotted against sinking speed for oleos of various lengths of stroke. The importance of the long stroke is at once obvious. Taking a sinking speed of 8 m.p.h., a 3 in. oleo travel will give a load factor of 8.5, while the factor is only 4.3 for a 6-in. travel and 2.2 for a 12-in. travel. The travel of our present-day oleos is between 4 and 8 in. If we could design our plane to have an actual sinking speed of 12 m.p.h. with an oleo travel of 12 in., the pilot could cut the switch and settle into the ground without leveling out and the load factor would be only 5, which is not prohibitive.

If the engine is running at part throttle, the drag of the propeller is eliminated, and if the landing is made at somewhat above the minimum landing speed (that is, a two-point landing at part throttle), the rapid increase in wing drag is also eliminated and we approach the theoretical sinking speeds shown in Fig. 7. Thus it is perfectly possible with present-day aircraft to land without levelling out, as has been repeatedly demonstrated by students, without damage to themselves or to the plane. The load factor in these cases must be below 4, and the sinking speed between 6 and 8 m.p.h.

No discussion of landing speed is complete without mention of the usual auxiliary devices for reducing the landing speed, namely, flaps and slots. This is a very controversial subject and we shall only touch upon it lightly. We must again recognize that the flight test is the only reliable test, and that the wind tunnel is open to error in high-lift tests because of scale and turbulence effects.

The original Fairchild monoplane of 1926 was equipped with flaps. This machine is still in commission. A reduction in landing speed of 3 to 4 m.p.h. was actually obtained. In spite of this, it is our constant experience that the pilots prefer to land at the higher speed rather than operate the very simple flap control, even after considerable experience in using it. More recently, a standard Fairchild FC-2 was fitted with an auxiliary leading edge along the entire span, closely resembling the well-known Handley Page slot. The landing speed was reduced about 5 m.p.h., corresponding to an increase in area or in lift coefficient of 17.5 per cent. In this installation, difficulty was experienced in adjusting the leading edge so that the ship was neither wing-heavy nor inclined to yaw.

The most successful slot installations are not intended to decrease the landing speed, but to increase the lateral stability in a stall, in which they are undeniably effective. Such installations are found in the DH "Moth" and the Avro "Avian." We must not expect these machines to land appreciably slower. No amount of wing slots or flaps will decrease the vertical velocity or sinking speed. On the contrary, they are apt to increase it, since they increase the parasite drag and decrease the L/D. The best way to get low landing speed is to have low wing loading. No matter how effective the auxiliary devices may be, they are open to the distrust of most pilots and all maintenance men who see in them just one more "gadget" to get out of order. To solve the problem of the easy landing airplane, as with every other problem, we must not only recognize the facts which are known, but we must form a very clear idea as to the extent of our ignorance.

Discussion

HARLAN D. FOWLER.[2] The desire for low landing speed is always with us because of its safety element. Its limitation is gradually being deliberately evaded in the necessity of obtaining increased high speed due to commercial demands. That this is not conducive to the ideal condition is of course recognized by those who are bringing about higher landing speed.

It is an economic necessity to provide some reasonable wing device that is mechanically simple enough in principle to warrant its adaptation to everyday service requirements. We are advocates of the variable area wing, demonstrations of which have given very promising results. It is quite obvious that high landing speed brings with it higher sinking speed. It can be shown that with the variable area wing the sinking speed may be appreciably reduced from that of a high landing speed plane.

We will say, however, that for the same landing speed the extended wing will have a little higher sinking speed. The following table may be of interest in this respect. The actual sinking speed is taken as three times the calculated V_s.

Type	Actual V_s	Landing speed	High speed	Wing area	Span load, lb.
Conventional biplane	15.5	46.2	89.3	338	55
Normal monoplane..	25.2	58.2	98.8	136	66
Extended area.....	20.0	44.5	78.8	166	66

It is noted that for one-half the wing area a lower landing speed for the extended wing is obtained than for the biplane, with an increase in sinking speed of 4.5 m.p.h. Also that the normal plane had its landing speed decreased about 14 m.p.h. by using the extended area and also a decrease in sinking speed of 5 m.p.h. These figures are based on full flight data. An OX-6 engine was used.

It should be noted that the Fowler variable area wing has the decided advantage in that it can be set for any desired position, whether for best climb, high speed, or landing, and it will stay there without distracting the pilot's attention. Also

[2] Chief Engineer, Miller Corporation, New Brunswick, N. J.

that it cannot become misaligned or cause unequal controlling forces because of its positive means of sliding location.

The value of the variable area wing should be considered in the light of preference, whether to continue to go to still higher and more dangerous landing speeds or to accept the comparatively simple mechanical wing device and go back to where we do know what is best for us and still maintain the higher performances.

FIG. 9 FOWLER VARIABLE AERO WING

AUTHOR'S CLOSURE

Up to the present not one of the more experienced airplane manufacturers has been able to make use of a variable area wing, because of the complications in structure which this involves. It is extremely doubtful whether an airplane with a variable area wing could be sold to any operating company for the same reason. A variable area has the same drawbacks that are inherent in flaps and slots; namely an increase in the complication and maintenance features of the airplane, only with the variable area the case is somewhat more severe. At the present time the only means of obtaining low landing speed, which has proved successful in commercial operation, is a light wing loading, and it is yet to be shown that a light wing loading necessarily brings about a slow speed airplane.

Air Transport in New England

By SUMNER SEWALL,[1] BOSTON, MASS.

THE measure of usefulness of any vehicle of transport is its ability to deliver its load safely and speedily at a predetermined point. To perform this function today in New England with the conventional aeroplanes equipped with wheel landing gear is, with few exceptions, little short of complete folly. Few towns have seen their way clear to finance the construction of suitable airports, and there are still fewer natural landing fields in this beautiful scenic region.

There is another solution of the problem. If enough suitable landing fields for our present type aeroplanes cannot be constructed soon, airplanes should be built which will be suitable for landing on the surfaces which are already available. Efforts should be made immediately to develop and produce a satisfactory amphibian plane. This will extend in a large measure the advantages of air transport to every city of any size in New England, for almost without exception, these will be found to lie on bodies of water suitable in size and character to handle flying-boat operations safely. Not the boats of today, it is true, but those of tomorrow, for this type has demonstrated its capacity for greatly improved performance, under further scientific development.

Successful prosecution of this will open up the bays and harbors of the coastline, and the lakes and rivers of the interior. The tourist and sportsman can be transported to his favorite resorts, and the business man to his trade centers. The ski-pontoon combination if developed properly will land on the snow or ice if the surface of a body of water be frozen, and on the open water if it be thawed. A ski-wheel combination will land on either snow or bare ground as conditions may present themselves.

Such amphibian types have far greater value than is perhaps first realized. In addition to enlarging immediately the useful scope of the airplane many fold by increasing its landing availability, the amphibian also offers a far greater factor of flying safety than is possible in most types of conventional planes equipped with landing wheels. In this respect, it compares most favorably with that costly luxury know as the multi-motor plane in which machine at a tremendous cost in both capital investment and pay load, one is given reasonable assurance of staying up long enough to reach a suitable landing place, in case mechanical trouble develops. Isn't it better to have a plane constructed so that there is reasonable assurance of being able to effect a safe landing at almost any point along the route without need of elaborate airport facilities? At the present time, weather will force down a multi-motored ship as quickly as one powered with a single unit.

Another point, strongly in favor of the amphibian type, yet apparently entirely overlooked by the majority of operators, is its ability to cruise with the utmost safety at an extremely low altitude along rivers and waterways. It has often been strikingly demonstrated that passengers enjoy flying infinitely more at low altitudes than at high, as it is only when comparatively near the ground that one can appreciate the speed of flight, and view with interest the details of the country over which one is passing.

Furthermore, on days of low ceilings, it is not infrequent that a flying boat can, by flying close to the water, safely carry out a flight which would be extremely hazardous, if not impossible, to operate with a land plane. Thus, in this safe low-flying characteristic of the amphibian, there is both increased salability and improved regularity of service. Upon this latter point stands the basis of traffic.

During the last two years United States air-transport operators have been shown beyond shadow of doubt that Americans will fly. There is no country in the world where speed is at a greater premium than in the United States. Demand for aviation certainly exists. Great potential traffic awaits only suitable air-transport service. In New England at least, landing surfaces exist in generous abundance, but planes must be adapted to take advantage of them. This is a problem in design that is up to the engineer.

Discussion

B. A. POLLETT.[2] The basic reason for delay in the transporting of air mail is the weather. The figures of a year's operation of the Colonial show that 97 per cent of the uncompleted trips were uncompleted because of weather. Facilities for handling mail once it gets in the airport is very important, and perhaps for that reason it has not actually to do with the operation of the airplane itself. The airplane system is set up to operate in some 72 or 75 places, and it has attempted to coordinate with half a dozen different agencies which have been in existence for a period of time, and which find it difficult to change their methods. This refers primarily to railroad schedules, postoffice service, and the railway-mail service, which is another part of the postoffice department. The organization of the flying part of the air mail is gradually being coordinated with that of the various agencies, but when it is recalled that there are many places where adjustments have to be made in order to interlock with another, one can see where single letters or single pouches will be delayed, and will be transferred to the wrong train or to the wrong point.

An organization of that sort is allocated to different individuals who often are not very well informed. Things come up that they are not prepared for. A good example, and one which will more or less answer the question, is one that happens on the line with which the writer is connected. It takes mail from Boston to New York. Should the pilot fly as far as Stafford Springs, which is 15 miles this side of Hartford, and find a fog on top of the landing field, which happens time and again, the mail is taken back and discharged at an emergency field at Webster, ten miles from Worcester. From Webster it is taken to Worcester and supposedly transferred to the next train to go out.

The organization has not been formulated so as to take care of exigencies of that sort, and mail will arrive there and a number of men will look at the mail bag and wonder what is going to happen to it. They have little idea of the organization of the air-mail service, and they have only a general idea of what direction that mail has to go. That is gradually being eliminated, and one of the primary moves to eliminate that particular source of trouble is the reorganization of the postoffice department which makes the railway-mail service entirely responsible for the despatch of air mail between points.

REGINALD W. THOMAS.[3] The writer has flown seaplanes and

landplanes, and agrees with everything that Mr. Pollett has said about the feasibility of using amphibians. He states it is absolutely a job for the designer of new craft. After analyzing the best types of flying boats both in this country and in France, England, Germany, and Italy, it appears that there are only a few engineers in the world today who put all their time into developing flying boats or amphibian types of planes.

In this country Curtiss brought out the original flying boat, and every other design in this country has been influenced by Curtiss design. It happens that Curtiss' first boats were not of a graceful type to fly. They did not have especially good performance and did not give the pilots confidence. Practically every other boat in the United States, that has been built along that design, has had the same characteristics, which did not render them conducive to further development or use.

During the War Curtiss sold England many boats, and the English aeronautic press stated that if England had not seen a Curtiss boat, it would be five years ahead of its wartime flying-boat program. By the time it was found that the Curtiss boat was not what was wanted, they were actually five years behind, in developing a satisfactory machine.

There are four or five companies in France that are building flying boats. Germany has one or two, the Dornier and the Rohrbach. In Italy there are the Savoia and the Macchi boats. There is no question that flying boats and amphibian-type planes are very desirable, and are going to eliminate many of the conditions which now hamper transportation. As Mr. Pollet says, it is a job for new engineering by naval architects instead of aeronautic engineers to start thinking of boats. They have built very satisfactory land planes. The designers are concentrated on the land-plane type, and as soon as somebody says they want a plane for water transportation they stick on a couple of pontoons. The pontoon flying machine works out fairly well but it will not do the job as well as a well-designed boat. It is a job for engineers to get busy and build them from the bottom. French flying boats fly gracefully and easily, and they are just as easy to handle as any good-flying land plane. If flying boats are mentioned to nine-tenths of the pilots, they will say they do not fly well, that they do not like them. That is too bad, because there are a lot of boys who think a boat will not fly well and gracefully, and naturally that has been one reason boats have not been developed further.

Author's Closure

One discusser wished to know if it is practicable to use amphibian planes to reach inland cities on bodies of water. It is entirely practicable and has been done and is being done. Probably the only reason that amphibian planes have not been developed more is because their design at the present time has not been brought to the point where certain basic defects have been overcome.

The amphibian plane in order to be practicable for landing on water has to combine the quality of a boat and that of an airplane. They are heavy, they have considerable air resistance, and they require more power to get certain speeds. All of those things will have to be overcome. The design of them will have to be refined before the amphibian can be used practically by commercial operators. I think a good example of that is the Loening amphibian which is not commercially a good ship. It is reliable and well built, but it uses too much of its potential speed, its potential maneuverability, and of its potential dead load capacity in its design. That is the one impracticable feature of the amphibian, and is probably the reason it is not being used more generally by commercial operators.

The amphibian, combines the quality of the boat with an arrangement of wheels, retractable, or whatever arrangement there may be, which makes it possible to land at an airport or any place where an airplane can land. It can with practicability fly to any inland city and land provided the inland city is alongside a body of water.

AER-51-16

Ball and Roller Bearings in Aircraft

By FREDERICK W. MESINGER,[1] NEW YORK, N. Y.

MECHANICAL equipment of modern aircraft can be listed in a general way as engines, starters, magnetos, superchargers, instruments, generators, radio equipment, gearing and controls. This list does not, of course, include special equipment for aircraft designed for the Army and Navy. Bearings finding favor in aircraft construction include the straight cylindrical roller bearing, the orthodox rigid radial ball bearing, and the open-type ball bearing. These three types practically cover all the requirements of the makers of the mechanical equipment. Each of these bearings has a definite part to play.

The straight cylindrical roller bearing is selected where heavy radial loads are imposed and where definite space limitations control the size of the bearings. Radial ball bearings of the closed-race type are used where ordinary radial loads and thrust loads are encountered, while the open type is used in applications where advantage can be taken of the easy assembly feature of this type of bearings and its high degree of precision.

It is not possible to discuss every anti-friction bearing application that exists in the completely equipped airplane. It is, however, possible to examine the more interesting mountings that have been definitely adopted.

Engines

The Wright "Whirlwind" J-5 engine is the result of many years of development and research and is designed with equal thought to reliability and efficiency. The crankshaft is suspended on three bearings, two of which are of the straight roller type and the other a single-row radial ball bearing. The function of these bearings is very definite. The two roller bearings carry the main crankshaft radial loads. These loads are necessarily heavy and the bearings are subjected to considerable shock, since these two bearings must withstand the loads created by the power impulses in nine cylinders firing in rapid succession. At 1800 r.p.m., these bearings are subjected to 8100 load impulses per minute. All thrust load in the engine and created by the propeller is taken by the ball bearing. The propeller thrust, obviously, is considerable, but well within the capacity of the bearing selected. It has rarely been found necessary to replace these bearings during the life of the engine. Apart from their ability to handle the loads encountered, these bearings, because of their low weight per pound of load-carrying capacity and their small proportions, are highly desirable as keeping the weight per horsepower of this type of engine at such a low figure. The narrowness of these bearings has a direct effect on the overall dimensions of the engine and in reducing the amount of metal in the housing.

The Pratt & Whitney "Wasp" engine develops 425 hp. and together with its larger model the "Hornet" is finding much favor with the services as well as commercial organizations having use for such a large engine. The crankshaft bearing arrangement is virtually the same as that of the "Whirlwind" engine. There are some eight or ten distinct makes of radial engines available here and in Europe, all of which make use of this construction. The most interesting feature of this engine, from the viewpoint of the study of anti-friction bearing applications, is that of the built-in supercharger. This gear-driven unit, employing the General Electric type of impeller, operates at 22,000 r.p.m. at full throttle. Both the gearing and the impeller shaft are mounted on anti-friction bearings with the roller bearing receiving the assignment at the point of heaviest radial load, and the ball bearing doing the anchoring and absorbing of the thrust. A well-made and well-designed roller bearing, of the straight cylindrical type, can be operated at very high speeds equally as well as high-grade ball bearings. One of these engines has a log of over 800 hours. On the basis of average operation at three-quarter throttle, the supercharger impeller bearings have revolved over 400,000,000 times. Owing to the difficulty of lubrication and the angular application of the load, it has been found practical to use ball bearings in the rocker arms. Ball bearings are also used on the starter shaft and gun-fire control drive.

The Fairchild-Caminez four-cylindered unit has the camshaft assembly mounted on ball and roller bearings. The cam actuates the pistons by means of a cam roller built into the piston. This cam roller rotates on roller bearings built up to special dimensions to conform to the space limitations. The side links that control the proper relationship of the piston in the cylinders that are not transmitting power are also fitted with roller bearings. These again are special, due to the space limitations.

On the crankshaft assembly of the D-12 Curtiss V-type water-cooled engine, only one ball bearing is used. This bearing is incorporated to take care of the propeller thrust. The main bearings in this engine are still of the sleeve type, as the application of anti-friction bearings to multiple crankshafts presents a nice problem. It can, however, be accomplished either by means of a built-up crankshaft or by using a bearing with a large bore and introducing a split sleeve to make up this extra diameter. Ball bearings support the drives of the magnetos, distributors, cam, gun-fire control, generator, and water pump. Fifteen or sixteen radial ball bearings are used in this complete assembly. The simplified oiling system and the ability of these bearings to absorb the thrust created by the bevel gears have been the designer's justification for their use.

One engine that offers a particularly fitting application is the British Napier "Lion." This 12-cylindered engine is composed of three banks of four cylinders. Roller bearings have been applied to the main crankshaft. The means of accomplishing this is by supplying split sleeves to take care of the large bore necessary in threading over the crankshaft. It is often found in European practice that these bearings have been made somewhat special in order to simplify their housing construction. Contrary to American practice, the propeller thrust is taken on an orthodox thrust bearing, while roller bearings and ball bearings will be observed in practically all places where a bearing of any description is required. European aviation engines use anti-friction bearings extensively, and there are several instances where connecting rods are also equipped with ball bearings on the big ends.

Instruments

Under this heading, from an anti-friction point of view, can appear any instruments that have rotating elements, and possibly the most interesting is the Pioneer earth inducter compass.

[1] District Manager, Norma-Hoffman Bearings Corp. Assoc-Mem. A.S.M.E.

Presented at the Boston Regional Meeting of The American Society of Mechanical Engineers, Oct. 1 to 4, 1928.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

This instrument employs an anti-friction bearing at every point of rotation. The main shaft, which carries the armature, is suspended on three rigid-type ball bearings. In addition to this the governor uses four small ball bearings on the gimbles. Dealing with such minute currents, it was found necessary that

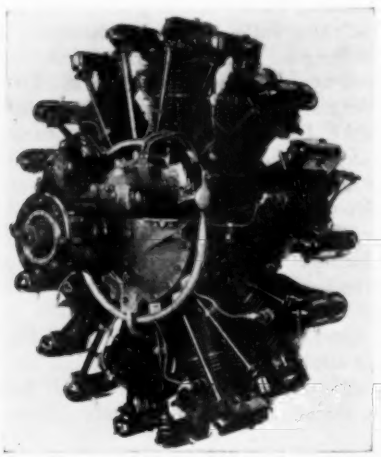

FIG. 1 WRIGHT "WHIRLWIND" J 5 AERO ENGINE

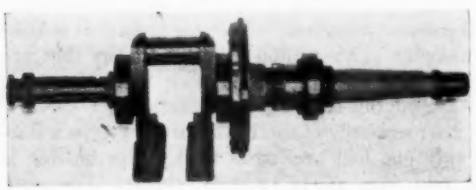

FIG. 2 CRANKSHAFT ASSEMBLY OF WRIGHT "WHIRLWIND" J 5 ENGINE

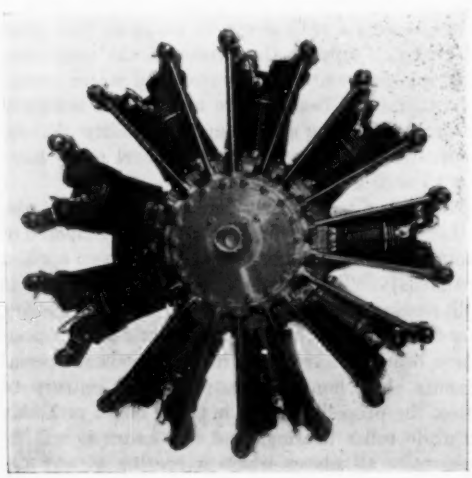

FIG. 3 WRIGHT "CYCLONE" AERO ENGINE

constant friction should be maintained in varying temperatures and with varying speeds. With this and the simplified lubrication required by these bearings, the use of anti-friction bearings was found to be a necessity.

Another instrument equipped with anti-friction bearings is the air-distance recorder. This instrument records the air distance by registering the number of rotations of the small propeller in the head. A fixed constant must be designed into the recording mechanism based on a uniform coefficient of friction for the bearings. Should this friction vary, the speed of rotation of the propeller for given velocity through the air would vary and cause the reading to be inaccurate. With varying temperatures, due to low and high altitude flying, any bearing depending upon an oil film, the consistency of which would undoubtedly change with the temperature variation, would not be able to maintain a coefficient of friction sufficiently constant to permit this instrument to return an accurate reading. Modern tachometers, to conform with Navy specifications, must now be fitted throughout with ball bearings. There is little doubt that commercial units will follow this specification also.

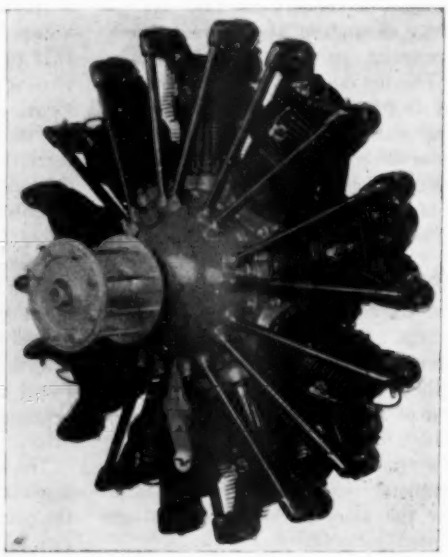

FIG. 4 PRATT & WHITNEY "WASP" AERO ENGINE

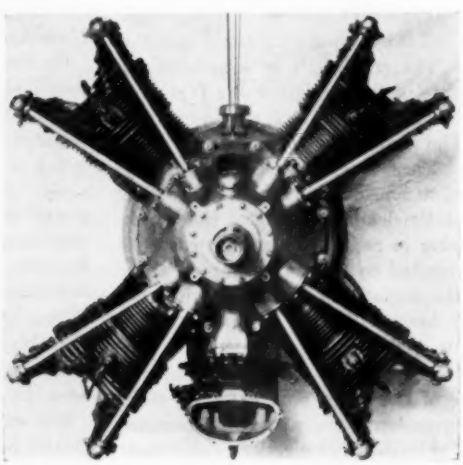

FIG. 5 FAIRCHILD-CAMINEZ AERO ENGINE

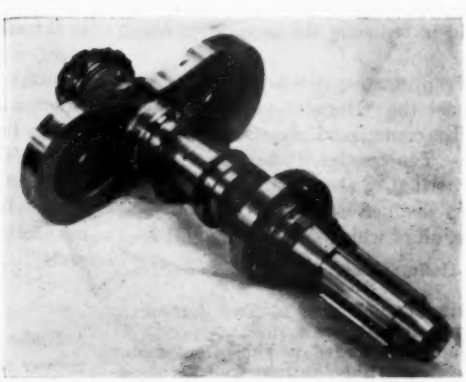

FIG. 6 CAMSHAFT OF FAIRCHILD-CAMINEZ ENGINE

STARTERS

There are not many makes of airplane engine starters on the market, but of those that are, undoubtedly the Eclipse starter is best known and more generally used. This starter is practically completely equipped with anti-friction bearings. The compactness of this unit is the direct result of use of anti-friction bearings. Due to the impracticability of fitting an airplane engine with a ring gear such as is used in automobile engines, the airplane starter is faced with the difficult problem of transmitting sufficient torque directly to the crankshaft. To do this a small flywheel is rotated at high speed to store energy later transmitted to the crankshaft through a clutch. The gear ratio from hand crank to fly wheel is 150 to 1, giving a flywheel speed of from 12,000 to 16,000 r.p.m. depending on the operator. Enormous pressures are exerted on the gears

and bearings, and with the simplified lubrication arrangement it is found that ball and roller bearings meet all requirements. This is a really severe service application.

Magnetos

While the magnetos on aircraft engines differ only very slightly from the familiar designs of the automobile type, they are nevertheless a very interesting application, since absolute reliability must be obtained. The rotating element must maintain a minute and uniform air gap between itself and the magnets, consequently every effort is put forward to obtain rotation with a minimum of eccentricity. It is for this reason, together with simplified lubrication at high speed, that the open-type ball bearing is selected for this service. The open-type bearing also lends itself admirably to ease of assembly. The Scintilla magneto uses this type of bearing. The distributor is also mounted on open-type bearings. A distinct development directed at the aircraft engine is the dual magneto. The saving of weight in this case, both in the magneto itself and the mount, will undoubtedly make this type very popular with makers of multicylindered aircraft engines. Ball bearings are generously used in this design.

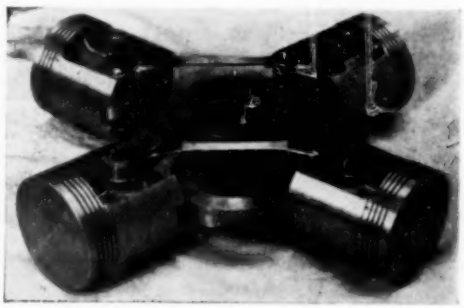

Fig. 7 Fairchild-Caminez Piston and Link Assembly

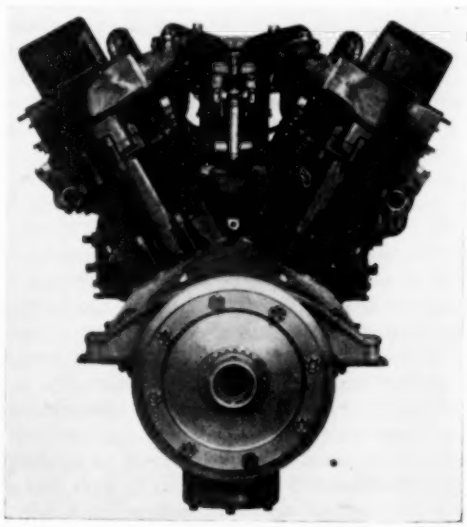

Fig. 8 End View of Curtiss D 12 Engine

Superchargers

Superchargers are becoming essential elements to the well-designed aircraft engine installation to such an extent that manufacturers are building them directly into the engine. This has already been mentioned in the cases of Wright "Cyclone" and the Pratt & Whitney "Wasp" and "Hornet," to which might be added the Bristol "Jupiter," the Curtiss "Chieftain," and many others. There are still a large number of engines that employ a supercharger that is attached. Of these the high-speed impeller type such as is developed by the General Electric Company, the Wright field engineers and the Roots blower modifications as built by the Allison Engineering Company predominate. In all cases anti-friction bearings are used, while in some instances bearing speeds of 50,000 r.p.m. are maintained.

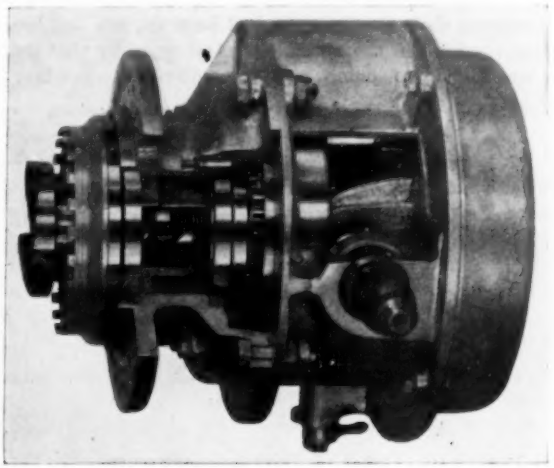

Fig. 10 Eclipse Inertia Starter

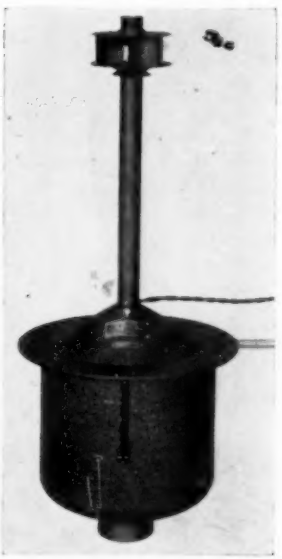

Fig. 9 Pioneer Earth Inductor Compass

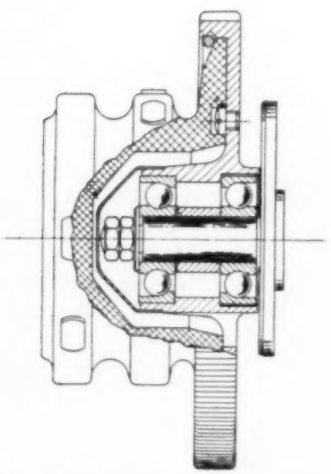

Fig. 11 Distributor Gear Assembly on Scintilla Aero Magneto

Generators

There is not much to be said under this heading, except that like the generators on automobiles, ball bearings are generally used. The service is more severe in the aircraft application, and therefore the design of the mechanical part of the electric generator must be somewhat more substantial.

Gearing

The geared engine in conjunction with three- and four-blade propellers has a definite position in the industry. These gear

reductions are sometimes built in and sometimes attached. In both forms ball and roller bearings are extensively used. The built in gearing of the Napier "Lion" engine has already been referred to. This application, as in most gear reductions for aircraft, is of the orthodox type employing spur gears.

There are still a number of applications that merit mention but which are more or less isolated. Wind-driven radio generators suspend their armatures on ball bearings, and ball bearings are incorporated in the variable-pitched propeller that governs the speed. Gyro bomb sights, bomb-release handles, fuel pumps, etc., depend upon ball bearings for proper functioning.

Ball bearings are being used extensively on the Ford ships. They are used in the hinges of the ailerons, the elevator fins, and the rudder. Throttle control for the outboard engines on these multiengined ships is obtained through a series of levers and cranks. In order to preserve the essential sensitiveness, ball bearings are used in all cranks. Other plane builders have designed ball bearings into vital control positions, and there seems little doubt that as airplanes grow larger this practice will increase.

Commercial Aircraft Engines of Medium Power

By RICHARD M. MOCK,[1] NEW CASTLE, DEL.

AMERICAN commercial airplanes were not produced in any considerable quantity until approximately 1925, when the OX-5 engines were selling at about $300 each. Naturally a power plant on the market at this price discouraged the development and manufacture of any new engines solely for commercial purposes. Commercial airplanes, rather than being built for a definite purpose, were being designed as a general type around this engine; hence, the great similarity in designs. This condition continued for some time, with the price of the OX-5 slowly rising and the supply diminishing. Toward the end of 1926 or early in 1927, manufacturers of airplanes began to sense that soon the supply of these engines would be exhausted; the price was then about $500. At this time a few modern engines were under development to replace the OX-5, but all were still far from the production stage. By the end of 1927, the OX-5 was no longer so cheap an engine that it could be discarded rather than go to the expense of overhaul, as had been the case in the past. In fact, aircraft engines of this size were so scarce that many airplane manufacturers found themselves with a number of completed planes in their factories but without engines. Desperately they began to look about for available engines, and many used and overhauled OX-5's were installed in new production airplanes. Other types that had been produced in smaller quantities during the war were used more and more to overcome the scarcity.

It was not long before airplane manufacturers began to raise their prices or sell their planes without engines, leaving it to the purchaser to supply his own power plant; of course, to be installed at the airplane factory. This situation brought a number of European engines to this country. In Germany, after the war, military machines were destroyed and it was some time before she was allowed to build powered airplanes. However, after the ban was lifted, Germany began production of airplane engines, and it was not long before they were being exported to this country. When the shortage of Curtiss OX-5 engines was first felt, a number of companies were formed or expanded for the importation of aircraft engines.

During this shortage of medium-powered engines, American manufacturers were not idle and many new designs were nearing the production stage. In the past year a number of new engines have appeared on the market, approximately a dozen. Many of these new engines are the result of considerable experiment, while a few were produced by organizations which seemingly had little use for or no intention of producing aircraft engines a year or a year and a half ago. In spite of this fact, it seems that most of the new engines are performing creditably.

It is quite generally accepted that the proper engine for a medium-powered plane shall be air cooled. As to the horsepower desirable, much depends upon the skill of the airplane designer. It appears that an engine of from 60 to 200 hp. should be sufficient for a plane carrying two to four people with a reasonable amount of luggage and gasoline. In order not to have the power loading too high and to have a reasonable amount of reserve power, the rated horsepower might be anywhere between these figures, depending upon the gross weight and the efficiency of the airplane. Because of the lack of power plants of intermediate power, there has been a tendency in the past to design airplanes that are underpowered.

On the other hand, some more conservative designers, also lacking a power plant of intermediate power, have installed engines in their planes developing power greatly in excess of that required. The idea is to use the engine at part throttle and thus prolong its life as well as to have a reserve of power for use in an emergency such as taking off from a small field.

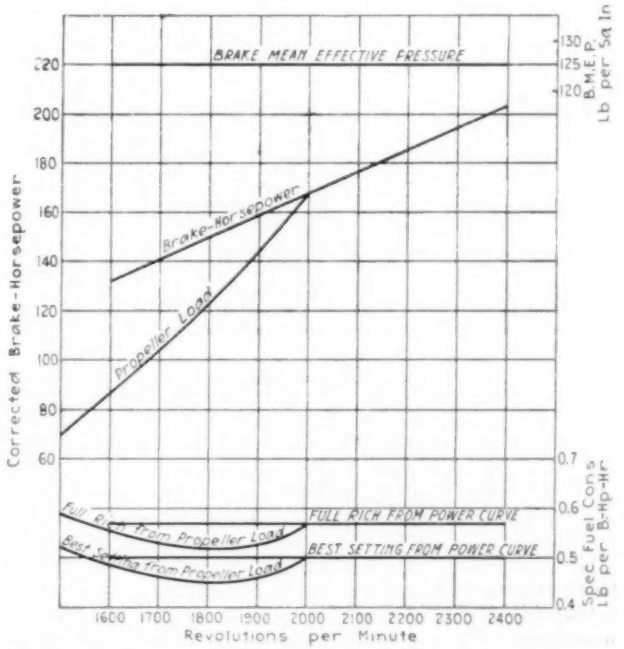

FIG. 1 ESTIMATED POWER AND FUEL CONSUMPTION OF WRIGHT MODEL R-540, FIVE-CYLINDER AIRCRAFT ENGINE. BORE 5 IN., STROKE 5½ IN., COMPRESSION RATIO 5.2 TO 1, ROTARY INDUCTION, AVIATION GASOLINE

It seems that the solution to the problem lies in having a variety of engine sizes available. These engines should have interchangeable mounting to facilitate installation in various types of planes without any changes in the primary structure of the airplane. Of course, this pertains only to engines with the same cylinder arrangement. Today, though many of the commercially available engines are similar in design, there are hardly two that have the same mounting-bolt dimensions.

There has been much discussion as to the best disposition of cylinders for a medium-powered, air-cooled engine. Of the engines now commercially available, there is a remarkable similarity in their design. The majority are air-cooled radials of the general type, construction, and arrangement of accessories of the Wright Whirlwind J5 except that, unlike the Whirlwind, the magnetos are behind the cylinders. Most of these engines, though using the best quality materials, are of somewhat cheaper construction, employing cast-iron cylinders, etc.

The question of cylinder arrangement is a subject in itself and becomes too involved for a complete discussion here. However, a few of the salient points of each of the various types will be mentioned. The single-bank radial engine has the advantage of even cylinder cooling and light weight, versus the disadvantage of a large frontal area, resulting in increased air resistance, poor vision, and valves actuated by push rods limiting the crankshaft speed. The two-bank, air-cooled radial with every odd cylinder slightly to the rear and having a two-throw crankshaft is very similar to the single-bank radial except that its overall length is slightly greater and that it is slightly heavier. It has an even number of cylinders, while the single-row radial must have an odd number. In a medium-powered radial engine an odd number of cylinders might not give proper mixture distribution and high enough mean effective pressure without a rotary induction system and it might therefore be necessary to reduce the number of cylinders. To develop the desired power, this might not be possible without having too few cylinders, which would result in a large bore and not allow sufficient cooling or result in an uneven-running engine. Hence it is often necessary in a radial to shift from a single bank to a double bank to obtain the required number of cylinders.

The "air cooled in line," which is usually of four cylinders, has the advantage of allowing an overhead camshaft and reduction of frontal area. There are now on the market a few

60–80 hp. Cirrus, four-cylinder-in-line air-cooled type. The cylinder arrangement, though causing an engine of slightly heavier weight than that of the radial type, has comparatively little head resistance and should therefore prove quite successful. It is understood that Louis Chevrolet also has a six-cylinder engine of this type under development in Baltimore, Md.

Another type that has been neglected, though it is believed to have possibilities as a commercial type, is the inverted one, air cooled in line with the crankshaft and with the crankcase above the cylinders. By inverting the engine, the propeller-thrust line is raised, allowing one to design the airplane structure close to the ground, avoiding a high landing gear. It also permits the thrust line to be closer to the wing on a monoplane. This is a subject that has brought much comment of late. In addition the cowling, from the point of view of appearance and cost, is cheaper and better as the crankcase itself can be of streamline shape with no covering. Other cylinder arrangements such as the air-cooled Vee and the "Hex" type are better adapted to large engines and have not yet been used for engines of medium power.

Though there is some tendency to use reduction gears on large engines, it is doubtful if the increased efficiency due to the slow propeller speed is worth the increased weight on an engine of medium size. However, the question of propeller and crankshaft speed is a vital one, and though more power may be developed for a given weight by increasing the crankshaft speed it has been estimated that an increase above 1800 r.p.m. for an airplane with a top speed of 120 m.p.h. is inefficient. In the design of these engines, a subject which until recently has been neglected is the arrangement for the exhaust manifolding. It appears that the tendency on many new radial engines is to have the exhaust port in front of the cylinder and to employ an exhaust collector ring which conforms with the streamline of the airplane. Another feature which deserves attention is the silencing of the exhaust. The British Cirrus engine is usually provided with an exceptionally long exhaust manifold over half the length of the airplane; this reduces the noise considerably. A muffled engine is a great factor in selling an engine or plane, as a quiet, smooth-running engine always creates a better impression, especially to the layman or the partly initiated buyer who is very apt to be the purchaser of a plane of this size.

There are now in this country in production about ten makes of medium-powered engines with another five in the experimental stage, but so far along that orders are being placed and promises made for delivery. In addition, there are between five and ten new engines which are undergoing tests either on the ground or in the air prior to being prepared for production. Though there are a number of commercial engines available, only five new production engines of this size have been approved by the Aeronautics Branch of the U. S. Department of Commerce at this time. These five are: (1) Fairchild-Caminez, 120 hp. at 960 r.p.m.; (2) Warner, 110 hp. at 1850 r.p.m.; (3) Kinner, 75 hp. at 1725 r.p.m.; (4) Velie, 45 hp. at 1750 r.p.m., and (5) Curtiss Challenger, 170 hp. at 1800 r.p.m. A sixth engine, the Curtiss Conqueror, is the only other engine to be approved by the Department of Commerce for use in licensed airplanes. In addition, there are the engines which have been approved

by either the Army or Navy and which are then automatically accepted by the Department of Commerce. Practically all of the war surplus engines come under this heading. It is understood that a number of new production engines are now undergoing tests and will be approved shortly.

The problem of choosing a power plant, with so many new and only partially proved engines on the market, is an exceedingly difficult one. The aircraft manufacturer does not want to do the test work for the engine he is buying nor does he want to sell

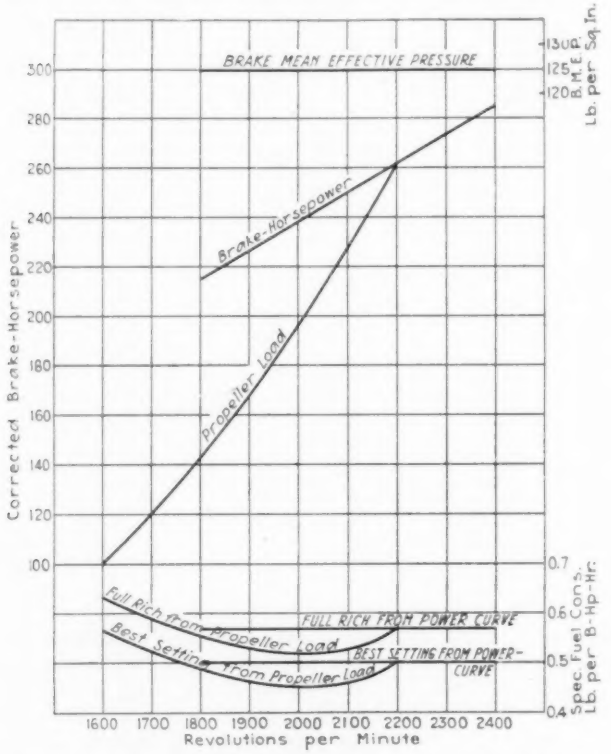

FIG. 2 ESTIMATED POWER AND FUEL CONSUMPTION OF WRIGHT WHIRLWIND MODEL R-760, SEVEN-CYLINDER AIRCRAFT ENGINE. BORE 5 IN., STROKE 5½ IN., COMPRESSION RATIO 5.2 TO 1, AVIATION GASOLINE

an airplane with an unknown engine. If he is assured that the engine functions properly, there is the additional problem of maintenance and cost of installation and assembly. In an effort to gain simplicity and low price, it is feared that a number of engine manufacturers will reduce their standards; that is apt to prove disastrous. Another important point is the availability of the product. Is the engine manufacturer properly financed and has he facilities to meet the production requirements of the airplane manufacturer without sacrificing the quality of his product? If the engine is available and is satisfactory mechanically and the airplane manufacturer decides to use it as standard equipment, he

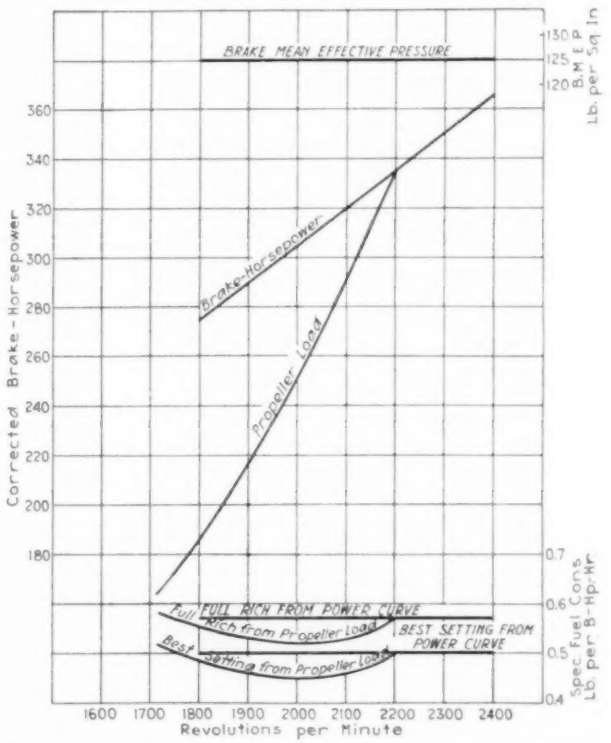

FIG. 3 ESTIMATED POWER AND FUEL CONSUMPTION OF WRIGHT WHIRLWIND MODEL R-975, NINE-CYLINDER AIRCRAFT ENGINE. BORE 5 IN., STROKE 5½ IN., COMPRESSION RATIO 5.2 TO 1, AVIATION GASOLINE

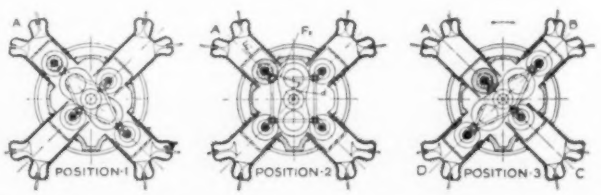

FIG. 4 DIAGRAM SHOWING CAM MECHANISM IN THREE POSITIONS DURING ONE PISTON STROKE OF FAIRCHILD-CAMINEZ ENGINE

must sell the engines as well as the airplane. For this reason, the question of interchangeable power plants is again stressed. A purchaser may then choose his own power plant and with little or no extra cost have it installed in a new plane.

AER-51-18

Aerial Photography Engineering

By E. R. POLLEY,[1] NEW YORK, N. Y.

Aerial photographic surveying is described, and its advantages over ground work are given. Maps may be made with almost perfect detail and at far less cost of time and money than required by survey work in the usual manner. The methods by which the many overlapping photos are taken and then assembled in the scale map are outlined, together with the supplying of stereoscopic photos for studying the contour and physical features of the terrain. Maps made from the air have a value to municipalities in zoning and taxation problems and to counties and states for highway and park and reforestation and waste-land activities.

THE subject of aeronautical engineering is of prime importance to every branch of engineering because of the influence which it exerts in the entire engineering world. Aerial engineering, aside from its extreme practicability, is injecting the factors of glamor and adventure into this field of endeavor. Aerial photographic surveying is comparatively new, and people are unfamiliar with this work and with its engineering position in this inventive age.

Of all the great steps in engineering one of the greatest was the development of the lens, with its resultant precision instruments, and in this field the last and greatest stride of all was the coupling of the airplane and the aerial camera. No longer does the engineer have to hew his way through canebrake and scrub nor wade through swamp and morass, but the modern surveyor takes unto himself wings and from a vantage point two to three miles in the air he maps portions of the earth's terrain accurately to scale, with almost perfect detail and at a great saving in both cost and time.

Method of Making the Aerial Photographic Map

The camera is installed in the plane with the lens pointing down through a hole in the fuselage. The elevation at which the plane must be flown is determined; for instance, if the area in question is to be mapped at a scale of 800 ft. to the inch and a lens of 20 in. focal length is used, multiplication of the two factors gives the altitude of 16,000 ft. which the plane must maintain.

The pilot outlines upon United States Geological Survey sheets the area to be covered and also denotes the guide or flight lines. From this marked map the "job is flown." The pilot flies along the guide or flight lines, back and forth, forming "strips," until the required area has been covered. The photographic film covered by each exposure is $7^1/_2 \times 9^1/_2$ in., the larger dimension forming the width of each strip. However, the net effective area of one exposure is about one-fifth of the total area, because of the overlap. The photographer times the consecutive exposures so that they overlap each other like shingles by about 60 per cent, and the pilot plots his flight lines so that the strips overlap each other by about 50 per cent.

Thus each object on the terrain is photographed five times. The overlap makes it possible to use only the center portion of each photograph, which alone is in true vertical projection. Discarding the edges of the photographs in making the map also avoids a certain amount of displacement of elevated ground objects due to conical projection caused by the diverging lens' rays. The overlap, moreover, allows stereoscopic study of the terrain, which adds the third dimension to any portion of the ground covered. With the completion of the photography the air work is done, and the films after development go to the engineering and mapping departments.

The layman usually is astonished when told that aerial maps are photographed from such altitudes as 16,000 and 20,000 feet, yet in a recent test an Army pilot and photographer took on one exposure 19 square miles of the city of Dayton, Ohio, from an altitude of 32,000 ft. This six-mile airplane climb put the photographer 3000 ft. higher than the top of Mt. Everest and brought him into a temperature of 60 deg. below zero.

The aerial photographic map is assembled as a mosaic by first plotting as a control map the existing survey data upon a suitable composition board and then superimposing upon this control the selected portions of the aerial photographs after they have been corrected to scale, now called ratio prints. This master map is then rephotographed in large sections. For study of an area enlargements are made, and a negative at, say, 800 ft. to the inch, can be enlarged to 200 ft. to the inch without appreciable loss of definition.

The practical application of this type of survey is typified by a recent instance. A few months ago one of the executives of the New England Telephone and Telegraph Company was impressed by a phrase in a scientific magazine which read: "In this modern period every executive is in duty bound to ask himself what is obsolete and what is more efficient." At the time he was engrossed in solving the problem of a potential telephone line. Knowing that in surveying a right-of-way it is impossible to secure too much detailed information, and with the quoted phrase in mind, a contract was given through his engineering department to have this right-of-way surveyed photographically from the air.

Briefly, the record is as follows: On November 17, 1928, the New England Telephone and Telegraph Company placed the order with Fairchild Aerial Surveys to map their telephone right-of-way area of about 26 square miles. On December 7 the Fairchild monoplane equipped with aerial camera climbed to an elevation of 9600 ft. and began the survey. As soon as the plane arrived over the eastern boundary of the area the photographer turned a switch which set the automatically controlled camera in action.

As soon as the aerial survey was completed the pilot and photographer descended from their chilly elevation, with a temperature of 17 deg. below zero, and rushed the film to the Fairchild photographic laboratory, where it was developed and printed. The photographs were delivered on December 17.

Closely following the delivery of the contact prints there was made a mosaic map which shows the entire area as a continuous photograph to the scale of 400 ft. to the inch, also a set of enlargements for field work, and a stereoscopic study to the control scale.

Thus from a height of nearly two miles in the air, this winged surveyor, invisible from the ground, used the modern instruments of his craft to secure an accurately scaled map of this right-of-way which enabled the company engineers to view each house, tree, road, and stream exactly as it is and with complete photographic detail.

There were no weary miles of walking and of carrying weighty ground instruments, no tedious sighting and compilation of field notes, no entrance of the human equation with its possibilities of forgotten chain lengths and mistaken bench marks and

---

[1] Fairchild Aerial Surveys, Inc.

Presented at the Third National Meeting of the A.S.M.E. Aeronautic Division, St. Louis, Mo., May 27 to 30, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

errors of computation, no protracted drafting of maps over a long period of time. The following points are so obvious that they lend their own emphasis:

First, instead of a period of months, only ten days elapsed from the time the first datum was secured to the delivery of the contact prints.

Second, the cost was less than one-fifth that which would have been incurred by an equivalent ground survey.

Third, instead of a line-drawn map embracing a maximum detail of, say, 20 per cent, as would have been the case in ground survey, the aerial map gives 100 per cent detail showing every object on the terrain exactly as it exists.

Fourth, it is a well-known fact that a line-drawn map is not always easy of interpretation even by the engineers, and to the layman it is a sealed book, whereas the aerial photographic map is readily interpreted by the non-technical executive.

Fifth, aside from the engineering value of the map itself, any two overlapping prints can be placed under the Fairchild mirror stereoscope and the relief of terrain be observed. Thus the company engineers can view the area with the hills and valleys showing in the third dimension, without the necessity of visiting the locality.

This new branch of engineering calls for the highest type of trained personnel. For instance, the Fairchild Company, which has mapped over 80,000 square miles by this method, has found that out of every one hundred trained commercial pilots only four are good mapping pilots, possessing that coordination of mind and muscle which enables them to maintain altitude, to fly the ship steady under all conditions, to orient themselves as to locality, and to follow imaginary flight lines on the ground below from an elevation of some two to three miles in the air.

It is believed that from this simply told story there may be envisioned the romance and adventure which are concealed within the telling—the cold of the upper-air strata; the carefully trained men, who are able to orient themselves as do the eagles from their station in the sky; the age-old battle of human progress in devising these perfected instruments of airplane and camera; the working of modern chemistry in the photographic darkroom; and the spirit of adventure which prompts both pilot and photographers—young men who no longer fight the hazards of new frontiers and boundaries, but who eliminate frontiers by facing and defeating the hazards of the air.

Briefly there may be outlined the practical application of aerial survey to the problems of municipal, county, and state engineers.

Tax Equalization

The president of a prominent appraisal company recently published the following statement:

"The first municipality ever reappraised in which aerial photographic maps were used is, to the best of our knowledge, that of Middletown, Conn. Let us compare the old and the new method in the two cities of New Britain and Middletown in regard to time and cost of mapping: Old method in New Britain—Area, 13 square miles; time required to secure maps, 4 years; cost, $48,600. Aerial method in Middletown—Area, 42 square miles; time required to secure maps, 60 days; cost, $4000.

"At the end of fourteen months it was made public that 1896 pieces of city property had been discovered which were not previously on the tax list and which had never before paid taxes. Aerial mapping has proved its case, and at the end of the first year the city or township finds itself firmly inventoried, soundly financed, well equipped with maps, and in possession of complete data with which to enter the next logical step of zoning."

Incidentally, since the Middletown maps were made, the Fairchild Aerial Surveys have mapped 12⅓ per cent of the area of the State of Connecticut.

City Planning and Zoning

The aerial map is of most practical use in city planning and zoning. Owing to the full knowledge of local atmosphere and conditions held by the municipal executives, the 100 per cent photographic detail of the aerial map lends itself to perfect zoning by the local executives. By the use of transparent colors on maps, the zones are not only established, but even the non-technical citizen can read at a glance what lies within those zones and why changes are advocated.

Aerial mosaic maps greatly reduce zoning costs and also eliminate the major part of the battles which are the almost inevitable aftermath of city planning and zoning.

Public Utilities

Men in public service companies find aerial maps of great value. F. A. Allner, general superintendent of the Pennsylvania Water and Power Company, referring to a 140-mile power-transmission-line route, writes as follows:

"We estimate that about one-half the cost of survey has been saved by aerial mapping. No preliminary surveys were run in the field. The alignment was practically fixed in the office on the map. We believe the saving of the preliminary survey would not be possible were it not for the accurate alignment of the photographs."

Timber Survey

Enthusiastic reception of this type of map has been accorded in timber survey. It eliminates the guesswork of the old-time timber cruising. All of the timber area is covered. It shows burnt-over areas, rock outcroppings, blowdowns, swamps, and stranded logs above river-flood lines. Distinctly separated are scrub brush, second growth, and primitive timber. A sharp line of demarcation separates the coniferous and the deciduous trees, and groupings of kinds are easily recognized.

Hydraulics

Recently aerial survey has given material aid in the study of watersheds and reservoir sites. Studied with the aid of the stereoscope, the terrain shows in relief, and the aerial map gives immediate information as to slopes, feeders, and approximate flood lines. To secure this data by old methods would take months of effort.

State Uses

If entire states were mapped photographically from the air, from these maps the agricultural department could note the percentage of land under cultivation, could mark down the waste lands for reclamation, could check off the sour marsh lands for chemical reclamation, and could plan for maximum agricultural efficiency.

Transportation lines and spurs could be located from these maps for commercially opening up present dead areas. The state highway department would be able to more intelligently plan main arteries of travel.

State park departments would be able to locate unerringly the proper areas for parks and reservations. The department of forestry could read these aerial maps and locate fire-observation towers, mark off fire lanes, and intelligently apportion ranger patrols. The forester would be able to recognize denuded areas where acres of stumps and dry brook beds might be benefited by reforestation.

The hydraulic engineer could locate potential power sites and figure to a nicety the undeveloped power of his state.

Regional Planning

Where original suburban settlements have themselves grown into cities, crowding and hemming in the parent municipality, or where a number of cities are separated by only a few miles, under these conditions the aerial map reaches the apex of its efficiency.

Not one of these cities has a problem confined to itself. The problems are regional. If traffic lanes are developed or widened in one city, they must connect with similar thoroughfares in adjoining municipalities, or otherwise the traffic load will "bottleneck" and results will be negative.

Regional service must be established in the form of communal sewer and water systems, power and light distribution, major zoning ordinances, and traffic regulation. Broad actual view of the entire area must be secured before real data can be accumulated and efficacious methods advocated. Obviously the aerial mosaic map is the only solution, and it has nobly proved its worth. Numerous other possible uses of aerial maps are cropping out.

FIG. 1 VOUGHT O2U-2 AIRPLANE

Application of Advanced Methods to Airplane Structural Analyses

BY DR. MICHAEL WATTER,[1] LONG ISLAND CITY, N. Y.

This paper urges the necessity of wider use of finer methods of structural analysis. It illustrates the importance of use of advanced methods not only from standpoint of structural safety, but also as a means of evolving new forms.

It outlines briefly some results from the author's experience, and in connection with the desirability of finer methods urges closer coordination between aerodynamical facts and structural requirements.

Certain present requirements are criticized and a suggestion is made to revise the conception of load factors in their relation to individual members.

IF ECONOMY is a purpose in other branches of engineering, it is a necessity in aeronautics. The performance of any airplane is a function of its weight, and military and commercial airplanes alike must be built as light as possible in order to allow greater military load in the former and greater pay load in the latter. The efficiency of any structure hinges on its uniformity of strength, and because of the comparatively small factors of safety allowed in airplane structures it is imperative that the designer should know, with the precision afforded to him through the finest methods available at present, the nature and distribution of the working loads. This necessity is not based solely on the requirements of structural safety or economy, for it also aids powerfully in the evolution of new and more perfect forms which may be desired because of performance or service requirements. The complexity of airplane structures dictates the use of advanced methods of structural analyses in order that the nature and distribution of loads may be properly determined.

While in other branches of engineering the method of calculation would more strictly apply to the determination of stresses, in aeronautical engineering the problem is further complicated by the necessity for evaluating acting loads.

Structural analyses of the airplane are intimately related to an accurate knowledge of the aerodynamic and dynamic loads acting on the structure, and the title of this paper refers not only to advanced methods of purely structural analyses but also to more rigorous requirements coordinated with available aerodynamic data. Application of the Berry method, the least-work theorem, the Williot diagram, method of elastic weights, method of work, etc., may well be wasted if the engineer does not take into account the actual condition of loading or if, in dimensioning the sizes of members, he neglects the real meaning of the factor of safety.

The author will endeavor to show briefly and by means of illustrations of actual cases met in practice the importance of finer methods of calculation, the better coordination of aerodynamical facts and structural requirements, and also the problems which must be taken care of in assigning the proper factor of safety to the main structure, and details in actual design.

Referring only to the method of determining the loads in various members of the structure, it may be well to point out that even conventional structural arrangements may in the case of simplified analysis lead to results which are sometimes quite far from the truth, as finer analysis would readily show.

STATICALLY INDETERMINATE STRUCTURES

It is beyond the scope of the paper to discuss the relative merits of statically determinate or indeterminate structures.

---

[1] Design Engineer, Chance Vought Corporation.

Presented at the Third National Meeting of the A.S.M.E. Aeronautic, Division of the A.S.M.E., St. Louis, Mo., May 27 to 30, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

It is true that in statically determinate structures the loads in the different members can be determined readily with the aid of definite rules, and often without the necessity of simplifying assumptions. On the other hand, with our improved control and knowledge of properties of materials and fine workmanship in airplane construction, the behavior of a statically indeterminate structure can be very closely analyzed by available methods handled by an experienced engineer. It is also well to point out that ideal statically determinate structures are never met in practice, and that in a number of cases the service requirements are such that an engineer is forced to adopt more complicated arrangements.

It is always tempting to make a simplified assumption, but it will be found that finer analyses will give a much more accurate picture of the load distribution, and thus lead to a more economical design of structure.

The Single-Bay Cell

By way of illustration the author will cite the case of a normal-type single-bay biplane cell designed for use on the latest Vought two-seater fighter. In this machine both upper and lower wings are parallel, have no sweepback, and are arranged with a stagger of about 12.9 deg. The flying wires are not in the plane of the beams, but are slightly brought forward. The outboard strut is a conventional N-strut arrangement.

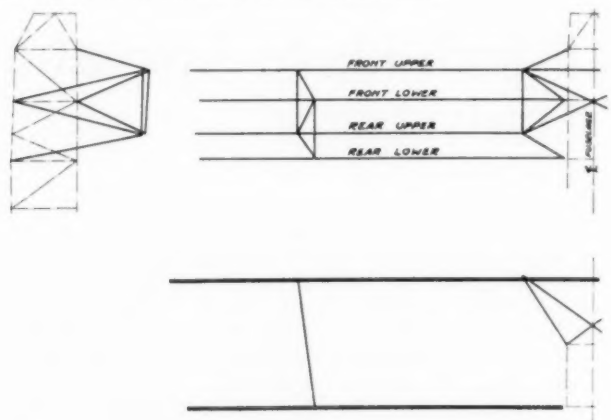

Fig. 2 Cell Arrangement

Fig. 2 gives the cell diagram. If an engineer had never made a least-work analysis of a similar cell, he would be tempted to make a few assumptions, with the intention of keeping reasonably on the safe side. Since the redundancy is caused by the N-strut, in view of the comparatively small stagger it would appear that in case of the high incidence condition the anti-drag components on the lower wing could be assumed as taken by the internal trussing of the wing, while the lift reactions could be resolved in the respective members of the N-brace. It would be safer to assume that the total air reaction (which, it should be remembered, includes the anti-drag) at the lower-wing-strut points is carried by the N-brace to the upper wing, but experience will prove that this assumption is fallacious.

The truss was solved on the basis of the first assumption, and the following loads were obtained:

Compression in the front beam = —17,620 lb.
Load in the front flying wires = +13,500 lb.

Since for design purposes it was necessary to analyze the structure as closely as possible, a least-work analysis was made, assuming as the redundant member the front strut of the N-brace, and the loads obtained were as follows:

Compression in the front beam = —12,516 lb.
Load in the front flying wires = +10,105 lb.

Similarly the loads in the upper anti-drag bracing proved to be considerably less than a simple analysis would seem to indicate. On the other hand, the loads in the rear flying wires and rear beam in case of a simplified analysis would be considerably underestimated. This is a very good illustration of how much it is possible to be in error as regards the magnitude of the loads in the structure if a finer method of analysis is not resorted to.

In connection with this the author would like to bring up a point in regard to present requirements in the case of statically indeterminate structures. These requirements specify that when allowance must be made for redundant members the loads shall first be computed for the statically determinate system obtained by neglecting the redundant members. The effect of the redundant members shall then be considered by the method of least work or by some other method, and the net loads obtained. In computing these net loads the effect of the redundant members shall be increased or decreased 25 per cent, whichever is the more conservative, in order to allow for play in joints, variation in cross-section, etc. It must be pointed out, however, that the loads obtained by means of a least-work analysis or other precise method will be the same irrespective of which members were assumed to be redundant, but widely different in the case of a simple analysis when different redundant members are assumed to be inactive. This leads to an uncertainty in deciding on the above-mentioned 25 per cent correction because, for instance, in the case illustrated above, the assumption that diagonal brace of the N-strut is redundant would lead to somewhat higher loads in the front beam and flying wires, and the design loads in consequence should be increased. It would be desirable to have this rule made more specific because in its present form it is somewhat ambiguous.

Beams

Since the purpose of the present paper is mainly to illustrate special cases and problems actually met in the author's experience, the design of beams and shallow trusses will not be discussed in detail, because besides classical treatises there are excellent papers available on the subject of combined axial and transverse loading and on the use of the methods of work, Williot diagrams, and of elastic weights in the design of trussed beams.

In practice it will be found that because of the comparative complexity of the latter problem there is a great deal more information available on stresses in individual parts of a trussed beam than on an ordinary webbed beam. This is of course partly due to the method of analysis necessary in case of trussed beams and partly because the webbed beam is usually proportioned by merely obtaining the maximum bending moment and the distance between the points of inflection. A word of warning may not be out of place that there may be a case in design of a webbed beam where the design section may not be at the point of maximum bending, but at the point of the next largest drag-load component.

If the engineer has available the true bending-moment diagram with a diagram of the axial loads drawn in their proper relation to the sections of the beam, he will be able to judge the condition and verify by calculation sections which appear to be more stressed than the section at the maximum bending moment.

In practice it will also be found that many times the shop has made small errors here and there which are not serious enough to warrant rejection of the beam and yet are such that the engineer may be in doubt whether the section in question is sufficiently strong. A diagram of the nature suggested will be of great help to him in such a case.

The author has evolved a simple and rapid graphical method of constructing the bending-moment diagram for a beam under combined axial and transverse loading which he has found of great help in his routine experience. The method was described in detail in *Aviation* of February 22, 1926 (vol. 20, no. 8) and only a brief outline of it will be given here.

Graphical Construction of Bending-Moment Curve for a Beam of Uniform Section Under Combined Transverse and Axial Loading

Referring to Fig. 3, draw the beam AB to any convenient scale and, on the vertical lines passing through the points of support, lay off downward the values of M_A and M_B. (The same notation and method are used here as in Pippard and Pritchard's book "Aeroplane Structures.") Join the two points thereby obtained and project the point of intersection of this line with the vertical line passing through the middle of the beam

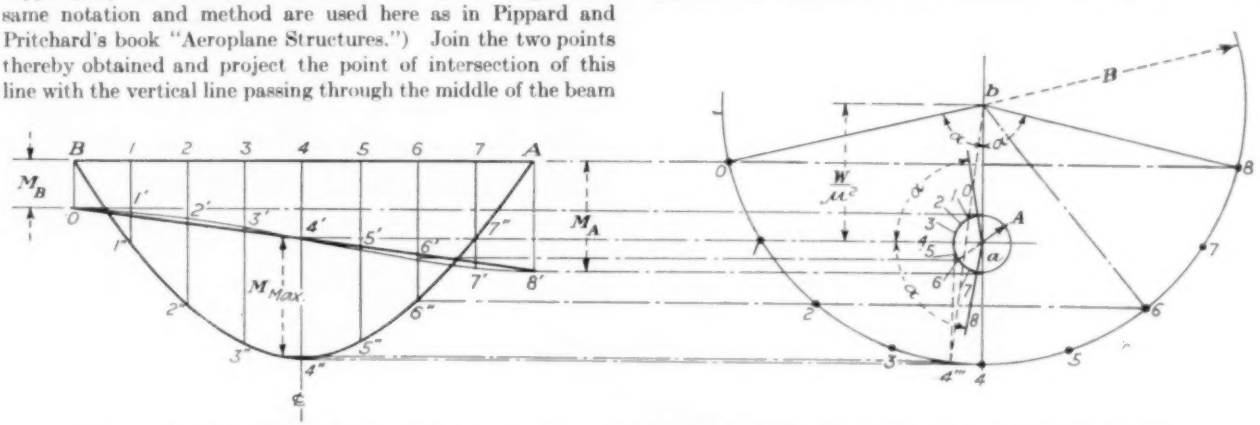

Fig. 3 Construction of Bending-Moment Curve for a Beam Under Combined Axial and Transverse Loading

on any arbitrary vertical line drawn on either side of the bay. In Fig. 3 this would be the line ab. Lay off on this line vertically upward, the value of W/μ^2 to a definite scale. At the points a and b draw the angles 2α where $\alpha = 57.3° \frac{l}{2}\sqrt{\frac{P}{EI}}$. Extend the line AB until it intersects the lines $b0$ and $b8$. The segments thus obtained give the magnitude of B. By drawing two horizontal lines through the points $0'$ and $8'$ until they intersect the lines $a0$ and $a8$, the magnitude of A may be obtained. It must be observed that $b0$ and $b8$ are drawn by measuring α from the vertical line, while $a0$ and $a8$ are drawn by measuring it from the horizontal line. With the radii thus obtained draw two circles B and A and divide the length of the beam and both segments into the same number of equal parts. Through point $1, 2, 3 \ldots 2m$ of the segments draw lines parallel to the axis of the beam, and their intersection with corresponding vertical lines will determine points $1', 2', 3' \ldots 2'm$, and $1'', 2'', 3'' \ldots 2m''$. It can be proved that the distances $1'\ 1'', 2', 2''$, etc., give the bending moment at the corresponding points in the scale in which W/μ^2 was originally drawn.

To locate the maximum bending moment lay off on the line $44''$ point $4'''$ such that $44'''$ is equal to A, and join the point $4'''$ with the center of circle B. Project the point of intersection of this line with the circle B on the curve $0''$, $1''$, $2'' \ldots 2m''$. The corresponding ordinate of the bending moment diagram gives M_{max}. Since there are two such points of intersection, it must be understood that the point in question is on the side of the diagram where curve $0'$, $1'$, $2' \ldots 2'm$ mounts upward.

New Structural Forms

In connection with the mention of the cell arrangement, it is interesting to point out one novel feature which was incorporated in the center section. While it was believed that the wing arrangement was the most advantageous from a combat viewpoint, it was nevertheless felt that for gunnery and general use a large center section was undesirable because of the blind angle resulting from it.

In order to retain the general cell arrangement and yet to improve the upward and forward vision of the pilot, attention was concentrated on the center section. Since ordinarily the location of the rear spar limits the depth of cut-out, it was decided to change the standard structure of the center section by employing two rear beams crossed in the form of the letter X, which made it possible to double the depth of the cut-out obtainable. This resulted in the Vought "vision" center section, which was first incorporated in the Vought special observation airplane submitted to the U. S. Army and made its first actual appearance on the Navy 02U–2 airplanes. Figs. 4 and 5 show respectively the standard and "vision" type sections.

The first center section was metal with latticed beams and channel-type ribs. Because of the type of the structure and in order to improve vision, the center section was built in such a way that the original airfoil was approximately preserved across

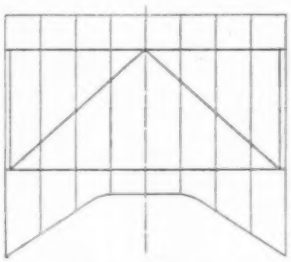

Fig. 4 Standard Center Section

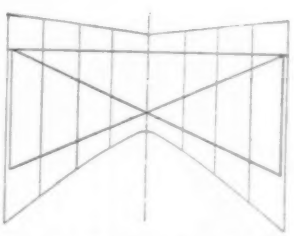

Fig. 5 "Vision"-Type Center Section

the center section, and therefore the beams were tapered with the lowest depth at the center. Further, the diagonal beams were not symmetrical about the mid-point. This presented almost a general case of a non-uniform beam under combined lateral and axial loads in which the lateral load varied throughout the length, the axial load being applied eccentrically and the taper reversed in the sense that the depth of the beam decreased toward the center.

In analyzing this structure the following method was adopted. The axial loads were obtained from the least-work analysis of the cell. In view of the uncertainties of the lift distribution over the span, it was felt that it was sufficiently accurate to employ the following assumptions. The load was considered to be a distributed load along the beam. The load per inch run was taken as proportional to the respective chord length.

The proportion of this load on each beam was then calculated by means of rib loading curves, the front beam taking the load from the leading edge to a point half-way to the middle beam, the middle one taking it from there to a point half-way to the rear beam, and the rear carrying the load from this mid-point to the trailing edge. In addition to the non-uniform loading and a tapered beam, there were also to be considered the eccentricities at both ends where the axial load was applied. The beams were analyzed graphically by drawing primary bending moments due to the axial and distributed loads. Then the primary M/I curve was drawn and deflection determined from it in order to obtain the secondary bending moment. In calculating the deflections in order to account for the fact that the beam in reality was a shallow truss, the value of $E = 10{,}400{,}000$ lb. per sq. in. for duralumin was taken as only 8,000,000 lb. per sq. in. After the secondary bending was obtained the new deflections were determined and the process repeated until the beam appeared to approach the condition of equilibrium, at

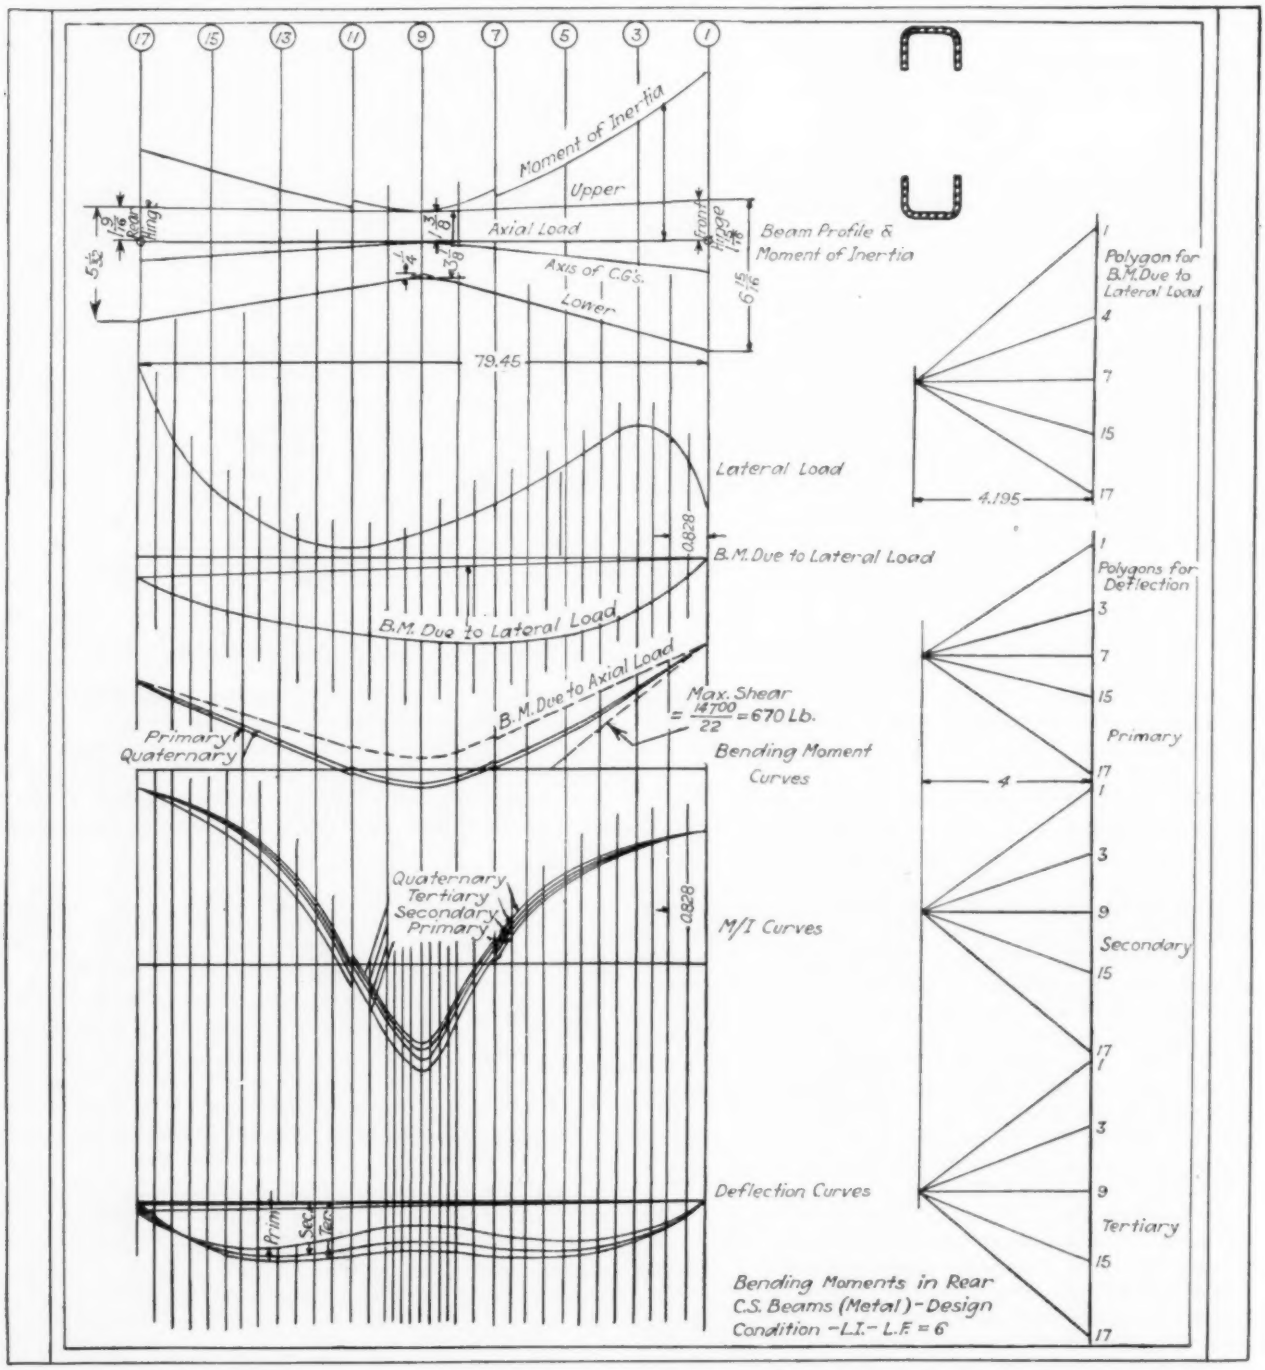

FIG. 6 GRAPHICAL DETERMINATION OF THE BENDING MOMENT DUE TO TRANSVERSE AND ECCENTRIC AXIAL LOADS ON THE REAR BEAM OF THE "VISION" CENTER SECTION

which point a final bending-moment curve was determined which was used in calculating the stresses in the beam. In order to design the diagonals, the shear was obtained from the slope of the final bending-moment curve.

In order to verify the assumptions used in the design of the beams, the front beam was tested under simple bending and the value of E obtained from the observed deflection. The figure obtained was 8,400,000, which was quite close to the assumed value.

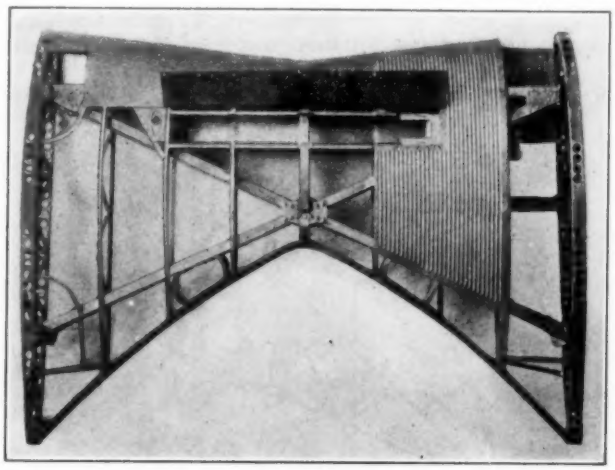

FIG. 7 METAL "VISION" CENTER SECTION

Split-Axle Chassis. Another example of a new structural form which necessitated the use of rather elaborate analysis is the split-axle-type chassis which was designed for the Vought "Corsair." Because of certain service requirements it was felt desirable that the wheels should move only in the vertical plane and that the chassis should be independent of the wing structure. The arrangement which met these requirements, despite its simplicity, was arrived at only after several tentative designs.

The present chassis structure consists of a total of six members. Each wheel is supported by a front oleo leg of the spring-oleo type, a diagonal axle and a rear strut, these two being in the same plane. Since the axles cross in the same plane, one is provided with a ring structure to allow for independent movment of either of the two wheels. When the front oleo leg shortens under the load, the rotation occurs about the transverse axis passing through the upper attachment of the axle and rear strut. The lower rear-strut attachment is such that theoretically it does not take any bending caused by the part of the component of the load in the plane of the rear struts.

In view of the complexity of the problem the following assumptions were made:

1 Referring to Fig. 9, the loads applied to the frame by the wheels were resolved at point A into axial loads in the front strut, rear strut, and axle; a bending moment in the axle from the cantilever load in the plane of rear strut and axle; and a torsional couple in the plane perpendicular to the plane of rear struts and axle.

2 The fact that the axle and rear strut are not perpendicular to the plane of the torsional couple was neglected, and sections were taken perpendicular to the longitudinal axis of the member.

3 In calculating the angle of twist of the rear strut an elliptical section of the same major and minor axes was substituted for the streamline section actually used.

For convenience the bending moment caused by the component of the load in the plane of the rear struts and axle was called the primary bending moment, and that resulting from the method of attachment and the torsional couple at the lower point A was called the secondary bending.

In endeavoring to solve for the secondary bending and torsion in the rear strut and axles, it was found that the standard equations of statics and least work were inadequate and the question arose as to what equation or equations might be lacking. By studying the structure, however, it became evident that what was lacking was an expression of the equality of the torsional deflections of the rear strut and axle.

In connection with this stress analysis it became necessary to find an expression for the angle of twist of a streamline tube, and a study was made of the problem. The difficulty of this problem lay not only in finding a suitable formula for the angle of twist, but also in the lack of information on the modulus of rigidity of chrome-molybdenum tubing; however, it was felt that for the latter a value of 12,000,000 lb. per sq. in. should be sufficiently close for all practical purposes. The problem of finding a suitable formula for the angle of twist and the shearing stress of a streamline tube was approached in several ways, and since the theoretical solution presented insurmountable difficulties, several approximate methods were resorted to.

The first method, the one actually used in the analysis, was to assume instead of a streamline tube an elliptical tube whose major and minor axes were equal to the axes of the streamline tube. Since, to the author's knowledge, there is no expression of the angle of twist of a hollow ellipse available, a formula was

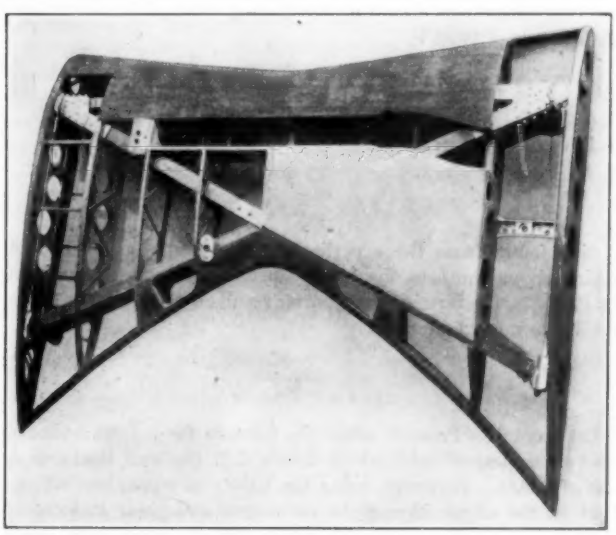

FIG. 8 WOODEN "VISION" CENTER SECTION

derived by analogy with a circular tube, the following nomenclature being employed:

θ = angle of twist in radians
f_s = shearing stress
a = major axis
b = minor axis
subscript 1 indicates outer dimensions
subscript 2 indicates inner dimensions
T = torsional moment
l = length
G = modulus of rigidity
A_1 = area enclosed by outer boundary of section
L_0 = length of the median line.

The angle of twist of a solid elliptical section as given in Morley's "Strength of Materials," p. 295, is:

$$\theta = \frac{16}{\pi} \frac{(a^2 + b^2)}{a^3 b^3} \frac{Tl}{G}$$

For a hollow circular section (D_1 and D_2, respectively, outside and inside diameters),

$$\theta = \frac{32}{\pi} \frac{1}{(D_1^4 - D_2^4)} \frac{Tl}{G}$$

so that the twist of the hollow ellipse may be written by analogy as

$$\theta = \frac{16}{\pi} \frac{Tl}{G} \left[\frac{1}{\frac{a_1^3 b_1^3}{a_1^2 + b_1^2} - \frac{a_2^3 b_2^3}{a_2^2 + b_2^2}} \right] \quad \ldots\ldots [1]$$

One of Bach's works gives the following formula for the strength of a hollow ellipse which was used to determine f_s:

$$f_s = \frac{16T}{\pi} \left[\frac{b_1}{a_1 b_1^3 - a_2 b_2^3} \right] \quad \ldots\ldots [2]$$

In order to check [1] several other methods were used, and it is of interest to review them here.

In Prescott's "Applied Elasticity," on pp. 165 and 166, are given formulas which hold true for thin tubes, that is, those where the wall thickness is small compared to the curvature of the inner boundary of the section. This is the case for streamline tubular sections except at the trailing edge. The expression of the angle of twist is

$$\theta = \frac{TlL_0}{4GtA_0^2} \quad \ldots\ldots [3]$$

and for the shearing stress:

$$f_s = \frac{T}{2tA_0}$$

It was found from the experiments, however, that instead of taking A_0 as the area inside the median line as recommended by Prescott, the formula gave better results if the area was taken within the outer boundary.

$$f_s = \frac{T}{2tA_1} \quad \ldots\ldots [4]$$

On page 168 Prescott gives the formula for a tube bounded by two similar ellipses, which means that the wall thickness is not constant. However, using the values of equivalent ellipse, that is, the ellipse having the same area and polar moment of inertia as the streamline tube, this formula gave fairly good results.

$$\theta = \frac{2}{\pi} \frac{Tl}{G} \frac{(a_2^2 + b_2^2) b_1}{a_2^3 b_2^3 t} \quad \ldots\ldots [5]$$

Another formula for the angle of twist was obtained as follows: For a solid ellipse the angle of twist in terms of fiber stress, as obtained by solving the equations for T and θ in Morley's work, p. 295, is

$$\theta = \frac{f_s l}{G} \frac{(a^2 + b^2)}{a^2 b}$$

Assuming that it holds true for a hollow ellipse also and substituting for f_s the value in Equation [2],

$$\theta = \frac{16}{\pi} \frac{Tl}{G} \frac{(a_1^2 + b_1^2)}{a_1^2 (a_1 b_1^3 - a_2 b_2^3)} \quad \ldots\ldots [6]$$

Tests. In order to obtain data on streamline tubing in torsion, for the purpose of checking the foregoing formulas as well as to obtain some idea in regard to the allowable shearing stress, two pieces of 1.25 × 3 × 0.064-in. chrome-molybdenum streamline tubing were tested in torsion. Tensile tests of two specimens cut from the same tube gave the following properties: Ultimate strength, 102,000 lb. per sq. in.; elongation in 2 in., 14.2 per cent. The average angle of twist of the tubes in radians under a moment of 4000 in-lb. was 0.0172. The angle as calculated by the formulas given above is as follows:

Equation	[1]	[3]	[5]	[6]
Angle of twist	0.0191	0.0191	0.0181	0.0171

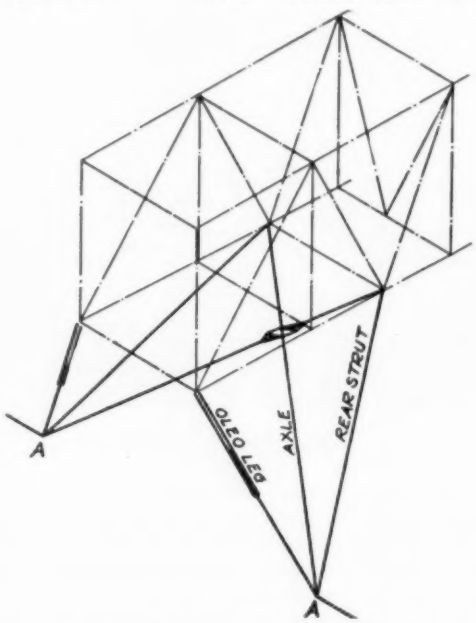

FIG. 9 LANDING-GEAR STRUCTURE

Using in Equation [3] the dimensions of an equivalent ellipse, the calculated value of θ is 0.0176.

Based on these two tests all formulas seem to give fairly accurate results. The torsional modulus of rupture as determined from the test for this tubing was 51,000 lb. per sq. in. (Eq. [2]) and 41,700 lb. per sq. in. (Eq. [4]). Since the torsional modulus is a function of the D/t ratio, it is rather hard to say which formula gives closer results. It is hoped that more experiments will be made on the torsion of streamline and oval tubing, when it will be possible to obtain accurately the variation of the modulus of torsion with the D/t ratio.

Because of the wide use of streamline tubing, the main properties of any standard streamline tubing of any practical fineness ratio are given below

$$I_{major} = 0.0838\, D^2 t(3L + D)$$
$$I_{minor} = 0.0960\, L^2 t(L + 3D)$$
$$A = 1.635t(D + L - 2t)$$
$$y = \text{distance of the minor axis from L.E.} = 0.485L$$

DESIGN OF DETAILS

The use of finer methods of analysis should not be limited to the major structures since analyses of details have still greater bearing on the strength and economy of the structure. Details are points of concentrated stresses and are often more susceptible to wear and deterioration than the main members of the structure.

Greater economy and better uniformity can be attained if every detail is carefully analyzed and designed.

A wing rib which is so often proportioned by simple experience can be much better designed if a truss analysis is made from the rib loading diagram and the member dimensioned by assuming a fixity of 2. In case of wooden ribs the strength of glue joints can be taken between 250 to 300 lb. per sq. in.

Requirements

Careful design and analysis of structure, however, can be economically justified only if the requirements are coordinated with actual loading conditions encountered in the airplane service. This hinges on our knowledge of aerodynamical facts and service conditions, close control of properties

Fig. 10 Landing Gear of the Vought "Corsair"

of material, and good workmanship. The problem of materials and workmanship will not be discussed here, but the coordination of aerodynamical and service facts and design conditions is a vital matter in structural analysis and its importance should be stressed. A number of failures of different parts of the airplane occur on the ground, and very seldom is an adequate explanation found. A case often met in the practice is the failure of cabane struts in bad landing. These struts may stand up successfully under the most severe conditions of aerial acrobatics and may show ample margins of safety for design conditions required by the present specifications, so it would seem unexplainable how they could ever fail in bad landing. A plausible reason would seem to lie in the inadequacy of the present side-load condition. The present specifications make no mention of how the structure should be assumed to be balanced to react against the external loads nor of the members which should be considered in this condition. It would appear logical to assume that the side loads are balanced by inertia forces of equal total magnitude acting in the opposite direction, and by rotative inertia forces opposing the rotation of the airplane about its own center of gravity. The latter forces are proportional to the weights and also to the square of their distance from the center of gravity of the airplane. Thus knowing the loads and reactions, it is possible to make a careful analysis of the structure. A similar analysis was made by the author and, while somewhat elaborate, it led to interesting results. It indicated that it is quite possible that cabane members and certain members in the fuselage truss may be designed by this condition, and because of that it is suggested that the side-load landing condition be revised and made more accurate and specific. It is believed that the requirements should not be made too elaborate, nevertheless they must more nearly approach the actual condition and should specify, if possible, definite means of analysis. In connection with the requirements for the landing condition a new condition should be added to protect the crew and passengers in case the plane should completely turn over in a bad landing. It is the author's practice always to analyze the cabane and center-section structure for this "tipping over" condition, and the load factor which he uses is 4. It may be safer to increase this factor to 6, but whatever it may be it must be ample to protect the occupants of the plane from possible failure of the center-section structure or the cabin superstructure.

As regards flying conditions, the nose-dive condition should be changed to more closely represent the aerodynamical facts, inasmuch as this condition is very important for military combat airplanes. We all are acquainted with the present requirements and specifications for analyzing the nose-dive condition and with the aerodynamical facts of the real nature of the loads and couples acting in nose dive.

A more accurate analysis can be easily made, and while it entails slight complication, it is, nevertheless, worth while to determine the structural strength of the craft by making full use of available aerodynamical information. The wind-tunnel test of the airfoil used gives the necessary moment coefficient to obtain the couples on the wings:

$$M = \rho C_m S V^2 c$$

where ρ = density
C_m = moment coefficient
s = wing area
c = chord
V = terminal velocity.

The drag loads must be obtained by writing the equation

$$D = \frac{C_{Dw}}{C_{Dp} + C_{Ds} + C_{Dw}}$$

where D = drag of wings
C_{Dw} = drag coefficient of the wings
C_{Dp} = parasite drag coefficient
C_{Ds} = drag coefficient of the propeller
W = gross flying weight.

To obtain the magnitude of the terminal velocity V in the dive, it is necessary to obtain the magnitude of C_{Ds} from available information on the propeller used (see Diehl, "Engineering Aerodynamics," pp. 134 and 221) and write the standard equation

$$\rho(C_{Dw} + C_{Dp} + C_{Ds})SV^2 = W$$

For planes not to be used in stunt flying the factor of safety must be sufficiently high to preclude any possibility of failure in the air, but it does not have to prevent the members of the structure from taking permanent deformation. On the other hand, planes which because of their service requirements have

to dive repeatedly must have a factor of safety sufficiently high to keep the stresses in all the members of the structure within the elastic limit of the material.

Factor of Safety

In aeronautical structural engineering we deal with load factors which are actually overload factors multiplied by a factor of safety. While this is a logical procedure, it is well to keep in mind that it provides only a general factor to be used in calculations of design loads, and that in the actual proportioning of the members one must take into consideration the nature of the stresses and the service conditions. This is particularly true in the design of details, but its importance should not be lost sight of in proportioning the major members of the structure. The actual factor of safety is equal to the breaking load of the structure divided by the maximum possible load on the structure in flight.

Since present design requirements are based on the ultimate strength of the structure, one must be particularly cautious that at no time shall any part of the structure be stressed beyond its elastic limit.

The factor of safety, generally speaking, must take care of—

1 Inaccuracies of calculations and overload assumptions
2 Possible increase in weight in future
3 Deterioration of the material with time
4 The condition that at no time of normal service conditions shall actual working stresses exceed the elastic limit of the material.

In the design of details there are three other conditions which should not be lost sight of by the design engineer, namely,

5 Variation in the material and inaccuracies in workmanship
6 Defects in the material
7 The effect of vibrations, reversal of loads, etc.

Conclusions

It is hoped that the examples of the structural problems given in this paper and met in a routine practice will emphasize the importance of using finer methods of calculation. A closer coordination of aerodynamical data and structural requirements will still further perfect our methods of structural analysis and thereby lead to mechanical and aerodynamical perfection of airplanes. Structural failures of well-designed planes in the air are almost unknown, and if such failures occur their origin can almost invariably be traced to causes other than the imperfection of present methods and requirements. But future development hinges not only on safety, which can always be obtained at the sacrifice of performance, but on economy as well.

Economy and efficiency of structure are the paramount problems in the design of the airplane of today and tomorrow.

The author is indebted to the Chance Vought Corporation for permission to use the examples of structures described in this article, to Mr. Charles J. McCarthy for his criticism and comments and to his assistants, Messrs. George W. Brady and Charles R. Strang, who made most of the calculations which are mentioned in the paper.

Discussion

Alfred S. Niles.[2] The author has criticized the rule that the effect of the redundant members must be modified by 25 per cent on the grounds that the resultant design load in any given member will depend on which parts of the structure were assumed to be redundant. This effect of the rule was thoroughly recognized when it was first adopted by the Air Corps, but no attempt was made to be more specific as to which members should be considered redundant for two chief reasons. The first was the practical impossibility of writing a generally inclusive rule unless it was provided that the members chosen as redundant should be those which would have the least influence on the stresses in the other members. This would often involve many computations to determine which members should be chosen, and the checking authorities would seldom be inclined to reject a stress analysis because it erred somewhat on the safe side. Furthermore, it would be difficult in some cases to decide which of several possible groups of redundant members had the least influence on the stresses in the others. The second reason was that the rule as worded gave a slight advantage to the clever designer who was able to pick out the members which would have the least influence on the others. The author shows that he obtained lower net loads by using the front member of the "N" instead of the center member, where another engineer might easily overlook this fact. This would permit him to use a lighter structure, a reward for intelligent design that the Air Corps would have been glad to allow him.

Though not mentioned by the author, the rule in question is ambiguous in another direction. It is not clear as to how the 25 per cent allowance should be computed when there are two or more redundant members that have opposite influences on a member of the included statically determinate structure. Suppose for example a certain member is subjected to a load of —4000 lb. if the redundant members are out of action; the effect of one of the redundant members is to subject it to + 2000 lb., and that of the other to subject it to —1000 lb. What should be the design load according to the rule? The most conservative interpretation is to compute the design load as follows: $P = -4000 - 1250 + 1500 = -3750$ lb., the 25 per cent being applied separately to the effect of each redundancy. An alternative is to apply the 25 per cent to the net effect of the redundant members, thus: $P = -4000 + 0.75\ (2000 - 1000) = -3250$. The writer believes the latter method to be sufficiently conservative, and hopes that the Department of Commerce will reword the rule so this interpretation will be specified.

The writer agrees that the present rules for the conditions of diving should be modified in such a direction that they will depend on the moment coefficients of the airfoil used. He does not believe, however, that the author's method is practical. Its chief defects are that it assumes that the airplane is diving at terminal velocity, and that it requires a knowledge of the drag coefficient of the propeller. With the exception of a few types of military designs, few if any airplanes ever dive at terminal velocity, and it would be as unfair to require that a three-engined airliner be designed for a dive at terminal velocity as to require that it be designed for a high-angle-of-attack load factor equal to the maximum that could be theoretically imposed in a sudden pull-out from a dive multiplied by a factor of safety. It would be much more logical and also more practical to design for a condition of a dive at a specified number of times the stalling speed. This number could depend on the size and type of airplane, if desired. The speed of dive would not be the only quantity specified, but it would be the chief one, and the others could be selected by the Department of Commerce when the revised rule is formulated. For pursuit airplanes the dive at terminal velocity is a reasonable design condition, but this could be covered by an empirically determined ratio of diving speed to stalling speed as well as by a study of drag coefficients.

The second weakness of the proposed method of determining the forces in the dive is lack of data on the drag coefficients of propellers at diving speeds. As long as there is a lack of reliable

[2] Guggenheim Aeronautic Laboratory, Stanford University, Stanford University, Cal. Mem. A.S.M.E.

data on this quantity one would be forced to make assumptions, and the writer believes that at present it is possible to assume diving speeds with more precision than propeller-drag coefficients. In fact, it would be necessary to compute the resulting diving speed from an assumed propeller-drag coefficient to learn whether or not the latter was reasonable.

JOSEPH S. NEWELL.[3] To the statement that "structural analyses of the airplane are intimately related to an accurate knowledge of the aerodynamic and dynamic loads acting on the structure" one might add "and to the allowable strength properties of the materials employed in the structure." With the conventional single-bay biplane this added phrase may be construed as applying to fittings and connection details, since it seems to be these items that give trouble during static tests. So far as the writer knows no airplane has yet passed the complete schedule of static tests established by the Army Air Corps without failures occurring in one of the test conditions at loads less than those specified for design.

A majority of these failures occur in or near connections even though the analyses are made on the conventional and generally conservative assumption that the diagonal members in the outer interplane-strut assembly are out of action. Such an assumption results in the design of a front truss having sufficient strength to carry a majority of the load on the wings when the center of pressure is forward, and a rear truss of sufficient strength to carry practically all of the load when the center of pressure is in its rearward position. In either of these conditions the heavily loaded truss would tend to deflect to a greater extent than the more lightly loaded one, and it is the function of the diagonal members in the interplane-strut group to equalize the deflection of the two trusses, or to transfer some of the load from the more heavily to the more lightly loaded truss.

The actual result of the incidence wires, or the diagonal of an N-strut, is therefore, a tendency to relieve one truss and add load to the other so one would naturally assume that conventional biplane cellules would withstand test loads greater than those used in making the structural analyses. In the case cited by Dr. Watter one would expect the ratio of actual load carried in static test to design load to be in the neighborhood of 17,620/12,516 if limited by the sizes of the front beam, or 13,500/10,105 if limited by the flying wires or their fittings, as the method of analysis takes into consideration the effect of the incidence wires. Or if, as static tests seem to show on other single-bay biplanes, connection details proportioned by conventional methods will not stand up to the anticipated load factors because of lack of knowledge concerning the allowable loads on thin steel plates, or concerning the actual loads imposted upon the members themselves, one would expect details designed for the loadings resulting from a least-work analysis to have strengths about in the ratio of 12,500/17,600. That is, roughly two-thirds of those obtained by conventional methods. In other words, the weakest details in a conventional cellule might well be further weakened if proportioned by more advanced methods of analysis.

That such a condition might logically be expected is obvious when one considers the simplifying assumptions ordinarily made when applying the method of least work to a complete cellule. In the first place, the work involved in the bending of the spars is entirely neglected although it may very well represent two-thirds or three-quarters of the total work done by the members of the cellule. The work done by the counter-wires in the drag trusses before they go out of action is also neglected, and it is seldom that any provision is made for effective changes in length of members due to play in pin joints and connections. Each of these simplifying assumptions results, therefore, in a modification of the relative deformations of the various panel points in the structure, and so renders the method of least work, which in the final analysis depends on the relative deformations of the structure, of doubtful value when applied to a wing cellule.

The 25 per cent increase or decrease in stress provided by the present rules of the Army, Navy, and Commerce departments is ambiguous and unsatisfactory as Dr. Watter points out. That some allowance must be made to provide for the "work" neglected in the ordinary least-work analysis is obvious, and the Department of Commerce is modifying its rule in this regard to differentiate between structures involving pinned connections, and those having rigid connections such as a welded fuselage. It is the writer's opinion that any of the methods for analyzing redundant structures should be applied with extreme caution to a structure involving a multiplicity of members and joints unless a final proof of the strength of the resulting "light" structure is obtained by sand testing a complete assembly to destruction.

The sole justification for present-day load factors lies in the fact that with conventional methods of analysis, they work out reasonably well in practice, and any method of reducing the effective strength of any part of an airplane structure, although having the virtue of lightening it, should be used with caution and with full knowledge of the uncertainties included in the simplifying assumptions which it involves. With such a knowledge, and with a judicious replacement of a portion of the material "saved" by the more precise method of analysis at points shown by static tests to be critical, it is probable that a somewhat better proportioned structure may be obtained with the more advanced methods of analysis than with the conventional. But such methods cannot be used as a cure-all, and a designer must constantly bear in mind that they are highly approximate as ordinarily applied to wing structures.

Moreover, when full-flight or model pressure data for complete cellules are investigated, and it is found that the front upper spar of a biplane may be subjected to loads approximately 25 per cent greater than those obtained by conventional assumptions as to distribution, a designer hesitates to employ advanced methods of computation which may reduce the strength of the structure 20 to 30 per cent below the "conventional."

From all of which one may conclude that the writer does not advocate the general application of advanced methods of structural analysis until research in the two fields of "actual load, or pressure, distribution" and "allowable strength of materials" has justified them. The advanced methods of analysis already exist, the knowledge of actual loads on the structure or of actual allowable stresses in the materials used does not, and it appears irrational to attempt extreme precision in one phase of design when such gross inaccuracies still exist in the other two types of construction.

It is imperative that these inaccuracies, or approximations, be eliminated as soon as possible and, as Dr. Watter has indicated, the landing chassis offers great opportunities for research. That we know little or nothing of the loads coming on landing gears or of the allowable stresses on the tubes used in chassis structures is indicated by the success of a split-axle landing gear, each member of which, by conventional systems of analysis and with conventional, conservative allowable stress data, showed a negative margin of safety in excess of 15 per cent. This particular type of chassis, to the writer's knowledge, passed a drop test satisfactorily, and has given no trouble in service during the past year although used on several airplanes in different parts of the country. Efforts should be concentrated on the determination of actual loads to be carried and actual allowable strengths of various materials, and use such methods of analysis as the precision of the "load" and "allowable load" data justify.

Author's Closure

Since the purpose of specifications is to standardize procedure and obtain uniformity, it is hardly fair to attempt justification of any rule because of the advantages which it may give to a clever designer. Mr. Niles' defense of the 25 per cent rule still leaves the question of ambiguity unanswered. As long as the rule remains in effect, however, it is very helpful to find Mr. Niles' example for the case of several redundancies.

Mr. Niles' criticism of the proposed diving condition may be justified in regard to diving velocity to be chosen for the design conditions. The author was concerned mainly with methods of design, and the choice of factors would be preferably left to a committee with sufficient experimental and theoretical data to justify their findings. Regarding the impracticability of calculating the terminal velocity of an airplane, the magnitude of the negative drag of the propeller is readily determined, and the necessary data could be gathered easily if required.

It seems that the warning sounded by Mr. Newell is based mainly on the fact that although the primary structure of an airplane usually withstands the loads imposed on it, the details of construction such as fittings usually fail before the design load is reached.

Although the author knows a number of cases where carefully designed structures withstood the loads imposed on them, the fact that details often fail is only another excellent justification for the necessity of finer analysis. In many cases the details present problems much more complicated than some primary structures, and in the design of a fitting, in a number of cases, the engineer has to resort to very fine analysis which must be further supplemented with knowledge of shop practice and working of material.

To attempt to justify simplified analysis, only because of slight inexactness in known data, may lead one to serious errors, and the dangers involved in approximations fully warrant the extra work which finer analysis usually entails. In the author's opinion, present knowledge of properties of material combined with the fine inspection method employed fully justify the use of advanced methods of analysis.

The Production and Uses of Helium Gas

By R. R. BOTTOMS,[1] LOUISVILLE, KY.

The author, after discussing the origin and occurrence of helium in natural-gas deposits, presents an estimate of the quantity available. He then describes in detail processes for separating the gas from the other gases with which it is associated, and for purifying and liquefying it. Following this he deals briefly with the questions of storage and transportation. In conclusion he enumerates the remarkable physical properties of helium, discusses its use for the inflation of airships, both pure and in a non-inflammable mixture with 20 per cent of hydrogen, and then gives estimates of the cost of helium storage, transportation, and purification facilities at an airship terminal designed to care for four ships.

HELIUM was first discovered as a terrestrial element in 1895 by Sir William Ramsay while investigating an inert gas given off from the mineral cleveite on boiling it with sulphuric acid. Ramsay thought this gas was argon, but upon examining the spectrum of the gas in a Crookes tube it was found to give a brilliant yellow line, designated as the D_3 line of the spectrum. This D_3 line had already been discovered in 1868 to exist in the spectrum of the sun and had been ascribed to a new solar element. Thus the solar element had been proved to exist on the earth. It was therefore called helium.

Helium belongs to the group of elements known as the rare gases of the atmosphere. The other gases of this group are neon, argon, krypton, and xenon. All are characterized by their comparative rarity, chemical inertness, and the fact that they are monatomic elements.

For about 15 years succeeding Ramsay's discovery of helium in 1895, a great deal of research was carried out on the occurrence and properties of helium. It was found to be a constituent, in small amounts, of the atmosphere, of gases from mineral springs, of volcanic gases, and occurred in minute quantities in sea water and was found to be present in the atmosphere to the extent of one part in 185,000, and to occur in minute traces in nearly all rocks and minerals.

Occurrence

In 1905, Cady and MacFarlane, of the University of Kansas, investigating a peculiar noncombustible gas from Dexter, Kansas, found 1.84 per cent helium in the gas. This discovery led them to examine other gases from the same locality and also gases from other points in Kansas, and in all of them helium was found. These investigations have been greatly extended by Cady and also by others since these discoveries, and today almost all known deposits of natural gas in the world have been tested for helium.

Only in the United States and Canada are helium-bearing gas deposits found with a sufficient helium content to make it economical to process them. In Italy, however, there are certain gases issuing with steam from boric acid fumaroles which might possibly be treated for the recovery of helium. These gases, after the condensation of steam, consist principally of carbon dioxide, but since the latter gas is very easily liquefied there would be no great technical difficulty in treating the gas. It has been estimated that from 200,000 to 250,000 cubic feet of helium per day could be obtained from this source.

In Canada there are two gas fields carrying a small percentage of helium—the Bow Island field in Alberta, a few miles north of the Montana line, and a field in Ontario north of Lake Erie. Neither of these fields carries a helium content of over 0.5 per cent. In this country, under present conditions, it would not be considered a commercial grade of helium-bearing gas.

In the United States helium occurs to some extent in most the natural-gas deposits. However, there are some gas deposits occurring on the Pacific Coast, on the Gulf Coast in Louisiana, and in the Rocky Mountain region which show no helium that can be detected by the usual analytical method.

Natural gases from different fields and even from different geological strata in the same field may differ widely in chemical composition and helium content. They fall into four main types: hydrocarbon, nitrogen, carbon dioxide, and sulphur, according as hydrocarbons, nitrogen, CO_2, and H_2S, are the most prominent constituents. A few typical analyses are given in Table 1.

The Helium Company has, during the last two years, been conducting an active survey of all the natural-gas resources of the United States in order to determine sources of helium-bearing gas.

[1] Kentucky Oxygen-Hydrogen Co., Inc.

Presented at the Third National Meeting of the A.S.M.E. Aeronautic Division, St. Louis, Mo., May 27 to 30, 1929.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Table 1 deals only with a few of the many hundreds of samples tested, but it gives an idea of the remarkable results obtained.

Origin of Helium

The facts relating to the origin of helium and the reason for its accumulation in certain natural-gas deposits have not been entirely cleared up. There are several theories relating to the origin of helium:

1 The radioactive theory, which assumes that the helium in natural-gas deposits has been accumulated by radioactive disintegration of radium-bearing minerals, distributed through the sedimentary rocks.

2 The theory propounded by Rogers that the helium occurring in natural-gas deposits is primordial in origin and has nothing to do with radioactivity. The evidence in either case is so meager that it is practically impossible to determine which of these theories is correct. Rogers objects to the radioactive theory on the basis that the quantity of radioactive elements necessary to produce the enormous volume of deposits would be greatly in excess of what is actually found in the crust of the earth.

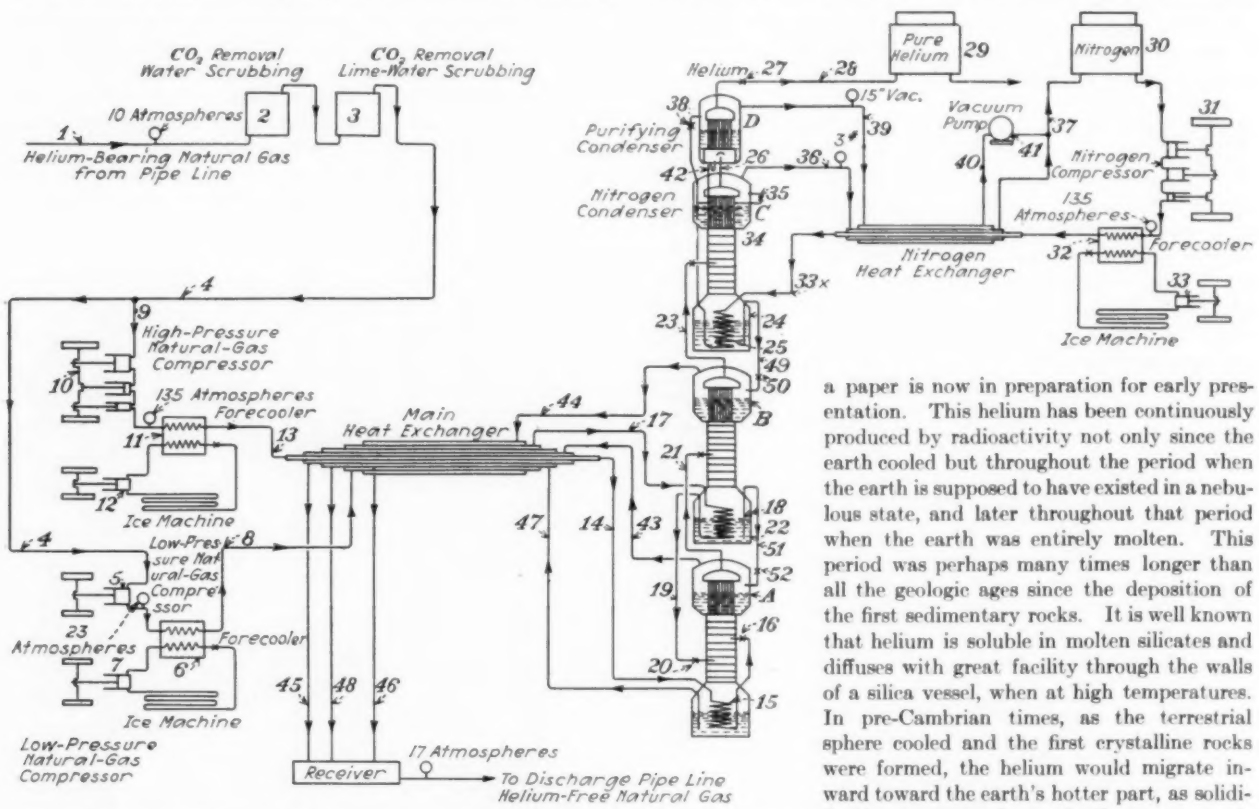

Fig. 1 Apparatus Used Until Recently at the Government Helium Plant at Fort Worth, Texas

The facts relating to the accumulation of helium of course are simple. A great deal of investigation has shown that it occurs in various sedimentary rocks overlying, or at least in the vicinity of, granite uplifts which have been faulted, and we find that along these granite folds the natural gas will usually contain anywhere from 0.1 per cent helium up to as high as 8 per cent, while the gas occurring outside of the faulted area is nearly always low in helium content.

A theory has been evolved by the author regarding sources of helium in natural gases which, if correct, will aid in the location of helium-bearing gas. Briefly stated, this theory is that the original source of helium is the basal crystalline rocks, underlying the sedimentary deposits, and that the helium with large amounts of nitrogen and carbon dioxide in the granite seeps into the sedimentary deposits through fissures, crevices, and fractures in the basal rocks and diffuses and migrates through the structural rocks until it is trapped underneath an impervious cap rock in anticlinal folds or domes. Whether the helium in the granite rocks is primordial helium or results from radioactive disintegration of uranium, radium, and thorium makes little difference.

In this connection it seems most probable that the helium now found in natural-gas deposits was produced entirely by the radioactive disintegration of elements with high atomic weights. A revolutionary theory has been evolved concerning this point and a paper is now in preparation for early presentation. This helium has been continuously produced by radioactivity not only since the earth cooled but throughout the period when the earth is supposed to have existed in a nebulous state, and later throughout that period when the earth was entirely molten. This period was perhaps many times longer than all the geologic ages since the deposition of the first sedimentary rocks. It is well known that helium is soluble in molten silicates and diffuses with great facility through the walls of a silica vessel, when at high temperatures. In pre-Cambrian times, as the terrestrial sphere cooled and the first crystalline rocks were formed, the helium would migrate inward toward the earth's hotter part, as solidification progressed, much the same as air migrates to the interior of a cake of ice as it freezes. Thus, whenever in later times there has been any volcanic activity tending to form fractures in the crystalline rocks, this concentrated helium tends to escape. These fissures, cracks, or fractures may occur whenever there is an area uplifted by volcanic activity, especially if accompanied by faulting.

If this theory is correct then we should feel more certain of finding helium in the vicinity of major granite uplifts or folds, especially if faulted, and in the vicinity of other volcanic activity which would tend to open up passageways for helium from the interior of the earth.

The helium-bearing gas, accumulating as just described, will probably consist entirely of non-combustible gases, principally nitrogen and carbon dioxide. Unless hydrocarbon gas forms in surrounding source beds and migrates into the same reservoir and dilutes the accumulating volcanic gas, the helium-bearing gas as described would consist almost solely of nitrogen, carbon dioxide, and helium. If dilution has taken place the helium content of the gas would depend upon the extent of that dilution.

The Helium Company, the latter part of 1928, using this theory as a guide began some investigations looking toward the discovery of helium in those parts of the country where the necessary geological conditions seemed to be favorable toward the accumulation of helium-bearing gas. As shown in Table 1, data are being accumulated which will form a favorable guide for intelligent exploration and will ultimately give the airship industry the necessary assurance as to the location and extent of its helium supply.

Quantity of Helium Available

There seem to be some misgivings in the minds of those interested in airship development regarding the amount of helium available for airship use. These misgivings are entirely unfounded. A recent estimate of the total available helium already in sight is about as follows:

Kansas	2,000,000,000 cu. ft.
Texas	3,000,000,000 cu. ft.
Colorado	2,000,000,000 cu. ft.
Other states	3,000,000,000 cu. ft.

This gives us a grand total of 10 billion cubic feet of helium, which, if used at the rate of 10 million feet a year, would last for 1000 years, and if used at 10 times that rate would last for 100 years.

This estimate merely gives the present status of the helium supply. About a year ago the estimate of the available supply

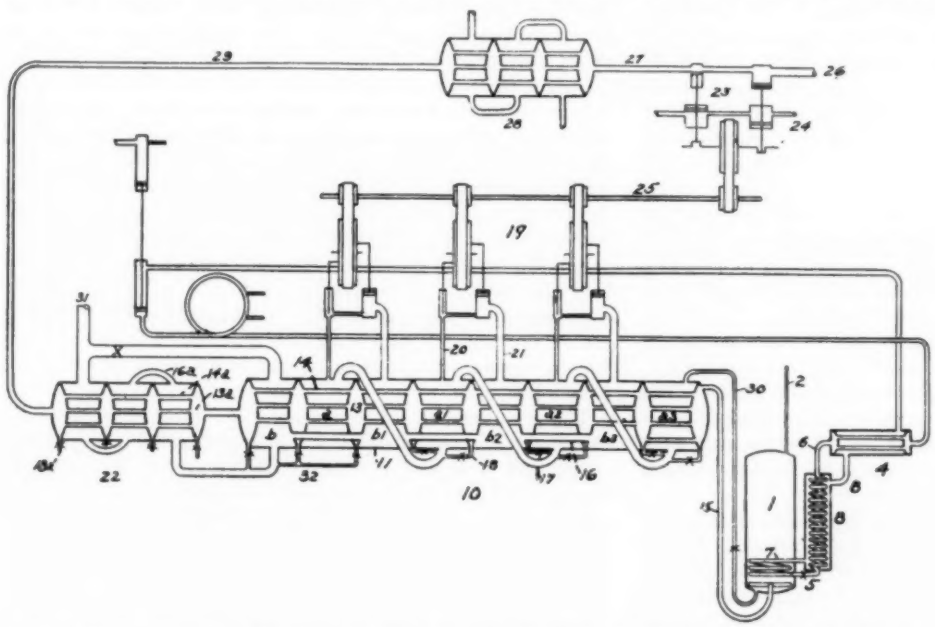

Fig. 2 Modification of Jeffries-Norton Process Used in 1918–1919 at Bureau of Mines Helium Plant, Petrolia, Tex.

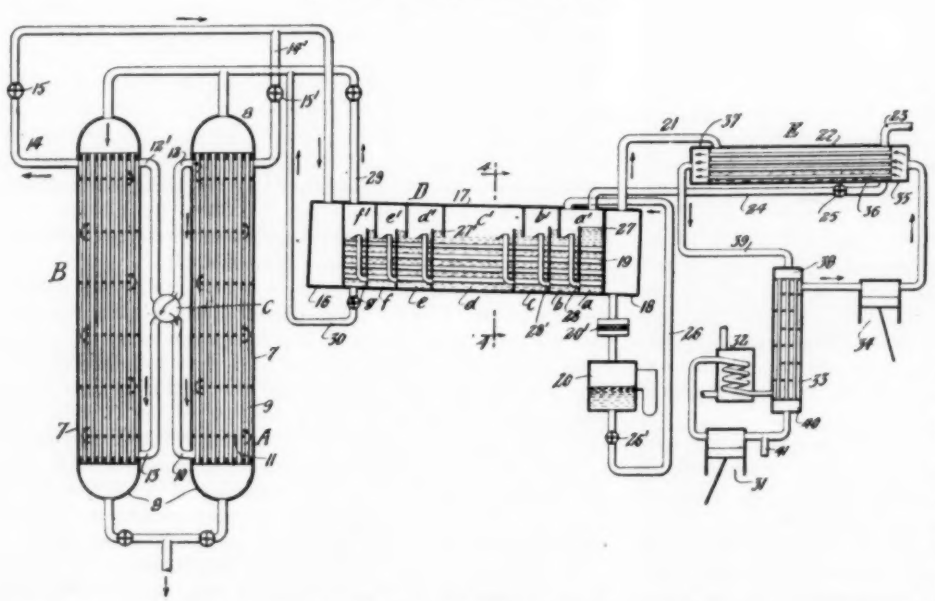

Fig. 3 Schematic Drawing of Apparatus Now Being Used in the Government's Plant at Amarillo, Tex.

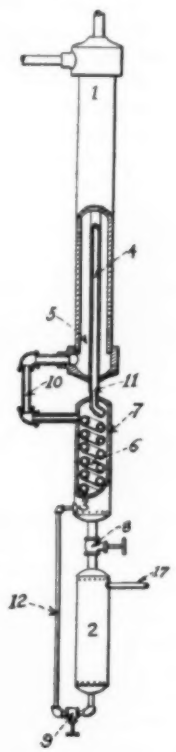

Fig. 4 Author's Process as Installed in the Helium Company's Plant at Dexter, Kan.

in sight amounted to about 7 billion cubic feet, but two of the largest helium-bearing areas in the world have been discovered since that time.

Methods of Production

The technical methods of producing helium are based on the fact that all gases, with the exception of helium, can be reduced to the liquid phase at readily acquired temperatures. Helium being a most difficult gas to liquefy and so refractory in this connection that it has been liquefied at only two places in the world, makes it very easy, therefore, to separate helium from

the other constituents with which it is associated by simple liquefaction of the other constituents and the separation of the gaseous helium from the liquids. Every process for the production of helium is based on these facts.

The accompanying illustrations, Figs. 1 to 4, are given in schematic form and show processes for the production of helium.

Government Plant, FORT WORTH, TEX. Fig. 1 shows the apparatus which was used until recently at the Government plant at Fort Worth, Texas. This is a highly complicated apparatus. Its action is about as follows:

The helium-bearing gas, previously deprived of its gasoline constituents, and arriving at the plant through pipe line 1, at or above 10 atmos. pressure, is scrubbed at that pressure in scrubber 2 for the removal of carbon dioxide. Owing to the increased solubility of carbon dioxide at such pressures, water alone acts as a very effective agent for removing carbon dioxide. If a more complete removal of carbon dioxide than can be obtained with water alone is desired, the gas may be passed to a second scrubber 3, where it is treated with a solution of an alkaline substance such as lime water. The absorbent action of lime water is also increased by the pressure.

From scrubber 3 a portion of the gas passes through line 4 to low-pressure compressor 5, where its pressure is brought to about 23 atmos. The compressed gas passes through a forecooler 6 refrigerated by an ice machine 7, and thence through line 8 to the main heat exchanger.

Another portion of the helium-bearing gas, after removal of the carbon dioxide, is drawn through line 9 to high-pressure multistage compressor 10, and is brought to about 135 atmos. The high-pressure gas passes through a forecooler 11 refrigerated by an ice machine 12, and is carried through line 13 to the main heat exchanger, but is kept separate therein from the low-pressure gas entering through 8.

The high-pressure gas emerges from the heat exchanger through line 14, whence it passes to coil 15 immersed in a bath of boiling liquid at low temperature. After its final cooling in the coil, the high-pressure gas expands through valve 16 into the column at a point below condenser *A*. The low-pressure gas leaves the heat exchanger by line 17, passes through a coil 18 likewise immersed in a low-temperature bath of boiling liquid, and then flows through line 19 and valve 20 to the same column into which the high-pressure gas is expanded.

The expansion of the cooled high-pressure gas to the column pressure, about 22 atmos., absorbs a large quantity of heat. The less volatile constituents of both high- and low-pressure gas, for example the propane, most of the ethane, and some methane, are condensed, flow down through the column where they are subjected to a rectification to remove any dissolved helium, and collect in the kettle containing the coil 15.

Those constituents of the gas which are not liquefied on expansion, and including all of the helium of the gas, pass upward through the column to condenser *A*, where they are subjected to the temperature of the liquid boiling about the condenser, this liquid being held under a pressure of about 17 atmos. A further quantity of relatively non-volatile material is liquefied in condenser *A* and returns to the column below, in which it also is rectified.

The helium and other gases not liquefied in condenser *A* pass through line 21 to a column which is surmounted by condenser *B*. Condenser *B* is surrounded by a boiling liquid which is held at the same pressure as that which obtains about the condenser *A*, but the liquid surrounding condenser *B* contains most of the volatile constituents of the natural gas, such as nitrogen and methane, and hence is at a lower temperature than the liquid about the condenser *A*. As a result, an additional quantity of material is liquefied in condenser *B* and descends through and is rectified in the column immediately below, collecting finally in the kettle 22 in which is contained the coil 18 previously referred to.

The helium, still admixed with many times its volume of gaseous impurities, leaves condenser *B* through line 23 and enters the column which is immediately below condenser *C*, the helium-containing mixture being still at the same pressure of 22 atmos. Condenser *C* is cooled by substantially pure liquid nitrogen boiling at about atmospheric pressure, and hence the temperature of *C* approaches closely the boiling point of nitrogen, —193 deg. cent. As this temperature is considerably below the temperatures of condensers *A* and *B*, a further quantity of gas associated with the helium, now chiefly nitrogen, is condensed, and passes down through the column immediately below, where it is rectified to remove any dissolved helium. The liquid collects in kettle 24 at the bottom of the column and there surrounds and cools coil 25, which performs the function presently to be described.

Due to the temperature and pressure prevailing in condenser *C*, a helium concentrate containing about 90 per cent of helium will be produced. This concentrate passes through line 26 to the final condenser *D* where it is subjected, still at a pressure of about 22 atmos., to the temperature of nitrogen boiling under reduced pressure, say, at about 0.5 atmos. abs. This will give a temperature below —195 deg. cent. in condenser *D*, and as a result some of the small amount of residual nitrogen will be liquefied and a concentrate containing about 98 per cent helium, and usually considered pure enough for aeronautical purposes, will pass the condenser, expand through valve 27, and pass through line 28 to the helium holder 29.

The arrangement for producing the nitrogen baths which surround condensers *C* and *D* will now be described.

Nitrogen is drawn from holder 30 and compressed in multistage compressor 31 to a pressure of about 135 atmos. The compressed gas then passes through forecooler 32 refrigerated by the ice machine 33, and thence through the nitrogen heat exchanger. The cooled high-pressure nitrogen emerges from the heat exchanger through line 33 and passes through coil 25 previously referred to, where it is brought into thermal contact with the very cold boiling liquid in kettle 24. The liquid in kettle 24, it will be noted, is under a pressure of about 22 atmos. The nitrogen now passes through coil 34 disposed in the bath around condenser *C* and hence immersed in nitrogen boiling at a little above atmospheric pressure.

After the final cooling the nitrogen expands through valve 35, which results in its partial liquefaction. The liquid nitrogen collects about coil 34 in condenser *C*, where it boils away continuously and produces the refrigerating effect already referred to. The gaseous nitrogen produced by the boiling of this bath passes at slight pressure through line 36 to the nitrogen heat exchanger, where it cools the high-pressure nitrogen and then flows through line 37 to the nitrogen holder 30.

The space around condenser *D* is held, as already stated, under a partial vacuum. Liquid nitrogen will rise at a regulated rate through valve 38 and collect about condenser *D*, boiling there under the reduced pressure at a very low temperature. The gaseous nitrogen produced by the boiling of this liquid passes through line 39 to another section of the nitrogen heat exchanger, where it assists in the cooling of the high-pressure nitrogen, and then passes through line 40 and vacuum pump 41 to the nitrogen holder. The small quantity of liquid formed in condenser *D*, and consisting of pure nitrogen, returns through the trap 42 to the top of the column surmounted by condenser *C*.

The gases produced by the boiling liquids around condenser *A* and *B* pass through lines 43 and 44, respectively, to the main heat exchanger, where they cool the high- and low-pressure helium-bearing gas, and then pass through lines 45 and 46, re-

spectively, to a receiver which discharges helium-free gas into a pipe line to be transported to the place of its consumption. Since the baths about condensers *A* and *B* are maintained at 17 atmos. pressure, and the reverse-flow passages of the main heat exchanger are at the same pressure, the exit gases may enter the line without being further compressed. A portion of the liquid contained in the kettle around coil 15 is also continuously withdrawn through line 47 to the main heat exchanger, in which it evaporates and assists in cooling the high- and low-pressure helium-bearing gas, passing from the heat exchanger through line 48 to the receiver and pipe line already referred to. The exit gases passing through the main heat exchanger and lines 45, 46, and 48 constitute practically all the natural gas entering the plant with the exception of the helium.

FIG. 5 VIEW OF HELIUM COMPANY'S PLANT AT DEXTER, KAN.

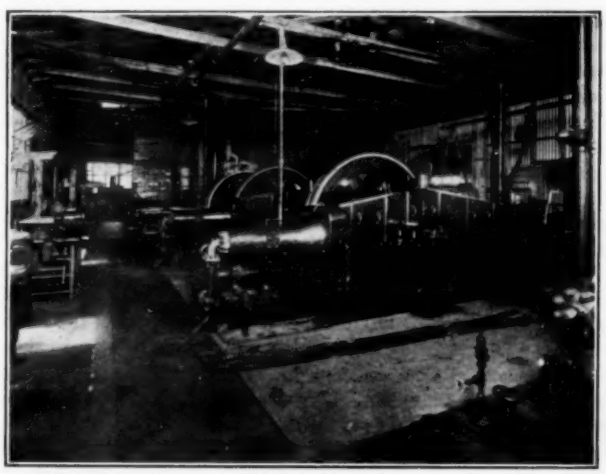

FIG. 6 INTERIOR VIEW OF HELIUM COMPANY'S PLANT AT DEXTER, KAN.

The condenser *B* is cooled by liquid which collects in kettle 24, and flows through line 49 and valve 50 into the space surrounding condenser *B*. Condenser *A* is similarly cooled by liquid which collects in kettle 22 and flows through line 51 and valve 52 to the space surrounding condenser *A*. At valves 50 and 52, the pressure on the liquids just referred to is reduced from about 22 atmos. to about 17 atmos.

Should it be desired to remove from the helium leaving condenser *D* the very small quantity of impurities contained in it, the apparatus shown in Fig. 4 may be used, being introduced into the system at an appropriate point—for example, between condenser *D* and the helium holder.

This apparatus consists of a series of identical absorbers comprising an inner chamber packed with activated carbon 53 and held between foraminous (porous) partitions 54. To facilitate the absorption of the impurity (nitrogen) in the carbon, the latter should be cooled to a very low temperature, and the author has shown the absorbers provided with jackets 55, through which may be passed a very cold medium, such as nitrogen from the space around condenser *C*. The absorbers may be small, as they are designed to take up an impurity which consititutes only about 2 per cent of the helium, the helium being less than 1 per cent of the gas treated.

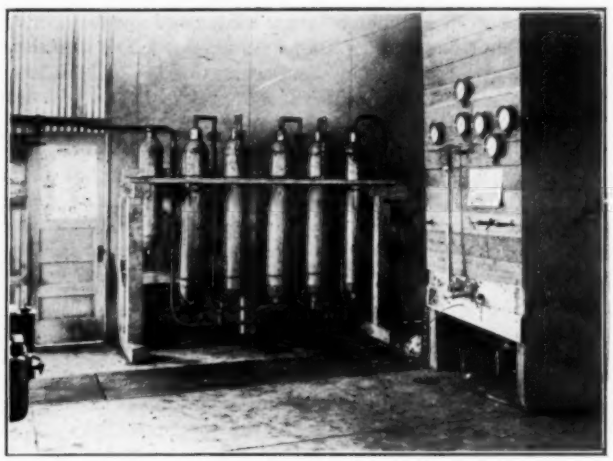

FIG. 7 GAS-DRYING BATTERY AND COLUMN IN DEXTER PLANT

FIG. 8 END VIEW OF NAVY DEPARTMENT'S HELIUM TANK CAR

When cooled to a temperature such as that indicated, activated carbon selectively absorbs the impurity with great efficiency, and the purity of the helium can be raised to any desired degree. When one absorber is saturated to the desired degree with impurity, it is cut out of both the helium and the refrigeration circuits and allowed to warm up to room temperature, whereupon the absorbed impurity will pass off through 56. The absorber is

then ready for use again as soon as it has been cooled to the required low temperature.

Fig. 2 shows a modification of the old Jeffries-Norton process which was used by the Bureau of Mines at Petrolia, Texas, in 1918 and 1919, but which proved to be a failure. No helium has ever been produced by this apparatus and a description of the process does not warrant the use of the space.

Government Plant, AMARILLO, TEX. Fig. 3 shows a schematic drawing of the plant which is now being used in the Government plant at Amarillo, Texas. This plant operates as follows:

The drawings show an interchanger having two units *A* and *B*, each unit comprising a casing 7, a pair of headers 8, and the tubes 9 extending within the casing 7 and connecting the two headers. The gas is admitted through the valve *C*, preferably at a pressure of approximately 30 atmos. and at a temperature of approximately 35 deg. cent., and passes via the pipe 10 into the casing 7 of the unit *A*, flowing from one end to the other in a tortuous path about the tubes 9, as indicated by the arrows, the interior of the casing being provided with several baffles 11 for this purpose. In passing through the unit *A*, the gases are somewhat cooled by thawing out the frozen water vapor in the unit, and they leave the unit *A* by way of the pipe 12, crossing over at the valve to the pipe 13 leading to the bottom of the unit *B*, where the gas is cooled by the return substances going through the tubes 9. A pipe 12′, corresponding to the pipe 12, is connected with the casing of the unit *B* so that the interchanger units may be reversed. The cooled gases pass out of the upper end of the unit *B* through the pipe 14, which is provided with a suitable shut-off valve 15 and which leads to the header 16 of the liquefier, indicated as a whole by the reference letter *D*. The gas enters the header 16 approximately at a pressure of 30 atmos. and a temperature of approximately —100 deg. cent., which is practically the dewpoint. An outlet pipe 14′ leads from the upper end of the casing 7 of the unit *A* and is connected to the pipe 14 and is controlled by a shut-off valve 15′, such valve being closed when the flow is first through the unit *A* and then through the unit *B*, as described, the valve 15 being closed and valve 15′ being open when the flow takes place through the unit *B* and then through the unit *A*.

The liquefier *D* comprises the casing 17, and the header 16 previously mentioned, the header 18 and the tubes 19 connecting the headers 16 and 18. This liquefier is preferably substantially horizontally disposed, with a slight inclination from the horizontal. The reason for inclining the liquefier is to cause the liquid condensing in the tubes 19 to flow as rapidly through such tubes as the gas or vapor above the liquid is being conducted through the tubes by the pressure drop. Thus the gases entering the header 16 at approximately the dewpoint are subjected to the action of the returning fluid as they pass through the pipes 19, and practically all of the readily liquefiable contents of the gas are liquefied, the liquid and gas passing along together, in intimate contact with each other and in substantial phase equilibrium, the composition of the mixture being approximately uniform through the length of the tubes 19, with a minimum variation in the composition of the vapor above the liquid. The condensate leaving the pipes 19 passes down into the chamber 20 connected with the header 18 through a filter 20, and the uncondensed vapors pass out of the header 18 approximately at a pressure of 30 atmos. and a temperature somewhat lower than the dewpoint mentioned, say, for example, —117 deg. cent., by way of the pipe 21 to the purifier, indicated as a whole by the letter *E*.

The gas entering the purifier *E* is an impure helium, the impurities being a small quantity of nitrogen and methane and traces of other constituents. The gas is subjected to the cooling action of an external cycle of refrigeration and the impurities referred to above are liquefied, collecting in the bottom of the horizontal casing 22 of the purifier, practically pure helium being drawn off by pipe 23 at a pressure of approximately 30 atmos. and a temperature of approximately —170 deg. cent. The liquid condensed in the purifier is returned to the liquefier by means of the pipe 24 provided with a throttling valve 25 which throttles the pressure down to preferably 20 atmos.

The liquid condensed in the tubes of the liquefier *D* is returned to the shell of the liquefier through the pipe 26 at a pressure of approximately 20 atmos. obtained by means of a throttling valve 26 and at a temperature of approximately —121 deg. cent.

The external cycle of refrigeration referred to will be described later.

The lower portion of the casing 17 of the liquefier is divided into compartments by means of division walls 27, forming the compartments *a*, *b*, *c*, etc., in the lower portion of the liquefier casing. The space above the liquid in the casing is also divided into compartments *a′*, *b′*, *c′*, etc., by hanging baffles or deflection plates 27. From the bottom of each lower compartment a pipe 28, 28′, etc., leads to the upper region of the next lower compartment. The return liquid is delivered by pipe 24 to the compartment *a* and by pipe 26 to the compartment *b*. From compartment *a* the liquid not evaporated flows through pipe 28 to compartment *b;* and from such compartment, the unevaporated liquid flows into compartment *c* by means of pipe 28′; and so on from compartment to compartment. Since the pressure of the vapor above compartment *a* is the same as the vapor pressure above the mouth of pipe 28, liquid accumulates in compartment *a* until there is a sufficient head to cause liquid to flow out of pipe 28 into compartment *b*, the liquid being discharged into the vapor in the upper compartment *a″*. This is true of the other compartments. The arrangement of baffling is therefore one tending to keep the liquid and vapor in intimate contact and to maintain phase equilibrium, this purpose being furthered by providing a broad lip or plate 28*a* at the orifice of the pipes 28, 28′, etc., over which the discharging liquid flows in a thin, wide, sheet-like stream insuring close contact between the liquid and the vapor. Also the vapor evaporated cannot take a free course directly to the outlet 29 of the liquefier but must bubble through the liquid in passing progressively under the baffles 27′ from compartment to compartment.

The gases returning from the casing 17 to the outlet pipe 29 are delivered to the headers 8 and pass through the tubes 9 of the interchanger securing the necessary heat transfer in the interchanger, the gas leaving the casing 17 at approximately a pressure of 20 atmos. and a temperature of —111 deg. cent., and leaving the interchanger at substantially 20 atmos. pressure and a temperature of +17 deg. cent. It will of course be understood that when the flow of the incoming gas is first through the unit *A* of the interchanger the gas from the liquefier is conducted through the tubes of the unit *B*, cooling the gases coming into such unit from the unit *A*, as before described; and when the flow of incoming gas is first through unit *B* and then through unit *A*, the gases from the liquefier are led through unit *A* to cool the gases coming thereinto from unit *B*. To this end the outlet pipes leading from the bottom headers of the unit are provided with valves.

Depending upon how closely equilibrium is attained, the last compartment of the liquefier, as it is arranged, may contain a liquid (such, for example, as methane) which has a relatively high boiling point, that is to say, is of low volatility; and if provision were not made for the abstraction of such liquid from this compartment, the liquefier would eventually fill with high-boiling-point liquid and its operation would be greatly impaired, if not destroyed. To meet this condition a lead 30 is taken from the bottom of the last compartment and connected to the return pipe 29 so that any relatively high-boiling-point liquid which may

be present in the liquefier shall be returned along with the gases, leaving the upper region of the liquefier casing to the interchanger where, of course, such liquid will be evaporated and effective heat transfer secured in the interchanger.

Referring now to the cycle of refrigeration by means of which the helium is purified in the purifier *E* by the liquefaction of the impurities, this is, as stated, an external cycle, whereas the refrigeration in the process up to this point is accomplished primarily by means of an internal cycle. Any suitable form of refrigeration may be employed for the purifier, but apparatus such as diagrammatically indicated is preferred, using an inert gas which does not condense easily. Nitrogen or helium is mentioned as a suitable medium for this purpose. This is drawn into the system and its pressure is raised to approximately 30 atmos. by the compressor 31, the gas being cooled to a temperature of about +35 deg. cent. in the aftercooler 32, from whence it is conducted to the interchanger 33 in which the gases are cooled to a temperature of approximately —104 deg. cent. The gases leaving the interchanger are then expanded by means of the expansion engine 34 to approximately one atmosphere of pressure and thereby cooled to a temperature of approximately —180 deg. cent., the expanded gases being led to the purifier at the header 35, passing therefrom through the tubes 36 to the header 37, and from thence to the header 38 of the interchanger by means of the pipe 39. The gases enter the header 38 at a temperature of approximately —123 deg. cent. and serve to cool the incoming gas. The gases leave the outlet header 40 of the interchanger at approximately +30 deg. cent. and are returned to the inlet side of the compressor. The cycle is thus in effect a substantially closed one, and any make-up necessary is supplied to the low-pressure side of the compressor at the point marked 41.

The reason for placing the helium purifier in combination with the auxiliary refrigerating system in a substantially horizontal position is the desire to keep the liquid and gas in contact so far as possible in order to approximate equilibrium between all of the gas and the liquid, rather than between the gas and the last portion to be condensed out, thus obtaining a higher purity of helium.

The progressive evaporation of the returning liquid provides for the elimination of high-boiling-point substances such as ethane and the higher hydrocarbons, as it insures their collection in the warm end of the liquefier where they can be returned to the interchanger without disorganizing or impairing the functioning of the system, particularly the liquefaction step. This also obtains maximum efficiency in the interchangers. The evaporation of the liquid in steps and the return of the liquid and gas together also make possible the condensation of the gas by evaporation of mixed liquids with a minimum pressure drop in the system.

Helium Company's Plant, DEXTER, KAN. Helium is produced at the Helium Company's plant at Dexter, Kansas, by means of the Bottoms process, one phase of which is illustrated in Fig. 4 and which is probably the least complicated of any process yet developed. This apparatus, which of course is shown schematically, operates about as follows:

Helium-bearing gas, previously compressed to a pressure of from 40 to 200 atmos., and freed of the greater part of its carbon dioxide and water vapor, is led into the apparatus through passages 4 of the heat interchanger 1, where it is cooled to a low temperature by a means that will shortly be more fully explained. The gaseous mixture passes from interchanger 1 through pipe 11 and enters tubes or coils 6 in condenser 3. Condenser tank 7 of condenser 3 is filled with the liquid constituents of the natural gas boiling at approximately atmospheric pressure. It is this liquefied gas that forms the cooling or refrigerating medium necessary to liquefy the before-mentioned easily liquefied constituents of the natural gas contained within tubes 6, the said liquefaction being facilitated by the natural gas contained in tubes 6 being at high pressure. The easily liquefiable constituents of the natural gas contained at high pressure within tubes 6 condense to a liquid, holding the greater part of the helium in solution and in the liquid phase. From tubes 6 the mixture of liquefied gases is passed to the liquid-collecting pot 2 through valve 8. In pot 2 the helium held in solution in the liquids is given off as a gas due to the reduction in pressure much in the same way that carbon dioxide is

FIG. 9 HIGH-PRESSURE HELIUM STORAGE AT LAKEHURST, N. J., BEFORE COVERING

FIG. 10 DETAIL OF STORAGE PLANT SHOWN IN FIG. 9

released from carbonated water upon release of pressure, the liquid gases and the gaseous helium separate.

The liquid settles to the bottom of the pot 2 while the helium, still at a pressure much above atmospheric, passes out of the pot through pipe 17 to the place where it is to be stored or used. The liquid separating out in pot 2 is drawn off through valve 9 and transferred to condenser 3 through pipe 12 where it is allowed to evaporate at approximately atmospheric pressure. The vapors from the liquid in condenser 3 pass out through pipe 10 to passage 5 of interchanger 1, and thence through passages 5 countercurrent to the ingoing gases in passages 4, where they are cooled to a low

temperature as previously stated. The said vapors in their passage from end to end of the interchanger 1 are warmed at the same time to a temperature that approaches the temperature of the ingoing gases.

At this time of writing (April 17, 1929) there is only one plant operating at all, and this is the plant of the Helium Company at Dexter, Kansas. The new plant at Amarillo recently built by the U. S. Bureau of Mines is not yet in operation, and it is not known when it will be placed in operation.

Storage of Helium

Since it is necessary to have large volumes of helium on hand at any major airship-operating station, some kind of storage

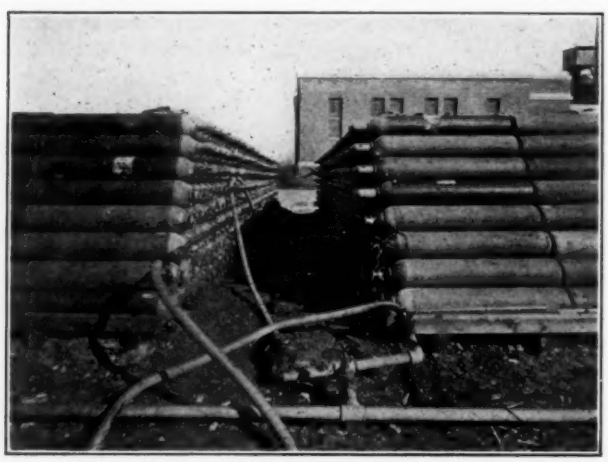

Fig. 11 Method of Discharging Helium From Small Cylinders at Lakehurst

Fig. 12 Interior View of Helium Purification Plant at Lakehurst

facilities will have to be provided. There are three general methods of storage:

1 Atmospheric holders or gasometers. A 6,000,000 cu. ft. holder of this type will cost about $1,200,000.
2 Storage in medium-pressure tanks, that is, about 60 lb. per sq. in. Tanks of this type having sufficient capacity to hold 6,000,000 cu. ft. would cost erected something like $560,000.
3 Storage in high-pressure containers, that is, in containers that will withstand an internal pressure of about 2000 lb. per sq. in. Such storage as this has been provided at the Naval Air station at Lakehurst, N. J. The present cost of storage facilities of this kind for 6,000,000 cu. ft. of helium would be, installed, about $400,000.

It therefore appears that the most economical method of storing helium at an airship depot would be in relatively large-size high-pressure storage tanks. There are three general types of these cylinders:

1 Relatively small cylinders capable of holding about 400 cu. ft. of helium each. These cylinders would be connected up in banks and manifolded with a common valve.
2 Medium-size tanks, approximately 4 ft. in diameter by 45 ft. long which are usually buried under the ground. Both of the above types of cylinders are seamless, forged, or drawn cylinders.
3 The third type is of welded steel, about 10 ft. in diameter by 100 ft. long.

Transportation of Helium

Due to the fact that helium deposits are usually located long distances from operating bases, it is necessary to provide transportation facilities. This transportation is one of the greatest problems in the use of helium in airships. The usual method of transporting has been in steel cylinders of approximately $1^1/_2$ cu. ft. dead volume. These cylinders are filled at about 2000 lb. pressure, and at this pressure hold something like 190 cu. ft. of helium. Each cylinder weighs from 125 to 135 lb., and approximately 600 can be loaded into an ordinary box car. The helium content of these cylinders will amount to approximately 100,000 cu. ft. The transportation charges on this amount of helium from the Mid-Continent field to the Eastern Seaboard will amount to about $1200, or approximately $12 per 1000 cu. ft. The freight on the empty cylinders returned will be about $600, making a total of $1800 or $18 per 1000 cu. ft. of helium.

In their efforts to reduce transportation costs both in freight charges and in handling charges at their terminal, the Navy Department, several years ago, developed a tank car which would transport approximately 200,000 cu. ft. of helium at 2000 lb. pressure. Due to a favorable freight rate obtained for this car a very material reduction in the total transportation charges has been obtained. Using such transportation the cost of transporting helium from Dexter to Lakehurst has been reduced to less than $4 per 1000 cu. ft. This tank car, which consists of three cylinders about $4^1/_2$ ft. in diameter by 39 ft. long, cost originally in the neighborhood of $98,000, but later developments have made it possible to reduce this cost to approximately $60,000 per car. These large helium tank cars can also be considered as mobile helium storage. Cars of this character can be purchased almost as cheaply as fixed storage of the same kind.

Helium transportation cars of this character were used to some extent in Germany during the war. In this country, however, the first tank car of this kind was built in 1923. The Navy Department, as early as 1920, had been looking into the matter of having tank cars of this type built, but it was not until 1923 that manufacturers were willing to undertake the work.

Properties and Uses

In spite of the extremely small quantities of helium available prior to 1917, its properties and physical constants had already been most thoroughly investigated.

Helium has several remarkable properties which make it of great interest and which will make it one of the most important of the industrial gases. It is colorless and odorless. It has a molecular weight of 4 and is only slightly heavier than hydrogen, which is the lightest substance known.

Helium is almost completely inert. It cannot be made to enter

into chemical association with any other substance, with the possible exception of mercury and platinum under special conditions.

It has been shown that helium is not soluble in metals, either liquid or solid. This property may indicate that helium may find extensive use in metallurgical operations.

The solubility of helium in water and in aqueous solutions is only about half that of nitrogen and its rate of effusion is more than three times that of nitrogen. For this reason Dr. Elihu Thompson suggested that helium might be used in admixture with oxygen as an atmosphere for deep-sea divers and caisson workers. Since that time the Bureau of Mines at Pittsburgh has carried out a series of investigations to establish the feasibility of using a helium-oxygen mixture for this work. It has been proved that divers can work at a greater depth with greater comfort and with a much shorter decompression period when a helium-oxygen mixture is used instead of air. In other words, helium prevents the development of caisson disease or "bends." "Bends" is supposed to result from the liberation of small bubbles of nitrogen which have been dissolved in the body fluids at high pressure, and which later is released, some of it perhaps in the brain tissue, which renders the subject unconscious. Helium mixed with oxygen as a breathing medium prevents this, due to the fact that it is less soluble and upon release of pressure escapes into the lungs at a more rapid rate than nitrogen.

The weight of 1000 cu. ft. of helium, under normal atmospheric conditions, is 11 lb. That of air under the same conditions is about 75 lb. Therefore the buoyant effect or "lift" of helium is 65 lb. per 1000 cu. ft. The two new ships recently contracted for by the Navy Department will have a capacity of 6,500,000 cu. ft. The total lift or buoyant effect of the helium in these ships will be over 422,000 lb. The actual weight of the helium used would be 71,500 lb., or over 35 tons.

Outside of the aeronautical field there are few uses to which helium is now put. The largest use is perhaps for the inflation of toy balloons, and the next largest volume goes for research work. As this latter progresses it is quite certain that increasing uses will be found for the gas.

The first serious suggestion to use helium for the inflation of airships was made in England in 1914, and the matter was taken up seriously and studied by Sir Richard Threllfall. Early in January, 1915, Threllfall sent a chemist to Fredonia, Kansas, who obtained samples of the natural gas there, which were sent to England for analysis. He then presented complete plans and specifications for an extraction plant to be built in Kansas by methods which are now employed. The cost, according to his estimate, was about £3,000,000, or approximately $15,000,000. Therefore the British had already gone far in their investigations relative to the use of helium in airships before the United States entered the war. As soon as the United States entered the war the matter of using helium in airships was brought to the attention of the Army and Navy officials and immediately met with a very favorable reception. Funds were allotted, and three experimental plants were built immediately. The results of these experiments pointed to the fact that the production of helium was feasible and that it could be made at a reasonable price. For that reason the Government built a large helium plant at Fort Worth, Texas, which was under the direction of the Naval Bureau of Steam Engineering. This plant has been operating and has produced, during its life, about 50,000,000 cu. ft. of helium.

This plant, which was later transferred to the jurisdiction of the Bureau of Mines of the Department of Commerce, has now been abandoned. In its stead the Bureau has built a new plant of large capacity near Amarillo, Texas. The manufacture of helium on a large scale by the Government tends to make it difficult for private individuals to establish themselves in the business.

The use of helium in airships presents two or three special problems, chief of which is the saving of the gas. It is necessary that airship fabrics be tight so as to avoid loss of helium, and that means be provided to prevent valving the gas in the maneuvering of the ship. The first of these problems has been taken care of through the use of goldbeaters' skin as a lining for the gas cells, and the second through the use of condensers for recovering water from the exhaust of the engines.

Assuming a 6,500,000-cu. ft. ship, the total lift will be 422,000 lb. The lift of the same ship, using hydrogen, will be 455,000 lb. Therefore the gain in lift by using hydrogen is 33,000 lb. Recent tests have shown that hydrogen can be used mixed with helium to the extent of 20 per cent by volume without danger of the mixture being inflammable. Methods of purification have been devised for purifying this hydrogen-helium mixture without any danger of explosion. Therefore with an 80–20 mixture of helium and hydrogen the total lift of a 6,500,000 cu. ft. ship would be 429,000 lb., or a gain by using 20 per cent hydrogen of 6500 lb. or a little better than three tons.

The helium requirements for the operation of an airship of 6,500,000 cu. ft. capacity, are about as follows:

For initial inflation, assuming 90 per cent of capacity	5,850,000 cu. ft.
Operating reserve, 50 per cent of capacity	3,250,000 cu. ft.
Make-up helium, to replace loss, about 60 per cent per year	3,900,000 cu. ft.

Therefore the first year's operation of one ship would require about 13,000,000 cu. ft. of helium, of which 9,100,000 cu. ft. will remain at the end of the year.

Of the above three items the first must be on hand at the initial inflation of the ship. As to the second item, steps should be taken immediately after the initial inflation to start building up this reserve to take care of contingencies and insure continuous operation. The third item should be delivered continuously throughout the year in approximately equal monthly quantities. Should more than one ship be operated, the first and third items would have to be increased by the number of ships operated. The second item would not necessarily be any greater for several ships than for one.

In major airship operations a helium-purification plant is necessary. A complete purification plant, including building, consisting of two units with all necessary piping and auxiliaries, will cost around $165,000. Experience indicates that the helium in a ship under usual operating conditions should be purified about four times a year. This does not mean that every three months the entire volume in the ship should be removed and purified, but that the helium in the various cells, as it becomes contaminated by the air, should be removed and purified. In this way there would be a continuous cycle of the purification of the gas throughout the year. The cost of purifying helium is approximately $1 per 1000 cu. ft.

It has been estimated that the investment in helium storage, transportation, and purification facilities at an airship terminal, for four ships, would cost about as follows:

Tank cars (8) for 1,600,000 cu. ft.	$ 480,000
Storage for 6,000,000 cu. ft.	450,000
Purification plant	165,000
	$1,095,000

The investment in helium inventory would be as follows:

Helium in 4 ships (5,825,000 cu. ft. in each ship or 23,300,000 cu. ft. for four ships at $35 per M, plus $5 freight	$ 928,000
3,500,000 cu. ft. reserve at $35 per M, plus $5 freight	140,000
	$1,068,000

Total investment in helium and facilities, $2,163,000.
The total annual cost of helium for 4 ships would be as follows:

10 per cent depreciation on investment	$ 111,500
Insurance, taxes, maintenance, and repair, 10 per cent	111,500
Loss of helium, 15,600,000 cu. ft. at $35 plus $5 freight	624,000
Carrying charges on inventory, 6 per cent	55,000
Labor (not including labor of purification)	10,000
Administrative overhead	101,000
Purification 92,800 cu. ft. per year at $1	92,800
Total	$1,105,800

This cost represents all of the costs of helium at the home port for four ships operating continuously. There will be required perhaps 500,000 cu. ft. of helium storage in each foreign port, which will increase the investment in storage facilities by about $40,000 and the helium inventory by about $25,000.

By using 20 per cent of hydrogen in the helium, the inventory for helium would be reduced about 20 per cent; instead of an annual cost for four ships of $624,000 as given, the cost would be $499,200, plus cost of hydrogen at $2.50, or $8875, making a total of $508,075, or a saving of $116,000 per year for four ships.

If hydrogen were used alone, and estimating the cost at $2.50 per 1000 cu. ft., the loss through valving to maintain purity, especially if that purity is maintained at a point to give any advantage over the use of helium, would amount to 40 per cent of the

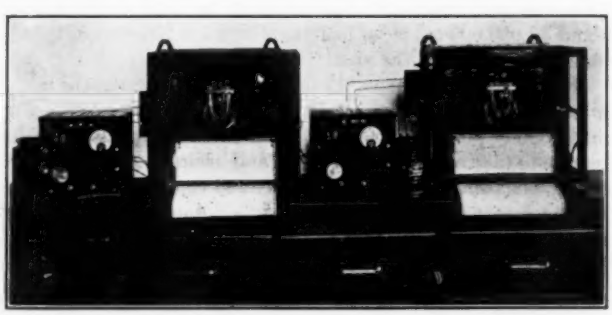

FIG. 13 HELIUM PURITY RECORDERS

(These instruments automatically record the purity of helium at the purification plant at Lakehurst. Instruments of the same type are used at Dexter, Kan.)

total volume per month, or 500 per cent per year. Therefore the annual cost of hydrogen would be $325,000 as against $624,000 for helium. This is less by $300,000 for the four ships, or $80,000 per ship. The saving in insurance on a helium-filled ship over a hydrogen ship would be very much greater than this, which would result in helium being the more economical of the two gases.

It is hoped that the presentation of these facts will serve to increase the public's faith in helium and strengthen its confidence in the continued supply of this commodity.

Discussion

R. A. CATTELL.[2] We wish to call attention to the following facts: The Amarillo helium plant of the U. S. Bureau of Mines has been in practically continuous productive operation since April 9, 1929. The Fort Worth helium plant was abandoned because the rapidly diminishing supply of helium-bearing gas there available did not warrant its further operation. The first helium tank car was supplied by the Army rather than the Navy.

[2] Chief Engineer, Helium Division, Washington, D. C.

R. H. UPSON.[3] The story of helium is one of the most fascinating in modern science, and it is natural to suppose that many practical uses will be found for a material of such unusual properties. But, although Mr. Bottoms does not say so, some one might get the impression that helium inflation is commercially a great boon to lighter-than-air craft and ignore the serious engineering objections to its use.

The direct cost of helium is not the big difficulty. The operating cost chargeable to the lifting gas in any case may be made comparatively small, especially with the improved gas-holding materials that may now be confidently predicted. But by the same token there should be no great difficulty about keeping up the purity of either hydrogen or helium. Helium at 97 per cent purity has a lift equivalent to hydrogen at about 90 per cent purity, or for equal purities there is about 7 per cent difference in lift. Then there is the important fact that a helium ship must take off with a considerable reserve space for expansion. Mr. Bottoms has mentioned 10 per cent, which seems a reasonable minimum, as a further deduction from the gross lift.

The next objection to helium lies in the very quality which is thought to be its chief virtue, its non-inflammability. If hydrogen, equivalent in lift to the gasoline consumed, is also burned in the engines, an additional distance range of about 20 per cent is obtained. This was demonstrated in England. The Germans accomplish the same thing more uniformly with their "fuel gas," filling the entire lower part of the hull.

There are of course redeeming features for helium. Its non-inflammability, as such, must not be passed lightly aside; though any ship in which gasoline and fabric play major parts can hardly be called fireproof. In a ship designed exclusively for helium, a slight saving could be made in structural strength and weight. Putting the engines within the hull is a substantial improvement, though not solely attributable to helium. On the whole the weights are probably about even, due to the extra water-recovery apparatus and other special equipment required by the helium ships.

Coming back to the more serious questions of lift and range, it is obvious that a pay-load of 20 per cent to 30 per cent of the gross, which is a good figure for hydrogen, will be easily cut in half if helium is substituted. With such a handicap in face of the rising efficiency of large planes, the future of commercial airships would be indeed dark.

But fortunately there are other possibilities besides the 100 per cent use of helium to which the foregoing remarks apply. A metal hull, Diesel engines, helium around the engine rooms and for emergency valving, and a substantial increase in strength and speed would seem to give to the airship its recognized advantages plus safety from fire and storm. Then will helium come into its own, and the fine work of such pioneers as Mr. Bottoms will have its due reward—but the way to get this golden egg is not by killing the goose!

R. B. MOORE.[4] The author's report on a natural gas containing as much as 7 per cent helium is extremely unusual, and if the volume of gas available is large, such a gas field should be of great use. I have been asked frequently whether there is enough helium in existence to take care of a reasonable demand for airship use when the number of airships is increased due to commercial demand for this kind of travel. The Amarillo gas field in Texas is probably the largest gas field in the world, and the Government has a lease on a portion of the field, containing a large volume of gas with a content of 1.7 per cent helium. For many years I tried to get Congress to appropriate money to acquire the whole of this field, but without success. If this

[3] Aeromarine Klemm Corporation, Keyport, N. J.

[4] Dean of Science, Purdue University, Lafayette, Ind.

could have been done, enough helium would have been available, and stored in the ground until needed, to take care of all the needs of the Army and the Navy for the next twenty-five or thirty years, besides having a surplus for commercial purposes. The United States is extremely fortunate in being the only country in the world having large supplies of helium-bearing natural gas.

The origin of helium in natural gas is very uncertain, as Mr. Bottoms has pointed out. I am not inclined to agree with any theory that depends on radioactivity for the origin of helium in natural gas. Of course, some of the helium in the earth's crust has a radioactive origin, as all rocks and minerals contain some radioactive material, but the helium that is concentrated in natural gas probably has another origin. The determination of the diffusion of helium through various types of rocks should be of great interest.

I trust that the company which Mr. Bottoms represents will be able to develop a satisfactory market for its helium. The Bureau of Mines has shown that helium can be substituted for nitrogen and an artificial atmosphere produced which can be used by those who are working in caissons under pressure. As helium is not as soluble in the blood lymph as is nitrogen, the use of such an artificial atmosphere instead of air largely eliminates trouble from the "bends." Further experimental work along this line should be carried out.

Author's Closure

Mr. Upson states that, although I do not say so, some one might get the impression that helium inflation is a great boon to lighter-than-air craft. I am sorry that I did not make myself clear on this point. If we remember correctly, the burning of the Goodyear blimp in Chicago, the destruction by fire of the *Roma*, the explosion of the *R-38* in England, and the burning of the French airship *Dixmude* were all milestones in the death march of lighter-than-air craft until helium appeared and gave renewed life to this mode of travel. It is my firm belief that without helium there would be no lighter-than-air activity in the United States today, and it seems a conclusion that helium is a great boon to lighter-than-air craft, regardless of any engineering objection to its use.

In regard to the difference in lift between helium and hydrogen, that difference is about 7 per cent, but Mr. Upson gives the impression that to this difference must be added the 10 per cent reserve space for expansion. Now this 10 per cent reserve space for expansion is necessary or desirable even though hydrogen is used; consequently, the difference is not 17 per cent but the original 7 per cent.

This difference in lift seems to the author to be the only point in which helium does not compare so favorably with hydrogen, but, on the other hand, in the ships now being built by the Navy Department the useful lift will probably be in excess of 40 per cent of the gross lift. Allowing for fuel for a 5000-mile cruise will still leave 25 per cent of the gross lift for pay-load even with the use of helium, and inasmuch as fuel consumed in a ship of this size is not over 3 gallons per mile it would seem that there would be no reason for the use of hydrogen even though it did not possess the dangerous qualities of explosion and inflammability.

Mr. Upson seems to assume that the non-inflammability of helium is a hindrance in view of the fact that hydrogen can be used as additional fuel. Hydrogen's B.t.u. value is only about 300 per cubic foot and the fuel gas used by the Graf Zeppelin about 1800 B.t.u. per cubic foot. The fuel gas floats in the air without giving either weight or lift, and these facts would seem to answer his question as to the inability of using helium as additional fuel in the engines.

He states further that a ship in which gasoline and fabric play major parts can hardly be called fireproof, but that the use of Diesel-engine and metal-clad ships will be one of the future developments. There seems to be no reason why helium cannot be used in metal-clad ships, together with Diesel engines, and make the whole thing 100 per cent fireproof. When the metal-clad ship is fully developed and the Diesel engine is perfected, there is no reason why helium will not add its further advantage of non-inflammability and finally bring lighter-than-air craft to a point of development where they will compete not with airplanes but with ocean-going surface craft. The day when the airplane can compete with airships in transoceanic service is indeed remote.

Another thing that would seem to make the use of hydrogen practically out of the question in this country is that hydrogen filled ships cannot be insured, while helium-filled ships can be.

Replying to Dr. Moore, I would say, first, on the question of new uses for helium, a research program is now being carried out for the purpose of discovering new uses and extending present uses for helium. One of the uses is of course in diving and caisson work, and it is planned, if possible, to establish a fellowship at one of the large universities for carrying on further study of the matter.

Dr. Moore does not agree with me thoroughly on the origin and occurrence of helium, but since the whole question as to the occurrence of helium has been unsatisfactorily explained, it is admitted that one guess is probably as good as another and probably will be until sufficient data can be collected to clear up the points not very well understood.

AER-51-21

Recent Developments in Aircraft Instruments[1]

By W. G. BROMBACHER,[2] WASHINGTON, D. C.

Aircraft instruments are separated into four groups by the author, (1) for the power plant, (2) for speed, (3) for altitude, and (4) for navigation. General performance requirements are outlined, and testing equipment and procedure used at the Bureau of Standards are described. Among operating problems the author considers instrument-board vibration as most serious. The variation in temperature to which aircraft instruments are subjected causes a severe lubrication problem.

Standard dimensions for some of the instruments have been adopted. This makes these instruments interchangeable on the instrument board, and this is considered an outstanding achievement.

AERONAUTIC instruments may be divided into two classes, flight instruments and ground instruments. Flight instruments include those installed in the aircraft and ground instruments those required on the ground in connection with aircraft operation. The dividing line between flight and ground instruments is very sharp. Flight instruments must be simple in construction and light in weight, must operate under difficult conditions, and must require absolutely the minimum amount of adjustment, etc.; while in contrast, ground instruments may be as complicated and heavy as is necessary.

Flight instruments may be divided into service instruments and experimental instruments, although the dividing line between the two classes is not sharp. Service instruments include, primarily, those which it is customary to install to aid the pilot in operating and navigating the aircraft. Experimental instruments are those used for performance testing in flight, for competitive flights, for free-flight investigations, new types of instruments not yet fully developed to the service stage, and instruments which are not generally used. Experimental instruments include many types which will be in common use tomorrow. An important distinction exists between service and experimental instruments from the viewpoint of the instrument manufacturer, since service instruments in general are needed for every aircraft, while experimental instruments are required only to a limited extent by aircraft manufacturers.

Service instruments as defined also include those needed especially for high-altitude flying, and in aerial photography. At the present time these instruments may be designated as experimental, since relatively few are required at the present time.

Aircraft instruments are particularly interdependent upon each other. Thus, a change from level flight to climbing will cause a decrease in air speed provided the engine speed remains constant, an increase in altitude, and a change in the indication of the fore-and-aft inclinometer. Further, a rate-of-climb indicator is used now as an inclinometer rather than to measure rate of climb. It is, therefore, with some reservation that the customary classification of service instruments is given. A number of experimental instruments under each class is included. Astronomical-navigation instruments are classed as experimental because their use is not common. They are needed only in experimental flying and in special long-distance flights, such as that of Hegenberger and Maitland from California to Hawaii and that of the *Southern Cross* to Australia.

CLASSIFICATION OF AIRCRAFT INSTRUMENTS

1	Power Plant Instruments	
	Service	Experimental
	Tachometers	Supercharger instruments
	Oil or water thermometer	Recording tachometer
	Oil- and fuel-pressure gages	
	Fuel-quantity gage	
	Fuel-flow meter	
2	Speed Instruments	
	Service	Experimental
	Air-speed meter	Air-logs
	True air-speed meter	Air-speed recorders
		Ground-speed meter
3	Altitude Instruments	
	Service	Experimental
	Aneroid altimeter	Absolute altimeter
		Barograph
		Free-air thermometers
4	Navigation Instruments	
	Service	Experimental
	Magnetic compass	Sextant
	Turn indicator	Chronometer or watch
	Bank indicator	Induction compass
	Drift indicator	
	Fore-and-aft inclinometers	
	Radio beacon	
	Clock	

The discussion which follows is almost entirely restricted to the round-dial instruments, however, some mention should be made here of vertical-scale instruments. Tachometers, thermometers, pressure gages, and air-speed indicators are available both in the vertical-scale and round-dial types. A combination vertical-scale instrument, known as an engine-gage unit, consists of the two pressure gages and the oil or water thermometer. Although the vertical-scale instruments have some advantages, notably that of conserving space on the instrument board, they compare unfavorably with the round-dial type in such essential factors as performance and cost. For single-engined ships the present trend seems to be toward the general use of the round-dial instrument. In multi-engined ships there is considerable advantage in grouping the power-plant instruments together, so that the use of the engine-gage unit mentioned is finding considerable favor. The use of the vertical-scale tachometer is also advantageous when it is possible to have all of the indicators side by side on the instrument board, to show at a glance comparative performance in case of multiple-engine installations.

General-Performance Requirements. The performance of aircraft instruments must be satisfactory under conditions of use which are comparatively very severe. Many of these conditions either do not exist or do not occur with the same severity in ordinary engineering practice, and therefore have not required special consideration from the manufacturer of engineering instruments. The severe conditions of use have been reflected in the acceptance tests required in the current specifications of the Army Air Corps and Bureau of Aeronautics. The tests have been divided into two classes, one including tests to which all instruments are subjected, the other including what are known as type tests, to which a limited number of samples are subjected. The individual tests under the first class include a scale-error test at room temperature, if the instrument is calibrated quantitatively, and such other tests as bring out individual differences in performance due to workmanship rather than to design. Low cost and ease of making the individual test are important factors. In type tests the instruments, in general, are tested for the effect of temperature in the range —35 deg. cent. to +45 deg.

[2] Chief, Aeronautic Instruments Section, Bureau of Standards, Washington, D. C.

Presented at the Third National Meeting of the A.S.M.E. Aeronautic Division, St. Louis, Mo., May 27 to 30, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

cent., the effect of pressure change, vibration, elastic defects such as drift, lag, hysteresis, and after-effect, seasoning, excessive friction, position error, time lag in the indication, proper damping, strength of parts subject to external stress, durability, and other properties which may have a bearing on the desired performance of the instrument. In addition to the above characteristics, all of which can be determined quantitatively in the laboratory, the weights of the instruments must be a minimum, they must have luminous dials, must be made of non-corrosive parts as far as possible, must have the mechanism balanced to minimize the effects on the indication of large accelerations, and must in general operate satisfactorily under all conditions of severe usage which occur in practice. In the current military specifications

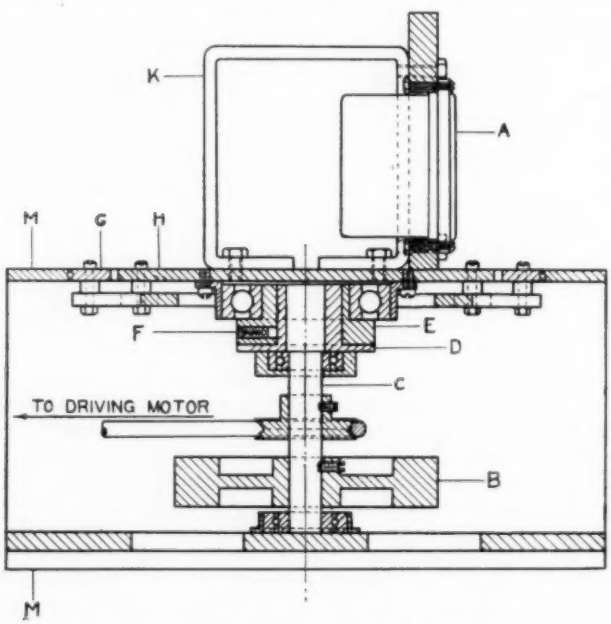

FIG. 1 BUREAU OF STANDARDS VIBRATION RACK

(E and D form an adjustable cam, which imparts a simple harmonic motion to frame G at right angles to the plane of the figure and to frame H in the plane of the figure. The amplitude is adjusted by rotating E with reference to D after loosening set screw F. An instrument under test is shown at A.)

the tolerances are based on the accuracy needed by the pilot when the instruments can be made to meet it. In the cases where the art has not progressed to the point of furnishing instruments possessing the needed accuracy, the tolerances express approximately the best performance which can reasonably be obtained. The performance of a number of service instruments will be given in more detail in following sections.

TESTING EQUIPMENT AT THE BUREAU OF STANDARDS

It may be of value to describe briefly the test procedure, and the quite complete testing equipment of the Bureau of Standards, since relatively few laboratories are equipped to test aircraft instruments completely. The equipment is described in a series of technical reports issued in 1921 (references 2 to 7) of the National Advisory Committee for Aeronautics, but in many instances improvements in equipment have made these descriptions out of date.

Practically all types of instruments must be tested for the extraneous effects of temperature, pressure, and vibration. Temperature and pressure control are required also for testing thermometers and pressure-measuring instruments. The equipment for these tests is, (*a*) temperature-control chambers, (*b*) pressure-control apparatus, and (*c*) vibration board.

Temperature-Control Chambers. At the present time there are available in the aeronautic-instruments laboratory three cork-insulated temperature chambers which can be cooled below room temperature by means of a common ammonia-refrigeration system, and can be heated by individual electric heaters. One of the chambers (inside dimensions 48 in. × 36 in. × 30 in. high) has been found sufficiently large to contain such instruments and testing equipment as it has been desired to test. As has been stated, specifications require tests at −35 deg. cent., +20 deg. cent. and +45 deg. cent. The ammonia-refrigeration system is inadequate in that −35 deg. cent. is practically the lowest temperature which can be attained with it, while a temperature of −50 deg. cent. is required often for special tests. Temperatures as low as −45 deg. cent. are now obtained in a bell jar of fair size using liquid CO_2 and it is planned eventually to change from the ammonia to a CO_2 refrigeration system. It may be interesting to know that a suitable apparatus for experimental-instrument work has been designed and constructed at the Langley Memorial Laboratory of the National Advisory Committee for Aeronautics (reference 15) in which a bell jar is cooled by liquid CO_2 from commercial cylinders.

The glass windows of the temperature chambers are prevented from frosting by using four to six individual glass windows, each separated by an air gap. A source of trouble is the difficulty in securing good service from electric ventilating fans mounted in the chambers. A non-freezing lubricant must be used if they are mounted inside of the chambers, but better service may be secured by mounting the motor outside the chamber, and passing the fan shaft through the wall.

Pressure-Control Apparatus. For testing altimeters, barographs, supercharger gages, compasses, and most other instruments the pressure-control apparatus consists usually of a bell jar and metal base, together with a suitable vacuum pump. For pressures above atmospheric, which are required for some of the above instruments, a bell jar is unsuitable for constant use, although with proper clamps it can be made to "hold." Shallow metal containers with glass covers are also available for pressure control, especially for values about atmospheric.

The size of glass bell jars is limited, and is often inadequate, notably in testing aircraft thermometers. For the above, and for other reasons a steel altitude chamber has been constructed. This has a diameter of 54 in. and a useful height of 96 in. with a door opening of 16 in. × 53 in. Pressures ranging from atmospheric to that equivalent to 30,000 ft. are obtained, and provision has been made for temperature control. A port hole 5.5 in. in diameter was found to permit ample vision into the chamber.

Pressure control for instruments with external pressure connections such as air-speed indicators is an individual and relatively simple problem.

Vibration Board. Within the past two years there has been designed and constructed a new vibration board which is now in constant use. Credit for the design should be given to Dr. V. E. Whitman. The chief improvement over the older type lies in the independent control of frequency and amplitude. In the older models the centrifugal force developed by a revolving eccentric weight was used to vibrate a panel containing the instruments. The panel was connected to its support by means of helical springs. The amplitude of the vibration depended on both the frequency, and the combined weight of the panel and instruments.

A cross section of the new model is shown in Fig. 1. The construction is essentially as follows: A motor-driven shaft carries an adjustable eccentric by means of which each of two plates properly restrained move in simple harmonic motion in planes at right angles to each other. The instrument under test

is mounted on one of the plates and is thus subjected to a uniform circular vibration.

Standards and Standard Instruments

Essentially the performance of instruments is determined by comparison of their reading with that of a master instrument. The latter may be a primary standard, but more often is a secondary standard which is used because of its greater convenience, its accuracy being determined from time to time by comparison with a primary standard. A brief discussion of the standard instruments, and of certain standard relations which are used in testing aircraft instruments follows.

Air-speed Standards. The air speed of airplanes is now usually determined by means of the differential pressure developed by a pitot-static tube headed into the free airstream. The relation between air speed and differential pressure which has been adopted for calibrating air-speed indicators contains the assumption that the air is compressible, and is as follows:

$$\frac{p + p_0}{p_0} = (1 + 0.34526 \times 10^{-6} V^2)^{3.5} \quad \ldots\ldots\ldots [1]$$

in which p is the differential pressure, p_0 the standard atmospheric pressure (760 mm. of mercury) and V the air speed in miles per hour.

The pressures determined by formula [1] are higher than those given by the familiar relation $p = {}^1/_2 \rho V^2$, in which the air is assumed incompressible, by 1 per cent at 150 m.p.h. and by 1.7 per cent at 200 m.p.h. Here ρ is the standard density (at 15 deg. cent. and 760 mm. of mercury). For further details see references 10 and 14.

Table 1 gives convenient values of the standard air speed and pressures for the calibration of indicators.

TABLE 1 AIRSPEED CALIBRATION VALUES

Airspeed, m.p.h.	Differential pressure, inches of water	Airspeed, knots	Differential pressure, inches of water
0	0	0	0
10	0.049	10	0.065
20	0.197	20	0.261
30	0.443	30	0.588
40	0.788	40	1.045
50	1.231	50	1.634
60	1.774	60	2.354

300	46.03	300	61.82

A suitable cistern-type water manometer is used as the standard in the calibration of the indicators.

Altitude Standards. The altitude of aircraft is still determined by the barometric method in view of the lack of an absolute type of instrument. A standard atmosphere was adopted in 1925 for use in the United States based on an arbitrary altitude-temperature assumption. The altitude-pressure relation of this atmosphere is used in calibrating altimeters. (See references 16 and 17.) Table 2 gives the pressure and temperature at standard altitude in the range 0 to 40,000 ft.

In laboratory tests the indication of the altimeter is compared with that of a standard mercurial barometer which differs from the Fortin type in that the cistern is made air-tight except for a pressure connection through which the pressure above the mercury in the cistern can be controlled. (See reference 2.)

Improvement is desirable in the standard for testing altimeters in field laboratories, since the latter are usually without facilities to check the mercurial barometers. One arrangement which has some advantages, and has given quite satisfactory service is that of a reservoir-mercurial manometer used with the altimeter testing equipment together with a Fortin-type mercurial barometer, the latter measuring the atmospheric pressure so that the absolute pressure can be determined. Another suggestion would substitute the use of an aneroid barometer as the standard. The latter suggestion has found little favor thus far because of the lack of sufficiently good instruments. The recent improvement in altimeters has gone far toward meeting this objection.

TABLE 2 U. S. STANDARD ATMOSPHERE PRESSURES

Standard Altitude thousand feet	Pressure Inches of mercury	Mm. of mercury	Temperature, deg. cent.
0	29.921	760.0	+15.0

40000	5.54	140.7	−55.0

A very convenient standard instrument for field use is the mercurial barometer suggested by Barnes (reference 18) which can be transported empty of mercury, and the proper vacuum above the mercury column obtained when desired by the use of a fairly good vacuum pump. Essentially the instrument consists of a U-tube manometer inverted into two cisterns. By controlling the pressure in both cisterns the mercury can be made to fill completely the manometer legs. If the mercury column is then broken at the bend of the U-tube, a vacuum will be formed above the mercury column, and one leg with its cistern then constitutes a mercurial barometer.

Engine-Speed Standards. Essentially the equipment already described (reference 5) is still in use and will not be discussed.

Miscellaneous Standards. A dead-weight oil-gage tester is used to test oil-pressure gages. In testing the gages at low temperatures (—35 deg. cent.) it was found necessary to avoid freezing the liquid in the cold part of the apparatus. The difficulty was finally met in a satisfactory manner by using an oil in the system which had a pour point of —40 deg. cent.

Standards and associated equipment are also available to test flow meters and accelerometers. This equipment is now undergoing further development, and a description will be omitted at present. Most other service instruments require standards of such relatively low accuracy, and are so well known that a description is not essential here.

Power-Plant Instruments

At present supercharger instruments are classed as experimental, due to the fact that superchargers themselves are experimental. No serious problems are involved in furnishing the pressure gages and thermometers which may be needed to control the operation of the supercharger. Recording tachometers are useful in flight-test work, and as an aid in keeping an engine

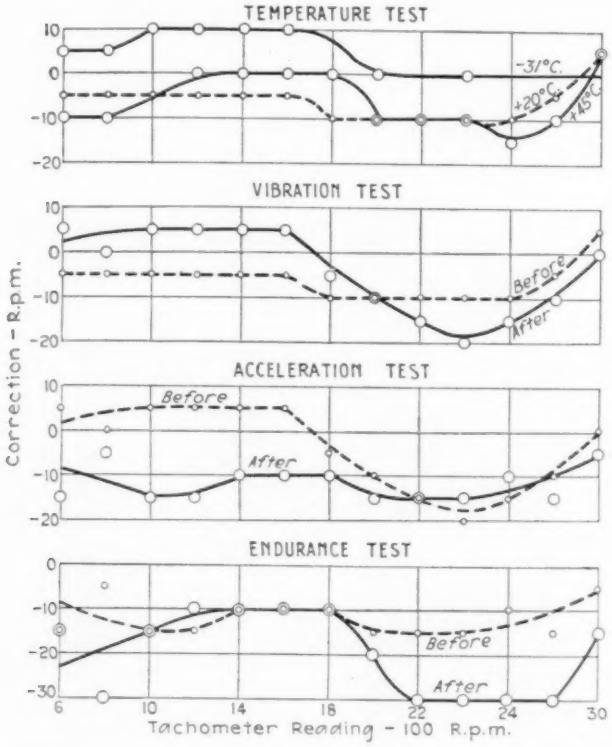

Fig. 2 Performance of a Recently Developed Centrifugal Tachometer

log. No recording tachometer of American make is commercially available at the present time. A detailed consideration of the service power-plant instruments follows.

Tachometers. At present the choice of a tachometer for single-engined airplanes is usually made between the chronometric and centrifugal-type instrument. These instruments are practically restricted to the case when a short drive shaft with few bends is possible. The essential features of these instruments have not changed in the last few years. For descriptions see reference 5. The performance of the chronometric instrument manufactured in this country has remained unchanged for many years. Except possibly for endurance, the performance is adequate. See reference 5.

Centrifugal tachometers are now being made by a number of manufacturers in this country. A recent development in these instruments has been the reduction from a $3^3/_4$-in. to a $2^3/_4$-in. dial by the manufacturers at the initiation of the Navy Bureau of Aeronautics. Improvement of this type of instrument is still believed desirable, and no doubt will be effected in the near future.

The performance required of centrifugal tachometers by the military services is based on securing an accuracy of approximately one per cent under all conditions. The instruments are subjected to the following tests:

a Test at room temperature for accuracy of calibration.
b Scale-error test at —35 deg. cent. and +45 deg. cent.
c Vibration for 3 hours and test to determine change in scale errors.
d Effect of over speed on scale errors.
e Effect on scale errors of accelerating to a given speed in one second for 500 times.
f Position error at various speeds.
g Change-in-scale errors after an endurance run of 300 hr.

The performance tolerances are most conveniently expressed for most of the type tests in terms of the average change in the error. A small number from a production lot of a recently developed centrifugal tachometer have been tested. These instruments have an equally-divided scale from 500 to 3000 r.p.m. indicated speed with 20 r.p.m. for the smallest scale division. Some of the test results on the best instrument are given in Fig. 2.

The direct-drive feature of centrifugal and chronometric tachometers is unsatisfactory in multi-engined ships where the distance from the cockpit to the engine is great. Current practice has been to mount the tachometer on a strut close to the outboard engine, thus forcing the pilot to turn from the instrument board in order to read the speed. Two of the possible types of instruments which permit an indication on the instrument board are now being developed by commercial organizations. One of these instruments consists of a commutator attached to the cam shaft of the engine, and an indicator consisting of an electromagnet and chronometric tachometer combined. A battery furnishes the power. The commutator controls the rate of operation of the electromagnet, which in turn operates a pawl forming the connecting link with the chronometric tachometer.

The other type of distant-indicating tachometer consists of the well-known direct-current magneto and voltmeter. Modifications are necessary however in order to make the instruments now available satisfactory for aircraft use. The bulk and weight of the magneto must be as small as possible, and the indicator should have a pointer motion greatly in excess of the customary 120 deg. in order to permit the use of an instrument of standard-case dimensions. A recent investigation in the Aeronautic Instruments Section of the Bureau of Standards conducted by J. B. Peterson has indicated the method by which complete compensation for the effect of temperature changes can be effected, and the extent to which this method can be used. It is essential to compensate the indicator and magneto separately since the temperature of each varies independently.

The importance of proper lubrication for tachometers should not be overlooked. If the instrument is to meet laboratory tests the lubricant should not freeze at —35 deg. cent., evaporate to any great extent at +45 deg. cent., nor require replacement during an endurance run of 300 hr. These conditions are not believed to be more severe than those obtained in service. Further experimentation on this point is desirable.

Aircraft Thermometer. These instruments are furnished in the vapor-pressure and the liquid-filled types. For descriptions see reference 5. An accuracy of about 4 deg. cent. is required of oil or water thermometers purchased under military specifications. This requirement causes no special difficulty to the manufacturer except for the effect of temperature on the line and indicator of liquid-filled instruments. Vapor-pressure instruments on the other hand have the disadvantage of being affected by changes in altitude (pressure effect), and also of having roughly only one-sixth the operating pressure per degree centigrade at 0 deg.

cent. as at 100 deg. cent. The vapor-pressure instrument appears on the whole to be the preferable type.

Oil- and Fuel-Pressure Gages. Since only a low degree of accuracy is required in measuring fuel and oil pressure (about 3 per cent of the maximum indicated pressure) no development work has been necessary on the gages. There have been changes, such as the reduction of the dial size to $1^7/_8$ in., and improvements in the method of connecting the tubing to the indicator. A further change may be desirable in the oil-pressure gage design in order to obviate the effect on the indication, of the oil freezing in the indicator and tubing at low temperatures. Fig. 3 is included to show the effect of temperature on Bourdon tube pressure gages.

Fuel-Quantity Gage. None of the variety of gages now available appears to give universal satisfaction. The instrument may be divided into the hydrostatic and float types. The indication of the hydrostatic-type instrument depends upon the density of the fuel as well as the head. The chief difficulty appears in securing a satisfactory instrument which indicates on the instrument board. In addition to the familiar aircraft and various automobile fuel gages available, two types may be classed as new developments, although not yet out of the experimental stage. In the first of these a pressure indicator at the instrument board is connected to the bottom and top of the tank by means of air lines. The line to the bottom of the tank is connected to a cellophane capsule. A quantity of air remains in the airtight system consisting of the pressure element of the indicator, the air line, and the cellophane capsule. The volume of the system is so proportioned, and the cellophane capsule so flexible that neither changes in air pressure nor temperature cause any change in the indication. The cellophane capsule is surrounded by the fuel so that its internal pressure is controlled by the hydrostatic head of the fuel thus affording a measure of the fuel quantity.

The laboratory of a large electrical company has recently announced the successful development of a distant indicating instrument which depends on the effect of the pressure head of the liquid on a carbon pile. No further details have come to the attention of the writer. Attention is directed to two gages of the float type (described in reference 9), which have met with some favor abroad.

Fuel-Flow Meters. A fuel-flow meter recently brought out commercially consists of a Venturi tube in the gas line, and an indicator on the instrument board. Two fuel lines lead from the Venturi tube to the indicator, one to a diaphragm capsule, and the other to the case of the instrument. This requires that the case be made airtight against a differential pressure of about five lb. per sq. in. For one type of Venturi tube now furnished, the differential pressure operating the indicator mechanism is about 16 in. of water for a rate of flow of 60 gal. per hour. Maintaining a leak-tight case under all conditions is problematical, so that it appears desirable to have a by-pass for the fuel around the case which can be controlled by the pilot. An indicator with two opposed diaphragm capsules would be a desirable development since it would make unnecessary the filling of the instrument case with the fuel. When calibrated in pounds per hour the following equation holds:

$$W = K_1\sqrt{pd} \quad \ldots\ldots [4]$$

When in gallons per hour

$$G = K_2\sqrt{\frac{p}{d}} \quad \ldots\ldots [5]$$

in which W and G are the rates of flow in pounds and gallons per hour respectively, p the differential pressure developed by the Venturi tube, d the density of the fuel, and K_1 and K_2 constants depending on the design of the Venturi, and on units of measurement.

Attention should be called to the recent announcement of the production by the British Royal Air Force of a fuel-flow meter of the sink-and-tube type (reference 9).

Speed Instruments

Of the instruments classified as experimental, the air log is useful in the dead-reckoning method of position finding, and the air-speed recorder in flight testing and flight research. The ground-speed meter is an example of an instrument which is desired for regular equipment, but none of the types now available are adequate since all depend upon the visibility of the ground for their operation.

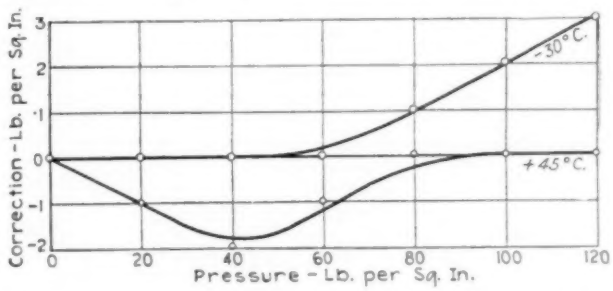

Fig. 3 Effect of Temperature on Scale Errors of an Oil-Pressure Gage

Air-Speed Meter. The air speed of airplanes is usually determined from the differential pressure developed by tubes such as the pitot-static and pitot-venturi types. The indications of the differential-pressure type instruments depend on the air density as well as the air speed. The instruments are calibrated to indicate correctly at one air density. A correction must be applied to the indications for deviations from this density. The reading of the indicator, corrected for instrumental errors but uncorrected for deviations in air density, is called the indicated air speed.

Since 1920 steady progress has been made in changing from the pitot-venturi type to the pitot-static tube-type instrument. The adoption of the pitot-static type instrument has required the development of the technique of making diaphragm-pressure capsules for the measurement of low pressures. Today there is in use an indicator with a $2^3/_4$-in. dial weighing 11 oz. in which the pointer has an angular movement of about 300 deg. for a pressure change as low as 10 in. of water (equivalent to 140 m.p.h.). The performance of the indicator is determined by the following laboratory tests:

a Test at room temperature for scale errors.
b Scale-error tests at —35 deg. cent. and +45 deg. cent.
c Vibration for three hours and test to determine change in scale errors.
d Drift test or change in reading in five hours at a given (high) speed.
e Seasoning or effect on scale errors of subjecting instrument to 100 full-scale deflections.
f Position error at various readings.
g Effect on scale errors of subjecting instrument to specified over pressures.

Usually the smallest scale division is five miles per hour or five knots which makes the least reading at best 0.5 m.p.h. or knots. Scale errors up to 1.5 per cent of the range are allowed. Average changes in calibration due to vibration, seasoning, and over-pressure have 0.5 per cent tolerances, and a permitted drift 0.6 per cent of the speed range. The change in scale value with temperature is somewhat larger, amounting in speed units to

about one to 1.5 per cent in the temperature interval —35 deg. cent. to +45 deg. cent. This is, as predicted by theory, about one-half of that caused by the change in the elastic modulus, but it can, of course, be much greater especially if the design is such that differential expansion is a factor. Fig. 4 shows the effect of temperature, vibration, and seasoning on a typical good indicator. The errors are larger at very low speeds owing to the small differential pressures available at lower speeds and the pointer position is also more uncertain.

The size of the pitot-static tube of the service-type air-speed meter is restricted because of the conditions involved in handling an airplane so that the openings are located in a position very close to the tube support. It is well known that the openings, especially the static openings, must be placed in the undisturbed air stream in order to develop the theoretically correct pressures. Finding the best location for a pitot-static tube with openings

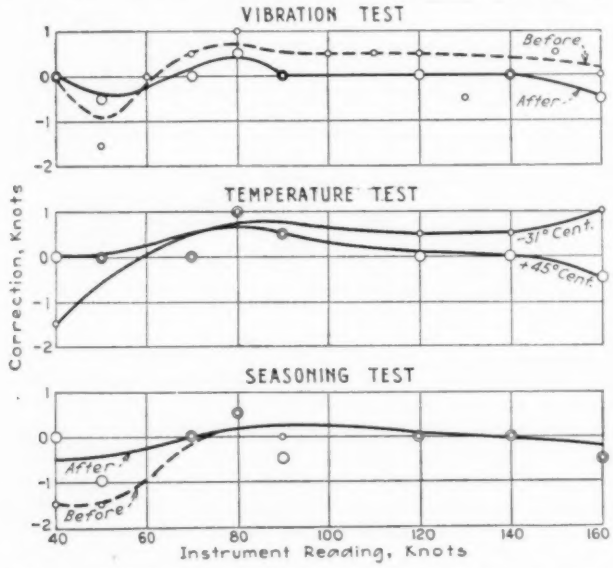

FIG. 4 PERFORMANCE OF AN AIR-SPEED INDICATOR OF THE PITOT-STATIC TYPE

four or six inches from a strut or 12 in. in front of the leading edge of a wing is an individual problem for each type of aircraft. In nearly all cases it is necessary to calibrate the complete installation over a speed course in order to secure the accuracy in the air-speed measurement consistent with the present high quality of the indicating instrument. The errors in air-speed measurement in flight with the equipment usually installed are greatest at the stalling speeds. The simplest solution of the problem appears to be that of having available for the pilot's use, the results of a speed-course calibration of the air-speed meter installation, at least for the cruising and stalling speeds.

In the operation of the pitot-static air-speed meter consideration must be given to preventing stoppage of the line by rain, snow, and the freezing of rain. Trouble with leakage in the line is largely avoided by the present practice of using an all-metal tube, avoiding even the use of rubber connecting tubes.

True Air-Speed Indicators. By definition these are instruments which indicate the air speed directly, without the necessity of correcting for deviations of the air density from the standard value. In terms of true air speed the stalling speed of an airplane varies with air density, but in terms of indicated air speed it is independent of density. A knowledge of indicated air speed is therefore of primary importance in airplane operation. However, for the purposes of navigation it is also desirable to know the true air speed.

In airship operation a knowledge of the true air speed is desired since the operation of the ship does not, as in the case of airplanes, depend upon a knowledge of the indicated air speed. This is made necessary further by the difficulty of measuring small values of the indicated air speed. In order to mount the air-speed element in the undisturbed air stream it must be mounted well away from the airship which almost necessitates a distant indicating instrument of the electrical type. For use on Navy airships the Bureau of Standards has developed the commutator-condenser type of air-speed indicator. A propeller in the air stream operates a commutator through which an electric capacity is alternately charged from a battery and then discharged through an ammeter. The ammeter can be calibrated in terms of true air speed since the number of discharges per second is proportional to the true air speed. (Reference 19.)

ALTITUDE INSTRUMENTS

Of the altitude instruments called experimental in this paper the absolute altimeter will undoubtedly be a future service instrument. Three possible methods of measuring the tape-line altitude of the aircraft, as contrasted with the pressure altitude, have been under intensive development in a number of laboratories both here and abroad. These methods have given rise to the following instruments: the sonic altimeter, the capacity altimeter, and the radio altimeter. No detailed description of the individual instruments thus far developed is available, but it appears at the present writing that absolute altimeters of one or more of these types will soon be available.

The barograph and free-air thermometer included under experimental instruments are largely used in the flight testing of aircraft and in special investigations and flights. Their consideration is beyond the scope of this paper.

Aneroid Altimeter. The service altimeter of today varies greatly in external appearance and performance from its predecessor of 10 years ago. The mechanism is now enclosed in a bakelite case, the dial size has been reduced from $3^1/_2$ to $2^3/_4$ in. and the weight from 14 to 11 oz. The ranges of the instruments commonly used by the military services are now 20,000 and 35,000 ft. with a pointer movement of two revolutions for the 20,000-ft. instrument, and $1^3/_4$ revolutions for the higher-range instrument. The older instruments are based on a pointer movement of one revolution for 20,000 ft. The scales of the instruments are equally divided, as has always been customary in this country. The most striking feature is the improved performance of the best present-day instrument as shown by the accompanying table. See also Figs. 5 and 6.

PERFORMANCE OF ALTIMETERS

Error	Instrument 1919	1929 Range in Feet	1929
	20000	20000	35000
Scale errors at +20 deg. cent. in feet	0 to 400	0 to 100	0 to 400
Maximum elastic hysteresis in per cent range	1.5	0.1 to 0.2	0.1 to 0.2
After effect in per cent of range	1.0	0.1 to 0.2	0.1 to 0.2
Drift in per cent of range	0.8	0.4	0.4
Change in reading at 760 mm. Hg in temperature interval +40 to —10 deg. cent., in feet	100 to 150	10 to 50	100 to 150
Change in scale value in per cent			
+40 deg. cent. to —10 deg. cent.	3 to 5	.....	.....
+20 deg. cent. to —35 deg. cent.	.....	1.0	1.4

The instruments contrasted are those of the best quality made in production, and not special hand-made instruments. The definitions of the above errors as used in aircraft instrument work are given below.

The *elastic hysteresis* is the difference in the scale error of the altimeter at a given reading, determined by subjecting the instrument first to pressures decreasing to the highest indicated

altitude and then to pressures increasing back to the atmospheric pressure.

The *after effect* is the hysteresis at full atmospheric pressure (0 altitude).

The *scale value* is defined as the ratio of the actual altitude change to the corresponding change in the indication of the instrument.

The *drift*, often spoken of as *creep*, is defined as the change in reading with time at some altitude other than zero, while the pressure is held constant.

The improvement of the elastic qualities of the altimeter has opened up a number of possibilities, among which may be mentioned its increased utility for landing purposes. If an instrument of good quality and with known errors is used, it is believed that the over-all instrumental performance can be depended upon to within 50 ft., even under severe conditions of usage. In order to avoid the inherent defects of the barometric method of measuring altitude, the effective use of the instrument is linked up with obtaining information from the proposed landing field as to the pressure of the ground level so that the pointer of the altimeter may be reset in such a way that it will indicate zero upon landing.

One of the problems of aerial photography is that of flying level. Methods have been proposed involving the use of a statoscope, a rate-of-climb indicator, or a sensitive altimeter, as well as methods of a more indirect nature. The present trend of development in altimeters indicates that the use of a sensitive altimeter may be the ultimate solution. Instrument makers are making effective progress at the present time in the development of an altimeter of 20,000-ft. range with the pointer making 20 revolutions for this range. One manufacturer now has available an instrument of this type with a six-inch dial. Further developments are under way and will be looked forward to with interest.

Navigation Instruments

The navigation of an airplane consists principally in maintaining the normal flying attitude and the proper direction of flight toward the destination, and in being able to determine the position of the airplane and to clear obstacles. In scheduled flights over airways, and in a large amount of other flying when the ground is visible, the navigation is of the simplest sort. The navigator determines his position and flying attitude almost entirely by observing landmarks. These are observed to give the position, and are used also to determine the direction of flight. The present movement to have the names of towns, together with the direction of the meridian and location of nearest landing field, marked on roofs and other suitable spots is a great aid to this type of navigation. The service type of navigation instruments listed in this paper are useful but not essential under these conditions.

An entirely different situation exists when the ground is not visible. Three elements must be considered, maintaining the proper flying attitude, the proper direction of flight, and making the landing. The proper flying attitude can be maintained only by the aid of instruments, of which all of those needed are now available.

The magnetic compass and the turn indicator are inadequate to maintain the proper course in flight under these conditions, since the drift cannot be measured when the ground is invisible. The radio beacon has been developed to meet this problem, and has been found to be indispensable in flights which are made during poor visibility.

The most recent work on the improvement of navigation during poor visibility has been in devising methods for making a successful landing. To do this the navigator needs to locate the landing field, and know his absolute altitude above it. The progress in developing absolute altimeters has been discussed. Progress has been made in the method of locating the landing field based on a property of the radio beacon. Although a considerable amount of development work is still essential in order to make landings during fog a common operation, it appears that promising methods for doing so have been found.

Aerial navigation by astronomical methods is commonly employed only in flights over oceans, and in long flights over undeveloped or unfamiliar country. The necessity for their use is becoming less and less as the operation of the radio beacon is extended to cover more and more air lines. The astronomical method of position finding has an inherent advantage over other

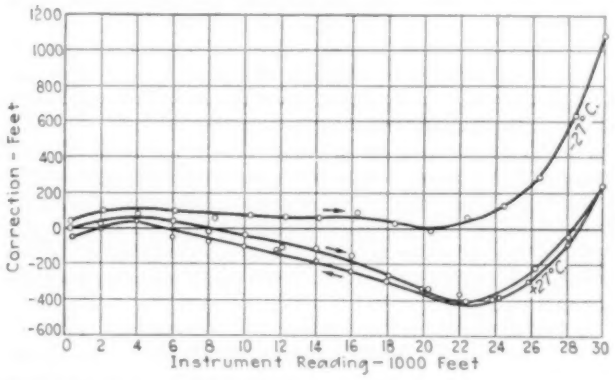

Fig. 5 Scale Errors and Elastic Hysteresis of, and Effect of Temperature on a 30,000-Ft. Altimeter. Pointer Motion for the Range Is 1½ Revolutions

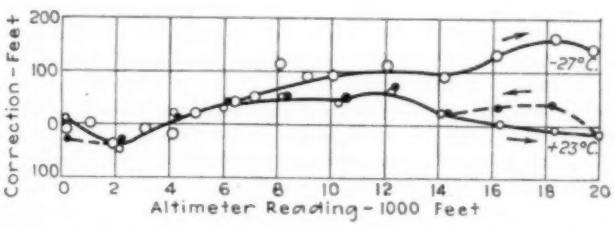

Fig. 6 Scale Errors at Two Temperatures and Elastic Hysteresis of a 20,000-Ft. Altimeter

methods in that it is independent of all ground equipment, for which reason its use will always continue in many cases. Important improvements are being made in the method of position finding by astronomical methods. The sextant and time pieces have been improved, as well as the methods of computing. For the latter see references 20 and 21. A discussion in detail is beyond the scope of this paper.

Magnetic Compass. There has been a slow and steady improvement in the performance of magnetic compasses. The important features of design are:

(*a*) Adequate provision for the expansion of the damping liquid due to temperature, and at the same time providing for the effect of low pressure.

(*b*) The reduction of the weight of the compass card consistent with securing adequate damping.

(*c*) Use of better magnet steels as these become available. Cobalt magnet steels are now being used, from which relatively stronger magnets per unit volume can be produced.

(*d*) The selection of the proper damping liquid. For some years mineral spirits or varnolene has been used as the damping liquid. A recent study by Keulegan (reference 13) of damping liquids from the viewpoint of their use in aircraft instru-

ments may make possible greater freedom in the selection of the liquid.

The chief difficulty with compasses at the present time is that associated with their installation in the aircraft. The effect of vibration and the effect of extraneous magnetic fields produced in the aircraft combine to make proper installation a comparatively difficult matter in many cases. The effect of vibration is being minimized by the use of vibration-absorbing mountings. No general solution for the effect of the extraneous magnetic fields has been found save that of changing the location of the compass. The compass must be compensated after installation against the effect of the magnetized parts of the ship, and for the deviation. For details see reference 12.

Compasses of new design are subjected to the following laboratory tests:

(*a*) The instrument is subjected to a pressure corresponding to the lowest altitude at which it will be used in order to determine the effect on the expansion chamber, and to note generally possible injurious effects of low pressure.

(*b*) The instrument is subjected to a temperature of —35 deg. cent. The liquid should not freeze at this temperature.

(*c*) The critical test for the adequacy of the expansion chamber is to subject the instrument to a temperature of +45 deg. cent. There should be no leaks at this temperature, nor should a bubble form in the compass bowl upon reducing the temperature.

(*d*) The period of the compass is determined at +20 deg. cent. The procedure usually consists in deflecting the compass card 45 deg. then allowing it to swing freely. While swinging the time interval is obtained for the card to swing through the zero position for the first and second time. Twice this time is the period. In order to be of any value these data must be obtained when the compass is in a horizontal magnetic field of standard strength (0.180 gauss). This magnetic field is practically never found inside of a building, so that recourse must be had to a suitable location out of doors. The period should be obtained at low temperature, but it is difficult to control both the external magnetic field and the temperature simultaneously. Qualitative data of some value may be obtained on this point in the low-temperature test above mentioned.

(*e*) Current specifications also give tolerances for the card error, balance of card, friction error, heeling, and levelling.

Although an experimental instrument, the induction compass should be mentioned. It may be also called a distant indicating compass since the chief advantage of this instrument is that its magnetic element may be placed in the most favorable part of the aircraft as regards freedom from magnetic disturbances. Since the announcement by Heyl and Briggs of the first working model in January, 1922, development work has been continuously in progress. Only one type, the Pioneer compass, is at present available commercially. Other types are being worked on experimentally which may lead to improved instruments. The improvements will consist of reduction in weight, improved reliability and perhaps reduction in cost. The induction compass is at present classed as an experimental instrument because it is not generally used, which is largely due to its relatively higher cost and its present lack of reliability as compared with the magnetic compass. Its ultimate adoption as a service instrument is sure.

Turn Indicator. New developments in the gyroscopic turn indicator have been largely along the lines of a general expansion of its use rather than along its further mechanical development. The wind-driven instrument giving qualitative indications has been available in substantially the same design for a number of years, and has usually given satisfactory service (reference 11).

Tests show that when properly lubricated with a low pour-point oil, the starting pressure and friction characteristics of the instrument are substantially the same in the temperature range —35 deg. to +45 deg. cent.

There is some difference of opinion on the part of pilots and navigators as to the proper sensitivity of the turn indicator. Military specifications require a deflection of $^1/_{16}$ in. in turning at a rate of 36 deg. per min., $^3/_8$ in. for 360 deg. per min., and $^3/_4$ in. for 1080 deg. per min. when the instrument is operating under a suction of 26 in. of water. This suction is developed only at one speed of the aircraft, so that the sensitivity of the instrument will in general be different from the above. The instruments, however, are provided with an adjustment for the sensitivity, and also for damping so that these can be adjusted as desired.

Bank Indicator. A curved-glass tube containing a steel ball, and filled with a suitable liquid for damping purposes is used as the bank indicator, and in the absence of turns, to indicate rolling. Until quite recently a $^1/_4$ in. ball has been used, but in the opinion of pilots this size of ball is too small. At the present time standardization appears to be taking place around the use of a steel ball $^7/_{16}$ in. in diameter. Proper damping is the controlling factor in a proper design. A satisfactory performance is determined by the results of two tests, vibration and time of roll at low temperature. If the viscosity of the damping liquid is inadequate at room temperature the ball spins when subjected to vibration, and in general will climb up the tube. Liquids which give entirely adequate damping at room temperatures will either be found to be frozen or so viscous as to be unsuitable when the inclinometer is cooled to —35 deg. cent. Preliminary experiments indicate that satisfactory low-temperature performance can be obtained with certain solutions having a viscosity as high as 0.04 poise at 25 deg. cent., which value is sufficient to damp out the effects of a vibration with an amplitude of approximately $^1/_{32}$ in. It is obvious, of course, that the performance of the inclinometer also depends upon the clearance between the ball and tube. If the inclinometer is designed to have a small clearance between the ball and tube, the cost of the instruments will be relatively great owing to the difficulty of obtaining glass tubing with a uniform bore. Tests show unexpectedly that better damping is secured by having relatively large clearances between the ball and tube. For data on damping liquids see reference 13.

Drift Indicators. The measurement of drift can at present be made only when the ground is visible. The methods used have not varied essentially in the past few years. There has been, however, a tendency toward more simple apparatus.

As is well known (see reference 7) the wind and ground speed of the aircraft can be determined from drift measurements if the true air speed be known. Further, the drift indicators commonly available contain suitable sights which with a stop watch, and a knowledge of the altitude also determine the ground speed. However, the common practice is to dispense with the possibility of determining wind and ground speed.

The proper heading only is determined. This is done by measuring the drift when on a compass course, adjusting the heading by the amount of the drift, and then repeating the process until on the proper course. When over water or flying at night smoke bombs or flares are used to furnish the object upon which to sight.

Fore-and-Aft Inclinometers. The instruments which may be termed fore-and-aft inclinometers are not strictly service instruments since their use is not common. Two types of instruments are available, one a liquid-in-glass type and the other a combined pendulum and gyro instrument. The first-named instrument is affected alike by inclination, and fore-and-aft accelerations. The pendulum-gyro type instrument gives indications which are

practically independent of the fore-and-aft acceleration. The indication of both instruments is affected by the angle of attack.

Experience with the capillary-leak tube-type indicator has shown the instrument to be of little use in indicating the rate of climb accurately. It has been further shown, however, that the instrument indicates qualitatively the fore-and-aft inclination. The instrument is free from the acceleration and angle of attack errors above mentioned. The indication depends on the rate of change of pressure.

A change in indication of the air-speed indicator associated with a constant speed of the propeller is also often used to indicate fore-and-aft inclination.

Radio Beacon. A discussion of the radio beacon is out of place in this paper except as regards its function as an aid to navigation. The chief use of the radio beacon is in flying during poor visibility and fog. It enables the proper direction toward the destination to be maintained. Without the radio beacon the direction of flight would have to be determined by means of the magnetic compass, a method which is unsatisfactory because of the impossibility of determining the drift, and correcting the heading for it. A further property of the radio beacon is now in the process of being utilized. When the airplane is equipped with a vertical-rod antenna, a drop in the strength of the signal received on the airplane occurs when directly over the beacon. This phenomenon gives a method of locating the landing field. The radio beacon is essential in fog flying since no other successful methods have been developed to maintain proper direction and to locate the landing field.

Operating Problems

A few general problems will be mentioned relating to the installation and satisfactory operation of aircraft instruments. The first of these problems is the effect of instrument-board vibration. This is most serious on the magnetic compass, and on other instruments of which the operation depends on very small forces. In some cases the vibration encountered is too severe for these instruments. There is apparently need to specify the vibration which instruments should be expected to withstand. All new designs should be subjected to this vibration, with suitable damping devices attached to the instrument when necessary. The damping device should be successful before the instrument is considered suitable for aircraft use. As has been stated a vibration test is now required in current military specifications, but it is believed that further experience will probably require some changes in the test.

It is well known that the static pressure in a cabin of an airplane differs from that of the free air. This difference affects the indication of altimeters and barographs particularly, and can be eliminated if found necessary by the use of airtight cases connected to the free air.

Trouble is often experienced with the breaking of the tubing of pressure gages, and oil or water thermometers. This is very often due to vibration, and occasionally to poor design of the connection or improper construction. It can be prevented in most cases.

A problem exists in securing proper lubrication on instruments with rotating elements such as tachometers, turn indicators, and induction compasses. The requirements are that the lubrication be satisfactory at least in the temperature range —35 to +45 deg. cent., and to lower temperatures occasionally. Further, the lubrication must be effective over a long interval of time as in some cases no provision is made for lubrication after installation, and in others the neglect of this necessity in operation must be anticipated. At the present time oils having a pour point of —40 deg. cent. can be obtained from several sources. The performance is satisfactory in the above temperature range, but it requires further experience to obtain data on its useful life.

Standardization of Instrument Dimensions

At the recent Army-Navy (AN) Conference at the Naval Aircraft Factory in Philadelphia attended by manufacturers, representatives of the Army Air Corps and Navy Bureau of Aeronautics, and others interested, new case dimensions were adopted for altimeters, tachometers, and air-speed indicators which are based on a $2^3/_4$-in. dial. This adoption makes these instruments interchangeable on the instrument board with minor modifications. Changed dimensions were also adopted for fuel- and oil-pressure gages, and oil or water thermometers, in which the dial size was reduced from two inches to $1^7/_8$ in. In each case the adoption of these new dimensions was preceded by a large amount of preliminary work which included the preparation of drawings and specifications by the Bureau of Aeronautics assisted by the Bureau of Standards on the tests and tolerances. This work was followed by the production of sample instruments by a number of manufacturers. This was essential since in some cases a redesign of the instrument mechanism had to be made in order to make it possible to insert it in the new size cases. In making the change other factors also had to be considered, such as the maximum pointer movement in its relation to sensitivity and the desired accuracy, the performance, and other design factors. The new sizes of instruments are being quite generally used in commercial aircraft, and it appears that the new sizes are in a fair way to be considered as the American standard, except possibly in the case in which vertical-scale instruments are used. This work is an outstanding achievement in the aircraft-instrument field and was made possible only by the close cooperation of a number of instrument manufacturers, and the Bureau of Aeronautics.

In order to make instruments generally interchangeable on the instrument board, and of course to simplify the board itself the manufacturers have produced instruments of other types which are interchangeable with the altimeter, tachometer, and air-speed indicator. These instruments with new case sizes include the bank and turn indicator, the clock, and magnetic compass, the rate-of-climb indicator, fuel-flow meter, fuel-quantity gage, and induction-compass indicators.

The assistance and cooperation of Messrs. H. C. Sontag, H. B. Henrickson, R. B. Block, and M. J. Evans, all of the Aeronautic Instruments Section of the Bureau of Standards, is acknowledged in the preparation of this paper, especially in securing the performance data on the various instruments. These data have been obtained largely on instruments submitted by the Bureau of Aeronautics for test in accordance with its specifications. The close cooperation of Lieut. T. C. Lonnquest, U. S. N., and C. L. Seward of the Bureau of Aeronautics of the Navy Department is hereby acknowledged. The credit for the initiation of many improvements in service instruments, and the carrying through of the recent standardization of instrument dials and case dimensions is largely due to them.

Discussion

A. H. Mears.[3] The paper by Dr. Brombacher adequately summarizes the development of aeronautic instruments during the last ten years. It points out that the innovations in service instruments have been largely in improvements and developments of materials of which the instruments are constructed, and of production methods rather than the development of new designs or principles of operation. The testing methods are practically the same as they were ten years ago.

There are two interesting points contained in the paper that appear to be worth calling to one's attention. The first is the change in the pressure heads of air-speed indicators from pitot-venturi to pitot-static heads. Ten years ago the speed of heavier-than-air machines was relatively slow so that pitot-static heads did not develop sufficient pressure differences, therefore, much expense and effort was spent in developing pitot-venturi heads that would produce large pressure differences. These were hard to construct, complicated, and often unsatisfactory. While this development was in progress, the speed of the airplanes was increasing rapidly, hence much greater pressure differences could be developed by the pitot-static heads. By slightly improving the air-speed indicators the pitot-static heads became entirely satisfactory. Such situations as these must be watched carefully by the aeronautic-instrument manufacturer to avoid losses and unnecessary developments. The second point is the change in the use of the rate-of-climb indicator to that of an inclinometer thereby greatly increasing the use of the instrument as a service instrument in the heavier-than-air field.

With the improvement in the performance of the altimeter, and the necessity of connecting to a static head for accurate readings, it seems that there might be many advantages of installing all altimeters in airtight cases provided with pressure connections. This would enable them to be checked when on the instrument board of the plane, and simplify the testing apparatus of altimeters.

In the temperature tests at sea-level pressure, the 35,000-ft. altimeter seems to have much more tolerance than is necessary, when compared with the 20,000-ft. instrument.

Victor E. Showalter.[4] Dr. Brombacher's paper makes available to the aeronautical engineer information heretofore obtainable only through tremendous effort on the searcher's part. Speaking authoritatively as Dr. Brombacher does, having been in touch constantly with the development of aircraft instruments for several years, his effort must be received appreciatively. It may be read in full confidence that it does not contain any sales argument, and that the data imparted are accurate.

AER-51-22

The Application of the Principle of Least Work to the Primary Stress Calculations of Space Frameworks

By C. P. BURGESS,[1] WASHINGTON, D. C.

A structure similar to the framework of a rigid airship is analyzed by three approximate methods commonly applied to such structures, and also by the mathematically exact method of least work. It is shown that the approximate methods may be very considerably in error. A short-cut method of least work, giving very satisfactory results, is described and applied to the structure.

Introduction

THE hull structures of rigid airships are typical of a large class of space frameworks, including gasometers and the wind bracing of steel-framed towers and buildings, in which the shearing and bending forces are distributed between such highly complex and redundant systems of members that mathematically exact methods of primary stress calculations are so difficult as to be rarely or never attempted. Several approximate methods have been developed and used by engineers and designers, but the known methods are not very satisfactory.

Even a mathematically exact analysis may yield results quite different from reality, because the mathematical theories of stress are based upon the assumptions that there are no initial stresses in the unloaded structure and the material behaves strictly according to Hooke's law, i.e., the ratio of stress to strain is constant. In all indeterminate structures, particularly wire-braced ones, there may be very considerable departures from both of these assumptions.

It is fortunate for the success of redundant structures that when a member is stressed to near or beyond its yield point, the stress/strain ratio diminishes, with the result that the overloaded member takes a decreasing share of the load on the structure and the less-stressed members take an increasing share. A mathematically exact strength calculation takes no account of this transfer of load from the more heavily stressed members in extreme conditions and therefore errs on the safe side.

In this paper a simplified method is developed for applying the principle of least work or minimum-strain energy to the stress calculations of highly redundant framed structures. Some simplifying assumptions are introduced, involving slight departures from reality, but in most cases the errors will be much less than when the customary approximate methods of stress calculation are used.

By way of illustration the new method is applied to the stress calculation of a framework resembling the hull structure of a rigid airship; and for comparison, the stresses are also calculated by the exact method of least work and three different approximate methods commonly used for the stress analysis of airships and similar types of frameworks.

Approximate Methods of Stress Calculations

The bending and the shear theories are the bases of two well-known methods of approximating to the stress analysis in framed structures of the type under consideration. The bending method is an application of the familiar beam-bending theory to the distribution of the longitudinal forces. The sizes of the shear wires are not considered to influence the distribution of the forces, except to a slight extent in the modified bending theory proposed by Professor Hovgaard, in which fictitious or imaginary bars are introduced to represent the contribution of the shear wires to the cross-sectional area of the structure. The shear wires are assumed to take the longitudinal shear between the longitudinal members without regard to the sizes or elastic properties of the wires.

The shear theory contrasts with the bending theory in that the stress distribution is assumed to depend only upon the elastic properties of the shear members, ignoring these properties in the longitudinals. The stresses in the longitudinals are calculated from the forces applied to them by the shear wires at the joints.

Attempts have been made to justify the use of the bending method by proving that it is consistent with the principle of least work. The line of reasoning has been to show (see Appendix I) that if the forces in the longitudinals are distributed according to the bending theory, the strain energy in the longitudinals has its minimum value, and therefore the bending theory must be correct. The limitation to this argument is that it may be shown equally well (see Appendix II) that, if the forces are distributed according to the shear theory, the strain energy in the shear members is a minimum. The conditions of any particular problem determine which distribution of force will produce less total work in the structure. Neither may give the least possible. In the event of a discrepancy between the results of the shear and bending theories, it is to be expected that the least total work will result from a force distribution lying somewhere between the indications of the two theories; nearer to the bending theory when the greater part of the work is in the longitudinal members, and nearer to the shear theory when the internal work of the shearing forces predominates. It might be thought that the work in the longitudinal members would constitute the greater part of the total strain energy in most practical problems; but in structures such as airship hulls, in which the length/diameter ratio is not large, and the longitudinal girders are of much greater cross-sectional area than the diagonal wires, it usually happens that there is more internal work in the wires than in the longitudinals.

When the bending and shear theories give the same results, both must be correct, because in that case there is the least possible strain energy in both the longitudinal and diagonal members. The only qualification to be placed upon this statement is that it often happens that the stresses in the longitudinals are not entirely the result of the primary bending of the structure. The longitudinal components of the tensions in the shear wires produce some compression in the longitudinals, over and above the direct effect of the bending moment, leading to small departures of the stress distribution from the bending theory.

It has been argued that the forces or stresses in the longitudinal and shear members can be considered separately, on the

Presented at the Third National Meeting of the Aeronautic Division, St. Louis, Mo., May 27 to 30, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

assumption that the stresses in the longitudinals are in accordance with the bending theory and the stresses in the diagonals conform to the shear theory. A stress calculation on this assumption will not show equilibrium of forces at the joints, except in the special case when the longitudinal and diagonal members are so proportioned to each other that the bending and shear theories are both correct. But it may be said in favor of this method of stress calculation that the largest bending stresses occur where shear is least, so that the internal work in the longitudinals predominates, and the bending theory should therefore have a good order of accuracy; and conversely, where the shear is greatest, the bending is small, with the result that the work is mainly in the shear members, favoring a distribution of stress according to the shear theory.

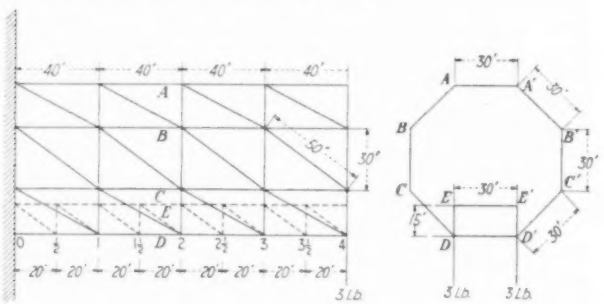

FIG. 1 SHOWING DIMENSIONS OF STRUCTURE

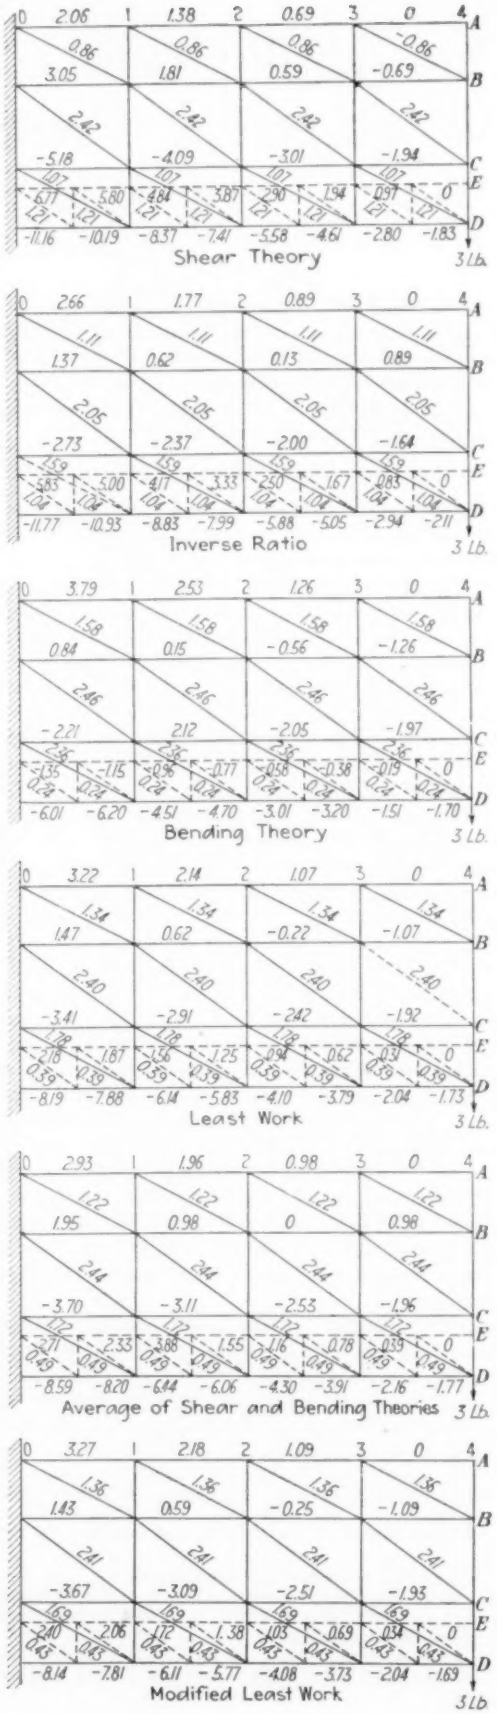
Attempts have been made to strike a weighted mean between the shear and bending theories, according to the ratio between the internal work of shear and bending, but the results have not been satisfactory.

A third approximate method of stress calculation is the inverse-ratio theory, which takes account of the elastic properties of all members. It is based upon the mathematically demonstrable theorem that, when a load is divided between two or more independent statically determinate systems, these systems share the load between them in inverse ratio to their internal work when each alone takes the entire load. This theorem ceases to be exact when the determinate systems react upon each other. It is impossible to divide a structure of the type under consideration into statically determinate systems which do not react upon each other to some extent. Consequently, the inverse-ratio theory must be classed among the approximate methods; but since it takes account of the elasticity of all members, it may be expected to give more nearly correct values than either the shear or bending theory when these differ from each other.

The proposed new method of stress analysis by a modification of the conventional least-work procedure is most conveniently explained after following the analysis in the illustrative problem by the principle of least work applied in the conventional manner.



Before proceeding to the least-work analysis, approximate calculations by the three methods already discussed are set forth briefly, and it is shown that the approximate methods give widely divergent results.

The derivations of the formulas of the approximate methods are not given here. They may be found in the chapter on the Longitudinal Strength of Rigid Airships in the author's book, "Airship Design."

ILLUSTRATIVE PROBLEM

The framework shown in Fig. 1 is to be analyzed by the three approximate methods of shearing, bending, and inverse ratio,

FIG. 2 (IN THE RIGHT-HAND COLUMN) SUMMARY OF STRESSES BY VARIOUS METHODS OF CALCULATIONS

and also by the mathematically exact method of least work and by the proposed simplified adaptation of least work.

The following assumptions are made in regard to this structure:

(*a*) All joints are pinned
(*b*) At the left-hand end of the structure, all longitudinals and diagonals are pin-connected to an absolutely rigid wall
(*c*) The frame at the right-hand end is rigidly cross-braced
(*d*) Intermediate frames are without cross-bracing
(*e*) The internal work in all transverse members, including the cross-bracing of the right-hand end frame, is negligible. This is equivalent to assuming that EA is infinite for these members in the least-work and inverse ratio calculations
(*f*) A single load acting vertically downward is applied to the right-hand frame.

Owing to the absence of cross-bracing in the intermediate frames, there can be no transference of the load at these frames from one row of panels to another. Consequently, the tensions are constant throughout each horizontal row of diagonal members.

The Calculations

(1) *The Shear Theory.* The expression for the tensions in the shear wires according to the shear theory is:

$$S = \frac{FA \sin\theta \sin\phi}{L\Sigma\,(A/L)\sin^2\theta \sin^2\phi}$$

where S = tension in any shear wire
F = total shear in the frame bay
θ = inclination of the panel to the plane of shear and bending of the hull
ϕ = inclination of the shear wire to the longitudinals
A = cross-sectional area of the shear wire
L = length of the shear wire.

The summation includes all the shear wires in the frame bay.

The following table shows the application of this method to the structure under discussion:

TABLE 1 CALCULATION BY SHEAR THEORY

Member	A	L	$\sin\theta$	$\sin^2\theta$	$\sin\phi$	$\frac{A}{L}\sin^2\theta \sin^2\phi$	S
A0–B1	0.0167	5.0	0.7071	0.5	0.6	0.00060	0.86
B0–C1	0.0333	5.0	1.0	1.0	0.6	0.00240	2.42
C0–D1	0.0208	5.0	0.7071	0.5	0.6	0.00075	1.07
E0–D½ } E½–D1 }	0.0167	5.0	1.0	1.0	0.6	0.00120	1.21
Total						0.00495	

$$S = \frac{FA \sin\theta \sin\phi}{L\Sigma\,(A/L)\sin^2\theta \sin^2\phi} = \frac{3 \times 0.6 \times A \sin\theta}{5 \times 0.00495}$$
$$= 72.8\,A \sin\theta.$$

The stresses in all members according to the shear theory are summarized in Fig. 2.

(2) *The Bending Theory.* The expression for the tensions in the shear wires according to the bending theory is:

$$S = \frac{FL\,\Sigma\,Ay}{I}$$

where S = tension in any shear wire
F = total shear in the frame bay
L = length of the shear wire
I = moment of inertia of the cross-section of the structure
A = cross-sectional area of any longitudinal girder (not of a shear wire as in the shear theory)
y = the distance of any longitudinal from the neutral axis of the structure.

The summation $\Sigma\,Ay$ is taken over all longitudinals beyond the shear wire under consideration in the direction away from the neutral axis.

Tables 2 and 3 show the application of the bending theory to the problem in hand.

The stresses in the longitudinals are shown in Fig. 2, calculated from the forces applied to the joints by the shear wires, instead of by direct application of the bending theory to the longitudinals. By this procedure account is taken of the contribution of the shear wires to the longitudinal forces. In Table 2 the moment of the cross-sectional areas of the longitudinals are calculated about the geometrical axis (h = distance of a longitudinal member from the geometrical axis). The position of the neutral axis and the moment of inertia about that axis are then computed. From the data derived in Table 2, the shear-wire tensions are calculated in Table 3.

It may be noted that the keel shear wires are in compression. This is impossible in reality and would result in the counter-shear wires taking the load, but for the present purpose of comparison with other methods of stress calculation it is permissible to assume that the shear wires are able to sustain compression.

TABLE 2 MOMENT OF INERTIA CALCULATION

Member	A in.²	h ft.	Ah ft. in.²	y ft.	Ay ft. in.²	Ay^2 ft.² in.²
A	0.25	36.2	9.05	48.3	12.07	583.0
B	0.25	15.0	3.75	27.1	6.77	183.5
C	0.25	—15.0	— 3.75	— 2.9	— 0.73	2.1
D	0.60	—36.2	—21.72	—24.1	—14.46	348.5
E	0.40	—21.2	— 8.48	— 9.1	— 3.64	31.1
Total	1.75		—21.15			I = 1148.2

Neutral axis is at 21.15/1.75 = 12.1′ below the geometrical axis.

TABLE 3 STRESSES IN SHEAR WIRES BY BENDING THEORY

Member	L	$\Sigma\,Ay$	$L\,\Sigma\,Ay$	S
A0–B1	50	12.07	603.5	1.58
B0–C1	50	18.84	942.0	2.46
C0–D1	50	18.10	905.0	2.36
E0–D½	25	—3.64	—91.0	—0.24

$$S = \frac{FL\,\Sigma\,Ay}{I} = \frac{L\,\Sigma\,Ay}{383}$$

(3) *The Inverse-Ratio Theory.* In the application of the inverse-ratio theory, the structure is divided into four statically determinate systems, one for each row of shear wires. The internal work in each system when alone carrying the external load is calculated in Table 4.

Let Q_1, Q_2, Q_3, and Q_4 be the internal work in the top, middle, bottom, and keel panels, respectively, when each alone sustains the external load. Let q_1 to q_4 be the fractions of the total load which each panel takes when all are acting.

Then:

$$q_1 + q_2 + q_3 + q_4 = 1$$

And by the inverse ratio theory

$$q_1Q_1 = q_2Q_2 = q_3Q_3 = q_4Q_4$$

Whence

$$\frac{1}{q_1} = 1 + \frac{Q_1}{Q_2} + \frac{Q_1}{Q_3} + \frac{Q_1}{Q_4}$$
$$= 1 + \frac{425{,}280}{162{,}640} + \frac{425{,}280}{295{,}578} + \frac{425{,}280}{320{,}691}$$
$$= 1 + 2.615 + 1.439 + 1.326 = 6.380$$

Totals						425,280		162,640		295,578		320,691					

$q_1Q_1 = 66{,}641; \quad q_1 = 0.1567$

$q_2 = 66{,}641/162{,}640 = 0.4097$

$q_3 = 66{,}641/295{,}578 = 0.2255$

$q_4 = 66{,}641/320{,}691 = 0.2081$

1.0000

The stresses in the members of the four determinate systems are designated by S_1 to S_4, respectively. The total stress in any member is $S = q_1S_1 + q_2S_2 + q_3S_3 + q_4S_4$. These stresses are calculated in Table 4 and summarized in Fig. 2.

(4) *Least-Work Calculations.* In the stress analysis by the method of least work, the re-entrant keel at the bottom of the framework is assumed to be the basic statically determinate structure. The stresses in the keel members, when the side panels are inactive, are listed in the column headed S_0 in Table 5. The stresses due to 1-lb. tension in the diagonals of each row of side panels taken consecutively are listed in the columns headed S_1, S_2, and S_3 in the same table. As already noted, the absence of cross-bracing in the intermediate transverse frames leads to the wire tensions being constant throughout each row of side panels. These tensions are the variables to be determined, designated by X_1, X_2, and X_3, proceeding in order from the top to the bottom row. The total stress S in any member is given by

$$S = S_0 + X_1S_1 + X_2S_2 + X_3S_3$$

The total internal work W is given by

$$W = \Sigma \frac{(S_0 + X_1S_1 + X_2S_2 + X_3S_3)^2 L}{2AE}$$

where the summation is taken over all members in the structure.

When W has its minimum value,

$$\frac{\partial W}{\partial X_1} = 0, \quad \frac{\partial W}{\partial X_2} = 0, \quad \text{etc.}$$

By performing these differentiations and equating to zero, the following equations are obtained:

$$X_1\Sigma S_1^2L/AE + X_2\Sigma S_1S_2L/AE + X_3\Sigma S_1S_3L/AE + \Sigma S_0S_1L/AE = 0$$

$$X_1\Sigma S_1S_2L/AE + X_2\Sigma S_2^2L/AE + X_3\Sigma S_2S_3L/AE + \Sigma S_0S_2L/AE = 0$$

$$X_1\Sigma S_1S_3L/AE + X_2\Sigma S_2S_3L/AE + X_3\Sigma S_3^2L/AE + \Sigma S_0S_3L/AE = 0$$

For convenience L/AE is usually represented by the symbol U.

In practice, equations of the foregoing form are written directly without carrying out the differentiation by which they are derived.

The coefficients of the three variables and the constant terms are calculated in Table 5, giving the following equations:

$$14{,}919X_1 + 7{,}023X_2 + 4{,}755X_3 = 45{,}352$$

$$7{,}023X_1 + 19{,}333X_2 + 4{,}678X_3 = 64{,}138$$

$$4{,}755X_1 + 4{,}678X_2 + 9{,}010X_3 = 33{,}631$$

The solution of these equations is:

$$X_1 = 1.34$$
$$X_2 = 2.40$$
$$X_3 = 1.78$$

From these values of the tensions in the diagonals, the stresses in the other members are obtained statically, as shown in Fig. 2.

Modified Least-Work Method

Least-work calculations are long and laborious because of the large number of members which have to be taken into account in complicated framed structures. It is proposed to effect a great economy of time and labor by assuming that the transfer of longitudinal force from the diagonal to the longitudinal members is continuous, instead of being concentrated at the joints of the structure. By this device, the stresses in the members may be expressed as continuous functions of easily integrated form, and the number of members to be considered is greatly reduced. Moreover, an old but little-known or used method of solving least-work equations and checking the calculations as the work proceeds is explained in Appendix III.

Let P be the transverse load applied to the structure, and let h be the depth of the truss formed by any pair of longitudinals. Then at distance x along the longitudinals from the point of application of P the end forces in the two longitudinals are given by

$$S = \pm P\,x/h.$$

In the illustrative problem, P = 3 lb., h = 30 ft. in each of the side panels and 15 ft. in the keel. In longitudinal D,

$$S_0 = -3x/15 = -x/5.$$

Similarly, in longitudinal E,

$$S_0 = x/5.$$

The forces of 1 lb. in the diagonals of the side panels produce transverse forces of 0.6 lb. Hence in longitudinals A and B, the S_1 forces are, respectively:

$$\pm 0.6x/30 = \pm x/50.$$

The vertical component of the 1-lb. tension in the diagonals between A and B is 0.424 lb., producing S_1 forces of $\pm 0.424x/15 = \pm x/35.4$ in the keel members D and E, respectively. By similar procedure, simple expressions for the S_2 and S_3 forces in the redundant members and the keel are derived. The only catch to look out for is the S_3 force in longitudinal D; as a member of the truss between longitudinals C and D, its S_3 force is $-x/50$, but it also carries a force equal to $x/35.4$ as a member of the keel, so that $S_3 = -x/50 + x/35.4 = x/121$.

Since all four diagonals in any one row have the same tensions, they may be considered as one continuous member having a constant tension instead of four separate members.

The expressions for all the terms from S_0 to S_3 are tabulated in Table 6.

The calculation of terms of the form S_0S_1L/AE for the longitudinals is by a simple integration of the form

$$\int^{L} \frac{S_0S_1\,dx}{AE}$$

For example, in longitudinal D, taking the values of AE, S_0, and S_1 from Table 6,

$$\int_0^{L} \frac{S_0S_1\,dx}{AE} = 1.67\int_0^{L}\left(-\frac{x}{5}\right)\left(\frac{x}{35.4}\right)dx$$

$$= 1.67\int^{160}\frac{-x^2\,dx}{177}$$

$$= \frac{-1.67\times 160^3}{3\times 177} = -12{,}900.$$

The results of the integrations are listed in Table 6, and from the summations the following equations are obtained:

$$14{,}912X_1 + 7{,}076X_2 + 5{,}255X_3 = 46{,}308$$

$$7{,}076X_1 + 19{,}479X_2 + 5{,}254X_3 = 65{,}548$$

$$5{,}255X_1 + 5{,}254X_2 + 10{,}264X_3 = 37{,}195$$

The solution is:

$$X_1 = 1.364$$
$$X_2 = 2.414$$
$$X_3 = 1.690$$

The method recommended for solving least-work equations is explained in Appendix III and illustrated by solving these particular equations.

Discussion of the Results

Fig. 2 shows the results of six different methods of calculating the stresses in the given problem. These methods are:

(1) Shear theory
(2) Bending theory
(3) Average of shear and bending theories
(4) Inverse ratio
(5) True least work
(6) Modified least work.

The results of method (5) may be taken as the standard by which to judge the precision of the others.

There is a great difference between the results of the bending and shear methods; and as would be expected from the discussion of their theories, the truth of the matter lies between them. The simple average of the bending and shear methods gives quite good results, more nearly correct in fact, than the more laborious inverse-ratio method. This is, however, largely fortuitous and a result of the circumstance that the internal work in the structure happens to be about equally divided between the longitudinal and diagonal members.

The modified least-work method shows a very good order of precision indeed, in spite of the simplifying assumption made in regard to the transfer of force from the diagonal to the longitudinal members.

In the illustrative problem, the sizes of the members were selected with a view to bringing out the possible large discrepancy between the bending and shear theories. The least total internal work and probably the most efficient structure in regard to the ratio of strength to weight are obtained when the sizes of the members are so proportioned to each other that the bending and shear theories give concordant results; and also the stress calculations are very easily made in that case, since both of these simple methods are then correct. If it were not for the re-entrant keel, there would be no difficulty in proportioning the longitudinal and diagonal members to give the desired result. The keel makes this impossible, because, as may readily be seen, no matter what sizes of members are chosen, the bending theory will always show the re-entrant longitudinals to have stresses of the same sign as their neighbors, while the shear theory shows them having stresses of opposite signs. The inverse-ratio theory resembles the shear theory in this respect. A least-work calculation seems essential to determine the truth.

Stresses in the Second Main Frame Bay

At the cross-braced main frames, the stresses in the shear wires may be redistributed, even if no additional external load is imposed at the frame. The modified least-work method may readily be extended to the computation of the forces in the main-frame bays at successive intervals from the point of application of an external load. The second bay is assumed to be loaded by the end forces calculated at the fixed end of the first bay; although actually some discrepancy will result from the fact that when the second bay is introduced, the first bay no longer has a perfectly fixed end. The expressions to be integrated for the stresses in the longitudinals are the same functions as in the first bay, except that a constant term equal to the end load re-

ceived from the first bay is to be added. The modified least-work calculations for the second main frame bay are given in Table 7, from which the following equations are obtained:

$$\begin{aligned} 14{,}912X_1 + 7{,}076X_2 + 5{,}255X_3 &= 52{,}670 \\ 7{,}076X_1 + 19{,}479X_2 + 5{,}254X_3 &= 70{,}198 \\ 5{,}255X_1 + 5{,}254X_2 + 10{,}264X_3 &= 43{,}480 \end{aligned}$$

It may be noted that only the constant terms differ from the equations derived for the first main bay, so that in practice it is only necessary to compute the constant terms for successive bays, unless the sizes of the members are changed from bay to bay.

The solution of the new equations is:

$$\begin{aligned} X_1 &= 1.61 \\ X_2 &= 2.43 \\ X_3 &= 2.16 \end{aligned}$$

The stresses in all members of the second main bay are shown in Fig. 3. It is interesting to note that in the second bay the

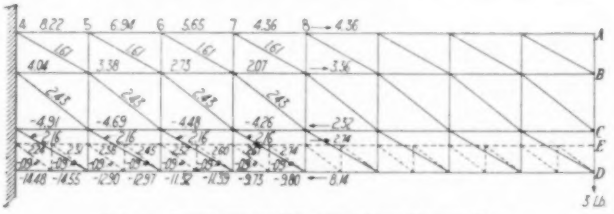

FIG. 3 STRESSES IN SECOND MAIN FRAME BAY

stresses are much closer to the bending than to the shear theory; and the stress in the keel diagonal is negative.

Appendix I

PROOF THAT DISTRIBUTION OF THE BENDING FORCES ACCORDING TO THE BENDING THEORY PRODUCES THE LEAST INTERNAL STRAIN ENERGY IN THE LONGITUDINAL MEMBERS

The fundamental assumptions of the ordinary theory of bending are that the stresses in the longitudinal elements of a body or structure subject to pure bending are proportional to their distances from the neutral axis, their cross-sectional areas, and moduli of elasticity. The validity of these assumptions will now be proved by the theorem of minimum strain energy; that is, distribution of the stresses according to the assumptions of the bending theory results in minimum internal work in the longitudinal members.

Let B and C be any two longitudinal members of a structure, or small elements of the cross-section of a body of length L subjected to a pure bending moment. Let M be the portion of the total bending moment resisted by B and C. Let A_B and A_c be the cross-sectional areas of B and C; E_B and E_c the moduli of elasticity of their materials; H_B and H_c their distances from the neutral axis; S_B and S_c their longitudinal stresses.

According to the bending theory,

$$\frac{S_B}{S_c} = \frac{A_B E_B H_B}{A_c E_c H_c}$$

It is required to prove this relation by the principle of least work or minimum strain energy.

Proof:

By moments

$$S_B H_B + S_C H_C = M$$

whence

$$S_B = \frac{M - S_c H_c}{H_B}$$

$$S_B^2 = \frac{M^2 - 2MS_c H_c + S_c^2 H_c^2}{H_B^2}$$

The internal work in the two members is given by

$$W = \frac{L}{2}\left(\frac{S_B^2}{E_B A_B} + \frac{S_c^2}{E_c A_c}\right)$$

$$= \frac{L}{2}\left(\frac{M^2 - 2MS_c H_c + S_c^2 H_c^2}{E_B A_B H_B^2} + \frac{S_c^2}{E_c A_c}\right)$$

$$\frac{dW}{dS_c} = L\left(\frac{-MH_c + H_c^2 S_c}{E_B A_B H_B^2} + \frac{S_c}{E_c A_c}\right)$$

When the strain energy is a minimum, $dW/dS_c = 0$, whence

$$\frac{-MH_c + H_c^2 S_c}{E_B A_B H_B^2} + \frac{S_c}{E_c A_c} = 0$$

$$S_c = \frac{ME_c A_c H_c}{E_c A_c H_c^2 + E_B A_B H_B^2}$$

Similarly,

$$S_B = \frac{ME_B A_B H_B}{E_B A_B H_B^2 + E_c A_c H_c^2}$$

and

$$\frac{S_B}{S_c} = \frac{E_B A_B H_B}{E_c A_c H_c}$$

which proves the assumptions of the bending theory.

Appendix II

PROOF THAT DISTRIBUTION OF THE SHEARING FORCES ACCORDING TO THE SHEAR THEORY PRODUCES THE LEAST INTERNAL ENERGY IN THE DIAGONAL SHEAR MEMBERS

The shear theory for the analysis of stresses in a redundant framework is based on the assumptions that when the shear between any two transverse sections of the structure is resisted by tension or compression in two or more diagonal members, the stress in these members is proportional to the sines of their angles of inclination to the direction of shear, to their cross-sectional areas and moduli of elasticity, and inversely proportional to their lengths. It will be proved that distribution of the stresses according to these assumptions results in the minimum internal work in the shear members.

Let B and C be any two diagonal shear members between two consecutive transverse frames. A transverse shearing force F is divided between these members. Let L_B and L_c be the lengths of B and C; A_B and A_c their cross-sectional areas; E_B and E_c their moduli of elasticity; θ_B and θ_c the transverse inclination of the panels containing B and C to the direction of shear; ϕ_B and ϕ_c the inclination of the wires to the longitudinals. The components of the wire tensions in the direction of the transverse shear are $S_B \sin\theta_B \sin\phi_B$ and $S_c \sin\theta_c \sin\phi_c$.

According to the shear theory:

$$\frac{S_B}{S_c} = \frac{L_c E_B A_B \sin\theta_B \sin\phi_B}{L_B E_c A_c \sin\theta_c \sin\phi_c}$$

It is required to prove this relation by the principle of least work.

Proof:

$$S_B \sin\theta_B \sin\phi_B + S_c \sin\theta_c \sin\phi_c = F$$

Totals.....									−52,670	−70,198	−43,480

$$S_B = \frac{F - S_c \sin \theta_c \sin \phi_c}{\sin \theta_B \sin \phi_B}$$

$$W = \frac{S_B^2 L_B}{2E_B A_B} + \frac{S_c^2 L_c}{2E_c A_c}$$

Substituting the value of S_B, differentiating, and equating to zero:

$$\frac{dW}{dS_c} = \frac{-FL_B \sin \theta_c \sin \phi_c + L_B S_c \sin^2 \theta_c \sin^2 \phi_c}{E_B A_B \sin^2 B \sin^2 B} + \frac{S_c L_c}{E_c A_c} = 0$$

$$S_c = \frac{FL_B E_c A_c \sin \theta_c \sin \phi_c}{E_c A_c L_B \sin^2 \theta_c \sin^2 \phi_c + E_B A_B L_c \sin^2 \theta_B \sin^2 \phi_B}$$

Similarly:

$$S_B = \frac{FL_c E_B A_B \sin \theta_B \sin \phi_B}{E_B A_B L_c \sin^2 \theta_B \sin^2 \phi_B + E_c A_c L_B \sin^2 \theta_c \sin^2 \phi_c}$$

$$\frac{S_B}{S_c} = \frac{L_c E_B A_B \sin \theta_B \sin \phi_B}{L_B E_c A_c \sin \theta_c \sin \phi_c}$$

which proves the assumptions of the shearing theory.

Appendix III

Method of Solving and Checking Least-Work Equations

The following method of solving simultaneous equations of the first degree was invented by the mathematician, Gauss, about a century ago. It was used in the stress analysis of the lock gates of the Panama Canal for solving least-work equations in which there were fourteen variables. It is described in a paper on "The Distribution of Stresses in Mitering Lock Gates, with Special Reference to the Gates on the Panama Canal," by Henry Goldmark, Mem. A.S.C.E., published in the Proceedings A.S.C.E., August, 1917. In spite of its ancient lineage, the method is not to be found in any structural textbook known to the author, and it appears to be practically unknown to aeronautic engineers. The method is so good and yet so little known and used that a repetition of Goldmark's account of it seems appropriate in this paper addressed to aeronautic engineers. By way of illustration, the solution of the three equations is given in detail.

The typical form for, say, three simultaneous least-work equations is:

$$ax + by + cz + m = 0 \quad [1]$$
$$bx + dy + ez + n = 0 \quad [2]$$
$$cx + ey + fz + p = 0 \quad [3]$$

It is required to find the values of x, y, and z.
From Equation [1],

$$x = -\frac{by + cz + m}{a}$$

and substituting in Equations [2] and [3],

$$\left(d - \frac{b}{a}b\right)y + \left(e - \frac{b}{a}c\right)z + \left(n - \frac{b}{a}m\right) = 0 \quad [4]$$

$$\left(e - \frac{c}{a}b\right)y + \left(f - \frac{c}{a}c\right)z + \left(p - \frac{c}{a}m\right) = 0 \quad [5]$$

which may be written:

$$d'y + e'z + n' = 0 \quad [4']$$
$$e'y + f'z + p' = 0 \quad [5']$$

These two equations are of the same form as the original three, but with x eliminated. By similar procedure y is eliminated from [4] and [5], and so on for any number of variables.

A check on the arithmetical work is obtained at each step by adding a summation term to each equation; for example, in Equations [1], [2], and [3], let

$$q = a + b + c + m$$
$$r = b + d + e + n$$
$$s = c + e + f + p$$

Similarly in Equations [4] and [5],

$$r' = d' + e' + n$$
$$s' = e' + f' + p'$$

But r' and s' may also be determined from r and s in the same way as the other terms of Equations [4] and [5] are found from the corresponding terms of the preceding set of equations. The check consists in computing the summation term for each new equation by the two methods and observing whether or not the results are the same. If there is a discrepancy, the work contains an arithmetical error.

In numerical examples the procedure is much less cumbersome than in the foregoing explanation where symbols are used throughout.

The coefficients of the variables, the constant terms, and the summation or check terms of the three equations are written out in tabular form in Table 8.

The first step in computing the terms of Equation [4] and [5] is to find b/a, that is 7076/14,912 = 0.47452.

All terms in Equation [1], except the coefficient of X_1, are then multiplied by 0.47452, giving the numbers 3358, 2494, 21,974, and 34,902, which are subtracted from the corresponding terms of Equation [2], giving the terms of Equation [4] in Table 8.

TABLE 8 SOLUTION OF LEAST-WORK EQUATIONS

No.	X_1	X_2	X_3	Constant	Check
1.....	14,912	7,076	5,255	46,308	73,551
2.....	7,076	19,479	5,254	65,548	97,357
3.....	5,255	5,254	10,264	37,195	57,968
4.....		16,121	2,760	43,574	62,455
5.....		2,760	8,412	20,876	32,048
6.....			7,939	13,416	21,355

$X_3 = 13,416/7,939 = 1.690$
$16,121X_2 = 43,574 - (1.690 \times 2,760) = 38,910$
$X_2 = 2.414$
$14,912X_1 = 46,308 - (2.414 \times 7,076) - (1.690 \times 5,255)$
$= 20,346$
$X_1 = 1.364$

Similarly, c/a = 5255/14,912 = 0.35240, by which the terms of Equation [1], except the coefficient of X_1, are multiplied, giving the numbers 2494, 1852, 16,319, and 25,919, which subtracted from the corresponding terms of Equation [3] give the terms of Equation [5].

The check is that the term calculated for the column headed "Check" in the new equations equals the sum of the other terms, and also the coefficient of X_2 in Equation [5] must be the same as the coefficient of X_3 in Equation [4].

Equation [6] is derived from Equations [4] and [5] in similar manner.

When there are only three variables, as in the present problem, the Gaussian method of solution has no very marked advantage over the more conventional tabular method in which the equations are successively divided by their first terms in order to obtain a new set of equations, all having the number "one" for the coefficient of the first term, so that the corresponding variable may be readily eliminated by adding or subtracting the equations in appropriate groups. The advantages of the Gaussian method become more pronounced as the number of variables increases.

Discussion

Ralph H. Upson.[2] There is not much to be said on Mr. Burgess' fine paper, as far as it goes. One can hardly argue with correct mathematics. The application of the method still leaves some room for discussion, however. Mr. Burgess has very well stated the principal physical limitations involved, but these in themselves should not be necessarily a bar to the more extended use of the least-work principle; for whenever design work can be founded upon fundamentally sound theory, the practical departure from the initially assumed ideal may usually be allowed for separately, provided the method itself is not too much involved in mathematical complications. The modified method proposed by Mr. Burgess is apparently well suited to structures with parallel longitudinals and as such is a step in the right direction; but unfortunately a modern airship hull or airplane fuselage is not only tapered but of continuously varying taper, for which Mr. Burgess' theory as it stands would still seem to be quite impractical. Is it too much to hope that Mr. Burgess himself will continue the good work which he has so ably begun toward making more general his method of taking the "work" out of least work?

[2] Aeromarine Klemin Corp., Keyport, N. J.

ALFRED S. NILES.[3] The problem discussed by the author is of much less direct interest to the airplane designer than to the airship designer. The former seldom has to design a structure of the degree of redundancy of the rigid airship framework, and so has less incentive to develop methods of handling a large number of redundancies. As a result he is likely to overlook methods of treating some of his design problems that would be very valuable to him. The author's modified method of least work appeals to the writer as pointing out the way to solve some design problems of considerable importance to the airplane designer.

The only application of his method illustrated by the author is the analysis of a cantilever space framework subjected to a single load at the free end. There appears to be no reason why it could not be applied to a similar framework subjected to a couple at the free end, or a combination of a single transverse load and a couple. This would make it apply to the analysis of a conventional fuselage in the maximum fin and rudder load condition.

By developing the method to provide for a load distributed along the span, it could be used for the analysis of a fabric-covered monoplane wing with metal truss spars and conventional drag trussing. The essential feature of the method is the treatment of the shear members as if they were continuous. In a monoplane with metal or plywood covering, or beam types of spars, the shear members are continuous, and it should be possible to extend the method to cover this type of construction also. It is probable that some difficulty might be encountered in extending the method to cover these additional cases, but the advantages to be gained by so doing would be very valuable to the designer.

As the author states, the use of the Gaussian method of solving simultaneous equations is of no particular advantage in solving only three equations, and he proposes it more for use when there is a large number of equations to be dealt with. The writer does not believe that the Gaussian method would ever result in less labor of correct computation than the ordinary system, no matter how many were the variables. Its real merit is in the fact that the steps can be checked as the computations proceed, errors are found almost as soon as they are made, and usually the engineer is saved from making calculations that are useless as they have been vitiated by a preceding error. When numerous simultaneous equations are involved this advantage in the checking becomes a most valuable feature, and the author is to be thanked for bringing the method to the notice of airplane designers.

[3] Professor of Aeronautic Engineering, Stanford University, Stanford University P.O., Cal. Mem. A.S.M.E.

AUTHOR'S CLOSURE

The author agrees with Mr. Upson and Mr. Niles that the particular problem taken as an example in this paper is much more simple than most of the space-framework problems likely to occur in practice. It does not seem possible to do nearly as much as one would wish toward taking the "work" out of least work. Nevertheless, the assumption of continuous, instead of discontinuous, transfer of the shear between the booms or longitudinals of a framed structure does seem to simplify the problem to a considerable extent. As Mr. Niles suggests, the assumption is particularly applicable to multi-spar airplane wings with metal or plywood covering.

The author does not agree with Mr. Upson that the proposed method is "quite impractical" with modern rigid airships because of the varying taper of the hull. For purposes of stress analysis, the hull is divided into bays or sections between consecutive main transverse frames; and the taper varies so little that no appreciable error results from considering the taper in these sections as continuous, or even as zero in that portion of the ship where the bending moment is large.

AER-51-23

Comparison of Reinforced-Shell and Steel-Tube Fuselage Construction

By W. C. CUMMING,[1] WICHITA, KANSAS

The author of this paper analyzes stresses in the reinforced-shell and steel-type fuselage of an airplane, and tells how various parts were constructed. Four types of construction were considered, and the reinforced-shell type resulted in a weight saving of 2 per cent.

In designing a high-performance sport and training airplane powered with from forty to sixty horsepower, it became necessary to refine the design to the utmost, both from the aerodynamic and structural standpoint. The aerodynamic design indicated an airplane of about the following characteristics: Wing area 175 sq. ft. with a tapered wing of 37-ft. span, root cord 72 in., and tip cord 43 in. The weight light was not to exceed 725 lb. Due to the high-aspect ratio, it was decided to make a wing in three sections, the two wings being of 15-ft. span with a 7-ft. center section. A normal two-spar construction was decided upon in the wing structure with box spars and built-up truss-type ribs. That gave a wing structure which was very efficient aerodynamically, but relatively heavy, and made it necessary to economize to the utmost on the weight of the rest of the airplane.

When a preliminary stress analysis was run, it was found that everyone of the members from the rear cockpit to the tail post, as designed according to the usual methods, was smaller than the minimum-design size recommended by the Department of Commerce. For example, the lower longeron which was critical in a maximum-stabilizer and elevator-load condition, had an indicated size of $^1/_2$ in. $\times$ 0.035 in., to the last two bays where the indicated size dropped to $^3/_8$ in. $\times$ 0.035 in. As these sizes were entirely too small to withstand the loads imposed by the shrinking of the fabric covering, and also those occuring in handling, it seemed advisable to make a survey to determine if other methods of construction might not be more suitable in this particular instance.

In view of these facts, four methods of construction were considered. (1) Steel tubing, (2) reinforced shell in metal, (3) reinforced shell using plywood, and (4) monocoque. Of course the tubing construction offers some disadvantages as mentioned. The all-metal construction was eliminated, due to difficulties experienced in experimental construction, and it was decided that a monocoque would be too difficult for field repairs in case a design was carried into production. The fact that two very successful English light planes, the Avro Avian and the D. H. Moth, used reinforced shell-type construction, and also that it had been more or less successfully used for some years in the DeHavilland mail planes operated by the government, seemed to point in favor of this type. It seemed advisable to carry out the construction from the rear cockpit forward in the usual steel tubing, not only because of the loads in this portion were of such a nature as to be carried economically by steel tubing, but also on account of added protection afforded the occupants in case of a crash. This would also allow the construction of the seven-foot center section of alloy-steel tubing as an integral portion of the front-section fuselage.

It was decided to design and construct an experimental fuselage section with the reinforced-shell type of plywood and spruce, and two methods of design were considered. These were as follows:

1. The plywood could be assumed to carry the entire load, the area of the truss members cut by any section being included with that of the plywood in calculating the properties of the section.

2. The truss framework could be assumed to carry the entire load, the plywood skin providing complete lateral support in its own plane only, to the truss members.

A preliminary estimate indicated that the second method was more conservative, and due to the fact that this type of construction was an experiment, this method was used.

The same preliminary stress analysis, which was used in the design of the steel-tubing fuselage, was used in the design of this new section, and no allowance was made for the change in the weight of the members or of their weight distribution. Since the change in the weight distribution was very small, and most of the members were critical in the maximum-stabilizer and elevator-load condition, this assumption effects the results very slightly. The design of the individual members of the truss was therefore reduced to taking the design load from the stress analysis, and in the case of compressive stress, designing them from a standard-column formula using the radius of gyration in a plane parallel to the plywood sidewall. In the case of the lower longerons which were supported in two directions, this was reduced to a determination of area required from the allowable compressive stress in spruce.

This portion of fuselage was designed and constructed, and was identical in its external dimensions to the steel-tubing design with the following exceptions. It was thought that due to the difficulty in attaching the fin, as designed for the tubing job, to the plywood construction, it would be advantageous to construct a cantilever fin as an integral part of the fuselage. For the same reason, an integral head-rest fairing was added.

Since this fuselage was not a production job, no attempt will be made to compare it with the steel-tubing production as to the amount of labor required. However, it was constructed from shop drawings by two men in approximately four days, which included application of plywood covering to the sides, turtledeck, and fin. The procedure in construction used was about as follows: All the members were cut to the size indicated in the drawing. The sides were built separately, fastening the web members to the longeron with small plywood gusset plates which were applied on the side, which afterward would be the inside of the fuselage. These two sides were then fastened together by means of the top- and bottom-web members using the same size gussets. The internal-fin structure was then added as were also the turtle-deck members. All of this, of course, was done in a jig similar to that used in the construction of a tubing fuselage with the exception that the jig was made very light with no provision to keep the members from warping as is necessary in a welding jig. After the framework was completed, it was checked for trueness and accuracy before the plywood was applied. The turtledeck, having been designed to a true conic section throughout its length, with the exception of a slight compound curve to the side, presented no especial difficulty in molding the plywood on it. The sides and bottom were covered with $^1/_{16}$-in. three-ply birch attached with water-proof glue and small nails. The turtledeck and fin were covered with $^1/_{25}$-in. three-ply birch using

[1] The Watkins Aircraft Co., Wichita, Kan.

Presented at the Third National Aeronautic Meeting of the A.S.M.E. at St. Louis, Mo., May 27 to 30, 1929.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the same method of attachment. After the plywood was applied it was sprayed with three coats inside and two coats outside with the best spar varnish, and the outside was finished in colored lacquer.

This portion of the fuselage was attached to the steel forward portion by means of five $^{3}/_{16}$-in. nickel-steel bolts through the longerons which were blocked up to compensate for the drilling of these holes. These bolts passed through a $^{1}/_{16}$-in. alloy gusset plate which was slotted into the longeron, and welded to the steel portion. The design load of this section was 1810 lb., and the section in static tests resisted an average of 2900 lb. Two blocks were attached to the truss members in the tail end by means of $^{1}/_{8}$-in. birch plywood gussets for the attachment of a spring-leaf tail skid. The stabilizer was bolted onto two specially built turn buckles which were passed clear through the fuselage and screwed up tight. The compression of these turn buckles was carried by a small steel "U" section which enclosed them.

There follows an analysis of the comparative weights of the steel-tubing fuselage section and reinforced-shell fuselage section. These are especially interesting in view of the fact that both are designed from the same stress analysis. The members of the steel fuselage are all of the minimum size recommended by the Department of Commerce where the size indicated by the design loads was below the minimum. The four longerons are $^{3}/_{4}$ in. $\times$ 0.035 in. and the web members are $^{1}/_{2}$ in. $\times$ 0.035 in. The weight of the tubing is calculated accurately from the weight per 100 in. of tubing as given in "Niles Airplane Design."

Weights in Pounds of Steel Tubing Fuselage

Side trusses	19.00
Top and bottom trusses	7.70
Transverse members	2.60
Turtle-deck members	11.94

Covering and finish	6.76
Total	50.00

While these weights are all calculated, they are conservative. The tubing fuselage section has not been built to date as construction is put off to find out how the plywood job will act in actual service. The fuselage section, actually built as described, weighed 41 lb. with finish, and subtracting three pounds (estimated) for the cantilever-fin construction in order to compare it with the steel tubing, would make the weight of the structure 38 lb. or a saving of 12 lb. over the steel tubing construction. As this is approximately 2 per cent of the weight of the airplane, it is considered well worth saving.

Problems in Flying

By J. H. DOOLITTLE,[1] NEW YORK, N. Y.

In this paper the author discusses many things that are now receiving attention to make flying safer. More and better airports are needed, and a low landing speed is essential. More attention is being given to airplane construction. The cockpit should be strong to protect the pilot in case of a crash, and there should be sufficient material between the pilot and ground to absorb the shock.

Work being done by the Weather Bureau in notifying pilots of weather conditions along the route is of great value. More frequent points for giving information will add to the service. Recent developments provide a satisfactory instrument for measuring altitude. More improvements are needed in the compass for blind flying. Flying in fog makes it necessary to direct pilots to landing ports, and to make it possible to land without seeing the ground. Much work is being done to solve these problems.

SAFETY in flight is the principal problem in aviation. Much has been done in recent years to this end, but there remains much yet to be done. More and better airports are needed. Many of our terminal airports are not as safe as it is possible to make them. They can be improved by increasing their size and by removing obstacles in the vicinity of the field. The ideal airway is one so studded with emergency landing fields that a pilot may land safely at any moment, should his motor fail or inclement weather make it advisable. Present-day motors are far superior to those of even a few years back, but power-plant reliability must be brought to such a point that motor failure will never occur where proper care is exercised in maintenance.

Sufficient importance is not given to the value of low landing speed even by pilots. If a pilot flies the same type of plane every day, he soon becomes accustomed to its landing characteristics, and is satisfied with them. He learns how large a landing field is required, and does not attempt to go into a smaller one. Still, when a crisis comes, one cannot get away from the fact that impact is a function of V^2 (velocity squared), and an airplane landing at 60 m.p.h. hits any obstacle in its path just four times as hard as an airplane landing at 30 m.p.h. The damage to plane and occupants would probably be severe or fatal in the first case and unimportant in the latter.

A feature to which insufficient attention is given is designing and constructing an airplane so that it crashes well. This sounds odd, but many lives have been saved because the cockpit was strong and there was sufficient material between the pilot and the ground to absorb the shock of crashing. This permits gradual, uniform deceleration between the instant of impact and the pilot's eventual coming to rest.

It is obviously desirable that airplanes be made as safe and as easy to fly as possible, but it is equally obvious that when in the near future the air becomes literally full of airplanes which will fly themselves, for the safety of one another the pilots should be able to manage them properly under any and all conditions. This will necessitate a very careful physical examination and adequate training before unrestricted solo flight.

A large percentage of the automobilists driving along the road should not be allowed to operate a car under present-day congested-traffic conditions. Take, for example, the one who always drives down the center of the road. He is not necessarily a "road hog," but stays in the center because his judgment of speed and distance is so poor that he is afraid to drive on his own side for fear of running off. He would rather depend on another's judgment than his own. How much more important that such a person should not be allowed to fly when the primary prerequisites for a pilot are accurate judgment of speed and distance, and quick, correct reactions, and that even with the present careful supervision over 80 per cent of the fatal accidents in aviation are due directly or indirectly to piloting errors.

From the point of view of congested traffic, aviation has one great advantage and one great disadvantage over any other means of transportation. The advantage is another dimension in which to dodge and the disadvantage is that a flier, to remain in the air, must "carry on." He cannot "lay to" when conditions become unfavorable. To stop is to fall. Thus, to fly requires more and quicker judgment than to drive a car.

The work that is being done by the Weather Bureau in notifying pilots of the weather along their routes is of inestimable value, but there is still room for considerable improvement. The two principal faults are:

1 The points from which weather information is available are too widely separated, so it is impossible to get more than a rough average estimate of the weather conditions along the route.

2 The weather information is now available for the past and present, and weather conditions for any time in the future cannot be predicted accurately. The pilot is not primarily interested in the present weather at his objective, but he wants to know what the weather will be several hours later upon his arrival. The hourly radio reports given out by the airways division of the Department of Commerce are a great step forward.

Our training in the past has been such that a pilot who used his flight instruments was termed "mechanical" and often thrown out of school. This condition should no longer exist. It has been proved that unless he can see some reference point a human being is not equipped with the senses necessary to permit him to maintain a level, directed course. He can do this only with the aid of suitable instruments.

For blind flying three primary instruments are required: first, something to give the attitude of the plane with respect to the horizon; second, something to give the direction of flight; and third, something to indicate whether or not the attitude and direction are coordinated properly. In the past it has been found that flight-attitude instruments operate satisfactorily only when weather conditions are favorable. For example, a pilot can fly blind for a considerable period of time if the air is smooth, but in bumpy air it is practically impossible to maintain a desired course at any given altitude. Furthermore, the pilot requires mental effort to utilize these instruments, and after flying blind for some time experiences fatigue.

There has recently been developed in this country the first satisfactory instrument for indicating the attitude of the airplane. This instrument consists of a single stabilized, nonpendulous gyroscope mounted with the axis vertical and operating, through a simple mechanism, a line which always remains parallel to the earth's surface. This line represents a "piece

[1] Lieutenant, U. S. Army, in charge of the flying operations of the fog-flying laboratory of the Daniel Guggenheim Fund for the Promotion of Aeronautics, New York, N. Y.

Presented at the Third National Meeting of the A.S.M.E. Aeronautic Division, St. Louis, Mo., May 27 to 30, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

of the horizon." Bank is shown by the apparent rotation of the line, and pitch by an up-and-down motion.

As the gyro in this instrument is not pendulous it is not affected by rough air, and as the gyro is stabilized it does not precess but remains always with its axis normal to the earth's surface. It is unaffected by a steep, continued bank to right or left, and after leveling out, the hand again immediately indicates level flight.

The magnetic compass is satisfactory for navigation in smooth air, but in very rough air, especially when flying blind, it becomes practically useless. This is true of any compass which operates through the effect of the earth's magnetic field. One confusing thing with the magnetic compass is that, due to the dip of the earth's magnetic field, when flying north if a turn is started to right or left the compass indicates that the pilot has started turning in the opposite direction. This is particularly annoying when flying blind. The tendency, inherent in all magnetic compasses except the aperiodic, is to swing past the course being flown, and require a considerable time to settle. This is bad.

An electric compass employing the earth's field and a heavy, pendulous, rotating armature will indicate a turn when the airplane pitches due to the precession of the gyroscope formed by the rotating part. The ultimate solution lies in a light, compact gyroscopic compass, and the immediate solution for blind flying lies in a turn indicator which mounts a compass card and which can be "indexed" or set practically on "north" at will by checking back from the magnetic compass. This will hold for some hours, depending upon the power and orientation of the gyroscopic element, and the pilot flying blind can immediately read his course, keep himself from deviating from it, and can at will change his course any desired amount by adding or subtracting the proper number of degrees, and turning until his lubber's line rests on the reading for the new course.

This latter maneuver is very difficult to execute at present, and can be done only by trial and error, and in very bumpy air only with the greatest skill and patience. This maneuver is of especial importance in landing blind as the beacon is usually some distance from the field and the pilot wishes, usually, to change his course an exact amount when coming in on the beam and getting the indication that he is exactly over the beacon.

The last fundamental instrument is merely the old level bubble or ball which tells the pilot if he is employing the proper bank in any turn, or, from the pilot's viewpoint, which rudder he should use to correct it if he is not.

The author has purposely avoided the problem of ice formation on the airplane as he feels that the excellent research work now being done by Dr. MacAdie at Blue Hill Observatory and the Weather Bureau with the cooperation of the Air Mail Services should soon give the contributory causes. It is then but a step to develop instruments which will indicate the approach of these conditions, and tell the pilot, provided he is equipped for indefinite blind flying, at what altitude or what course to fly in order to avoid them.

Another enemy to be overcome is fog. The problem of fog flying resolves itself into the ability to carry on flying operations under any and all weather conditions. That is, to take off from any point, arrive safely, and land at any other desired point regardless of the weather. One needs nothing more than the instruments at present developed in order to take off and fly indefinitely in fog no matter how thick it may be, but landing without being able to see the ground is a more difficult problem.

After taking off it is necessary that the pilot be directed to the general vicinity of the desired port. This can, at present, be done with either the visual or aural-type radio beacon. The aural type has the advantage of a somewhat greater range. The visual type has the advantages of greater ease in reading, less fatigue to the pilot, and of being affected less from interference with other stations operating on approximately the same wave length. This latter point is especially important near the seacoast where great difficulty is experienced in following the aural beacon due to interference from marine beacons.

It is possible, with either type of beacon, for the airplane to be led to a point exactly over the beacon tower, and for the pilot to know when he has arrived at that point. From here or from some other point along the beam it is necessary to direct the pilot to the exact point where he desires to land. For this a small localizer beacon or lead-in cable may be employed.

If we assume the worst conceivable case—when it is impossible to see the ground until the plane strikes it—a knowledge of the approximate altitude above the ground is required in order to avoid over- or under-shooting the field.

Several instruments to give true altitude are now in process of development, but no completely satisfactory one is at present available for general use. The simplest means of getting true altitude above the earth at any point now is by a combination of the aneroid or barometric altimeter and radio. If the ground station at the point of landing radios the ground pressure up to the pilot, he can set this off, and then he has true altitude. A rate of change of ground pressure corresponding to five feet per minute on that method is not uncommon, especially near storm centers, so the pilot must be acquainted with the exact ground pressure again just before landing. He can thus square off at a given altitude, at a predetermined point, and start his glide into the field following the localizer beam or lead-in cable. If a correction is made for the wind and he comes in at the proper air speed and rate of descent, he will arrive at exactly the desired point on the ground.

Recent tests have shown that in employing the method outlined, the pilot does not have to see the ground in order to land, but can make a good landing absolutely blind, provided the plane is held level in a steady glide at an airspeed of not over 20 per cent in excess of the stalling speed, and at a rate of descent of not over 500 ft. per min. In order that the angle of glide be sufficiently flat it is necessary to come in with the throttle cracked and the motor "reeving up" slightly. A little practice will give the best air speed and engine revolutions at which to come in. Care must be exercised to see that the glide into the field is straight, and started at an altitude sufficient to let conditions become steady before the airplane lands. The primary requisite is a good oleo landing gear. This maneuver cannot be executed with rubber shock absorbers as the plane will either bounce back into the air or the landing gear will carry away.

We have now, either in our hands or in process of construction, the instruments and equipment required to fly in fog and to land blind on a prepared airdrome. It is only necessary, before actual fog operation can be carried on, to coordinate these facilities and render them infallible.

Discussion

P. V. H. Weems.[2] In addition to the principal problem of safety, we have the important problem of flying on schedule. Our air-mail pilots have done wonders in going their appointed rounds regardless of adverse flying conditions. Much remains to be done to permit dependable scheduled flying over many parts of the country.

The importance of an instrument to indicate the attitude of the plane cannot be overestimated for blind flying. As Lieu-

[2] Lieutenant Commander, U. S. Navy.

tenant Doolittle brings out, it is when we need the aid of instruments for blind flying most that these instruments "act up" and are likely not to function properly. Hence the need is for exceptionally rugged instruments. Assuming that the instruments will withstand the conditions imposed in blind flying, an important point is to have the pilots so trained in good weather that they may react properly when the emergency occurs. I am of the opinion that the relief pilot in large passenger planes does not do as much training work as he should. He has an exceptionally fine opportunity to test instruments and to do as much navigation as facilities permit. Intensive training on the part of relief pilots would be a definite step toward greater safety and efficiency in air navigation.

Referring to the stabilized, non-pendulous gyroscope for indicating the attitude of the plane, there is a new style gyro mounted as described, but showing directly the attitude of the plane and the angle of bank, or angle of attack. The instrument was invented by Lieutenant Burgess of the Army, working with Mr. Schenck, a gyroscope expert who gained his experience in German Zeppelins and in German submarines. The instrument is called a turn-and-bank indicator, but it really shows the exact attitude of the plane to the earth. It is driven by air in the same way a windshield wiper is operated, but through a small turbine. It may be stopped and started in the air, and reset by leveling off by compass and an ordinary turn-and-bank indicator. Getting away from the deceptive bubble and the vagaries of the magnetic compass in blind flying is a big step in making blind flying practicable.

Another means for increasing the safety and efficiency flight lies in the use of practical celestial navigation. A skilled navigator, using present methods of celestial navigation, can take off through the fog, fly around the earth, and return within ten miles of the take-off point without once seeing the earth. For long hops over land or sea, celestial navigation affords a ready means of navigation independent of objects on the earth, and solves the problem of blind flying by keeping above the fog or clouds where the aircraft has sufficient ceiling.

With present equipment and methods (the latest), a position may be worked in a minute when stars are available, one subtraction being the only figuring necessary. During the day, when flying on schedule, a "line of position," at some point on which the observer's position lies, may be determined continuously, i.e., as quickly as the altitude of the sun or moon may be observed and plotted on a curve drawn on cross-section paper, say every 40 seconds, and this without so much as writing a figure! This method is possible by the precomputation of the sextant altitude which is suitably graphed on cross-section paper against time. All the computations for scheduled flying may be done before taking off. If the schedule is not followed in the air, considerable work over the older methods may be saved by computing the curve while in flight. Once the curve of altitudes is plotted, the observed altitudes and corresponding times give at once practically all the information which may be obtained from careful solutions by logarithms.

The promising feature about the latest methods and technique of celestial navigation is that a position may be determined easier than the drift is determined by the usual methods, and once the position is determined, the drift, course, and speed over the ground are given at once. It appears that the centuries of development of marine celestial navigation have in some respects been a disadvantage to the airman due to the fact that the extreme accuracy demanded in marine navigation has imposed somewhat difficult solutions which have always appeared a mystery to all but marine navigators. It might be added, however, that methods of marine navigation have already profited greatly by the methods developed to speed up air navigation.

With a suitable gyroscope for showing the attitude of the plane, with a dependable gyro compass, with efficient radio, and finally with a good sextant and other equipment needed for celestial navigation, a plane should be as dependable for following its schedule as an ocean liner so far as the navigation problem is concerned.

J. E. Gingrich.[3] Lieutenant Doolittle's excellent paper treats the subject from an experienced and understanding viewpoint, that of the flier. His are the troubles of the operator of the plane. How many airports are there along the route to be traveled? Does the plane have a sufficiently low landing speed to use a small landing field? If the plane crashes, is it so designed and constructed as to offer maximum chance of safety? In other words, he sees the problem from the viewpoint of immediate safety to the plane and pilot; and this, no doubt, covers the major part of the problems in aviation.

However, there is possibly another problem which the flier, when flying blind, and in making long distance flights, must face; that of fixing his position in the air with reference to the earth.

In the past, with few exceptions, long-distance flights have been attempted, flying by dead reckoning. Due to the fluidity and the variability of the medium in which the plane travels, and due to the unreliability of the magnetic compass, the plane may be swept hundreds of miles from its proper track; and the flight passes into the long list of unsolved mysteries.

Definite steps have recently been made toward facilitating the proper avigation of the plane by means of celo-avigation. The term avigation is derived from avis, a bird, and agere, to lead. Celo-avigation deals with the fixing of the plane's position in the air by means of astronomical observations.

The second-setting watch allows the second dial to be turned so that the watch may be set to keep exact Greenwich civil time. Sidereal watches with the movable second dial allow the keeping of exact Greenwich sidereal time. This solves about half the problem of working a sight.

The new Hydrographic Office navigation tables HO-208 conceived by Lieutenant Commander Dreisonstok, U. S. Navy, and the new line of position tables by Lieutenant Commander P. V. H. Weems, U. S. Navy, reduce to a minimum the labor of fixing the plane's position.

The problem of teaching the aviator sufficient spherical trigonometry to enable him properly to use the means of celo-avigation which he has at hand must be solved by proper instruction at the aviation school.

Sextants of the bubble type are in the process of development. This type of sextant was partially perfected, and was used by Commander Byrd on his North Pole flight. The present type of bubble sextant should be accurate to within 15 minutes of arc, or 15 miles. The further increase in accuracy of the sextant is still a problem.

The new sextant camera invented by Lieutenant Commander Pierce, U. S. Navy, is designed to photograph the time and the position of the sun or star, allowing the aviator to calculate his position from the picture. The further adaptation and use of this new instrument opens up vast possibilities in celestial avigation.

There are mechanical features of the celo-avigation problem which must be perfected, such as proper charts which will not tear or be ruined by the weather, proper map holders, and proper avigational instruments for rapid work while in the air. Above all, however, on long flights, the aviator must learn to understand and use the facilities for celo-avigation which are at present available.

[3] Lieutenant, U. S. Navy.

V. I. ZELOV.[4] Lieutenant Doolittle's paper is a valuable contribution to the rather scarce information available on the present status of flight instruments. The paper contains a general description of a number of new devices the development of which is apparently successfully approaching the desired results. But, as in most cases, the value is gaged upon the final shape of the instruments, and the discussion should be postponed until the new devices are completed. The principles upon which engineers are working are correct. It is hoped that instruments which are dependable, not prohibitive in price, and not too complicated will be available in the very near future.

It is extremely gratifying to the engineer in general and to the instrument designer and manufacturer in particular that a pilot rapidly and decidedly begins to appreciate the value of aircraft instruments. We do not have to remember far back when a pilot believing in his instruments was considered "scientific" or queer by his fellow fliers. The recent past has taught them differently; they now want better and more instruments. It is natural, since humans do not possess air-feel and since the same air either carries them on or brings them down, that one has to know when it is with or against him.

The accurately installed and maintained airspeed indicator shows not only the speed of flight but foretells stall and indicates proper landing speed. The accurate barometric altimeter should receive its share of attention and be properly read so as to warn of the approach to the ground when it is not visible. The magnetic compass is fully reliable if properly compensated and designed, so as to be free from spins and deviations. Rate-of-climb and turn indicators supplant the lacking "feels" and supply an ease in handling aircraft when erratic sensations begin to confuse usually cool-headed and experienced fliers.

It is apparent that a number of new instruments have to be developed to take care of the requisites of successful flight which do not exist or have not been experienced in our earlier modes of transportation. At the same time, the instrument board should not be studded with a multitude of indicators, which would certainly discourage the pilot. A number of instruments should be conveniently combined, their dials properly limited to operating zones and having unnecessary ranges of indication so placed as not to confuse the observer and detract his attention from more important observations.

Upon careful study of particular aircraft, the instruments should be set and their location adjusted so as to render them as easy as possible to read, with danger points well indicated.

Instrument knowledge can be easily imparted to the future pilot, prior to his exposure to the dangers of an enthusiastic beginner, and schools of blind ground "flying" will teach him to follow his indicators, which have to be foolproof and accurate. Movement of controls can be arranged with properly set limiting signals or stops interrelated to aerodynamic properties of definite aircraft. Wing-pressure indicators, center of pressure locators, stress recorders and other devices will prevent the abuse of a plane from a structural or aerodynamic point of view, thus eliminating a great number of so-called accident failures. With the elimination of fire hazards, proper knowledge of gliding flight, supplemented by a suitable system of airports and emergency flying fields, aviation will be made a sound undertaking and be assured as a successful method of transportation.

Air Navigation

An Estimate of Progress Made, and a Discussion of the Minimum of Theoretical Knowledge Required by Pilots

By GEORGE R. FAIRLAMB, JR.,[1] RICHMOND, VIRGINIA

THE term "navigation" embraces a variety of meanings. Employed not only in the scientific sense but also in the vernacular, it appears reasonable at the outset to define it and then to confine it. Used scientifically, navigation denotes the science which enables one to conduct a craft from point to point such that its position at any time during the journey is known. In a wider sense it includes the ability to go with reasonable assurance of safety under a variety of conditions. The problems of safety in flight under conditions of low visibility and with all auxiliary aids to navigation might well be included in a discussion of aerial navigation, but they constitute special problems in themselves and are so being treated. As here discussed, navigation will be limited for the most part to its meaning of determination of position in flight. Development of some of the means and methods to this end will be pointed out, and an endeavor made to classify the nature and amount of navigation knowledge needed by airplane pilots.

Air Navigation Abreast of Other Branches of Aeronautics

There is no doubt that air navigation has kept pace with progress made in other branches of aeronautics. The marking of the airways with beacons, the collection and dissemination of hourly weather reports direct to terminals and to radio-equipped planes in flight, and the successful application of the radio beacon to mark the course on airways are known to every one who is familiar with the aeronautical industry. Assuming that instrument flying will eliminate the danger of fog and low visibility, the radio beacon makes navigation on the fixed routes a foolproof and automatic affair, while development of further aids in the nature of high-sensitivity altimeters and leader cables are pointing the way to landing on fog-covered airdromes. The capacity altimeter, designed for high sensitivity, uses the principle of varying air dielectric of a condenser with altitude, the earth and a portion of the airplane being used as the plates. It is possible also that a radio altimeter, similar in principle to the marine sonic depth finder, may prove successful in this field. This instrument would measure the altitude in terms of time taken to send a radio signal and receive the echo signal reflected back by the earth. The leader cable is an underground wire extending from the airdrome. It transmits signals to guide the plane to the landing field, after which landing must be effected by use of the sensitive altimeter.

Publication of new inland-airway maps proceeds by the Department of Commerce, while the Navy Department is publishing airway coastal maps. These, when completed, will cover not only our own coasts but also western Canada, Mexico, and the Central American coasts to the Canal Zone, not to mention the West Indian Islands from Cuba to Trinidad, and the South American coast westward from thence to Colon, thus completely girdling the Caribbean Sea. Each month it publishes the "Upper Air Pilot Chart," giving meteorological conditions that may be expected over the Pacific and Atlantic oceans, and showing the best routes for pilots who have transoceanic flight ambitions. On the back of these charts is printed valuable information of a general navigational nature—varying all the way from curves showing the shift of winds at altitude to sample solutions of problems in aerial dead reckoning and celestial navigation. It also publishes "Notices to Aviators" which like the charts are identical in nature with its similar publications for mariners. It has completed the drafting of special mercator navigational charts from the equator to 48 deg. latitude and has developed the "air plotter" to facilitate the use of these charts. The air plotter is very simple, being a clear piece of square celluloid with compass bearings and distances etched upon it. Each 10-deg. bearing is marked by a line radiating from the center, while intermediate degrees are indicated on the edge. Concentric circles mark distances in increments of 10 miles. It is designed to do the work of parallel rulers and dividers, thus facilitating plotting and laying down or picking off courses from a chart.

Developments in Air Sextants and in Celo-Navigation Methods

The most interesting developments, however, have been in air sextants and in methods used in celo-navigation. The first air sextants were converted marine sextants, adapted for air use by attaching just below the horizon mirror a spirit level and a mirror to reflect the bubble. The image of the spirit level provided the aviator with a much needed artificial horizon.

Practically all later sextants have been refinements of this principle, in which a spirit level informs the navigator when the sextant is held in the horizontal plane, the altitude of the sun or star then being measured by bringing its image down to the image of the bubble in the level. Vibration, rolling, and pitching of an aircraft make it extremely difficult to hold a sextant steady. The result is that the bubble is rarely ever quiescent in the center of the level, as it must be to obtain an accurate sight. New designs have endeavored to dampen the oscillations of the bubble; to provide a more compact and easily handled instrument; to give the navigator a mechanical advantage of position in holding the sextant so that both sun and bubble may be sighted through an optical system by looking down, instead of the customary method of looking out directly toward the sun. It has always been customary to hold the marine sextant with the right hand. The newest air sextants are being made to hold in the left hand, so that the right hand may be free to note down the time and altitude. Here, as elsewhere, necessities of convenience and speed for the air navigator have greatly accelerated the development of equipment and methods which are proving a boon also to their brother navigators of the sea. One of the most interesting sextants is a photographic instrument developed by Commander Pierce of the Airship *Los Angeles*. This sextant avoids the oscillating movement of the bubble as follows: A photograph of the sun and the bubble is made simultaneously after the image of the sun has been brought down to the *vicinity* of the bubble. The photograph is taken at a moment when the bubble is centered. The film is self-developing in about a minute's time, and a small scale is used to measure the distance between the sun and the bubble. This distance in arc measure is applied to the observed altitude to get the corrected

---

Presented at the Third National Meeting of the A.S.M.E. Aeronautic Division, St. Louis, Mo., May 27 to 30, 1929.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

altitude. Commander Byrd took the first of these instruments on his polar expedition, and the second one is now being tested at Lakehurst. Taking celestial observations in an airplane is a difficult thing at best and requires much practice. When the air is rough, an error of forty or fifty miles in the observation is not uncommon. When the air conditions are good, the error of a skilful observer using a good instrument may be expected to average from 10 to 15 miles. But the air sextants of today are vastly superior to those of yesterday, and improvement continues.

Time is a vital element in celestial navigation, and there are three kinds of it to worry the navigator, namely, apparent solar, mean solar, and sidereal or star time. The declination of the sun, the equation of time, and the declinations and right ascensions of the stars are tabulated against Greenwich mean time, while the navigator solves the astronomical triangle for the moment of the apparent sun time or sidereal star time of his observation. To convert one time to another lengthens the solution and introduces additional probability of error. Hence it always has appealed to air navigators to have several chronometers—one carrying Greenwich mean time, one carrying Greenwich apparent time, and one carrying Greenwich sidereal time. No one has as yet built a watch, except on paper, to keep apparent time, yet a second-setting watch is now being made at the Naval Observatory which does almost as well. This watch, invented by Lieutenant-Commander Weems, has a ratchet which permits it to be set by the daily radio time signal to the exact second of time, only instead of setting it to the mean time a correction (the equation of time) is applied, and it then shows apparent time for the succeeding twenty-four hours. Incidentally, by resetting it each day the usual chronometer error is avoided. The time of an observation is noted from this watch or from the sidereal watch in case of a star, and several tedious arithmetical steps are saved in the solution for the position line.

Celo-Navigation and How It Is Done

Many have doubtless desired to know just how navigating by the heavenly bodies is done. Reduced to simplest terms and principles, celo-navigation enables the observer to obtain a locus of points—known as the Sumner line of position—upon which he is at the moment of observation. Intersection of two (or more) lines in a point, obtained by observations of two (or more) bodies, establishes a definite position called a "fix." The principle on which this is based is a pretty one, yet it has been known and practiced for less than a hundred years, having been accidentally discovered in 1837 by Capt. Thomas Sumner, an American Shipmaster. It depends upon the fact that for any given instant of time there is a series of positions on the earth at which a celestial body appears above the horizon at the same altitude. These positions lie on a circle described on the earth, the center being immediately below the body where the altitude is 90 deg., and the radius of the circle being in effect the given altitude. Such circles are called circles of equal altitude, and are of course nearly infinite in number. Looking at it another way, we may place the observer on one of these circles at an assumed position, denoted by latitude and longitude, and then calculate that at a given instant of time a particular body must have a certain definite altitude when viewed from that point. If at this instant the observer measures the actual altitude of the body by a sextant and it is different from the computed altitude, he is either inside the circle or outside according as the observed altitude is greater or less than the one computed. Solution of the astronomical triangle determines in effect, for the instant of observation, the direction of a very small portion of one of these circles and its distance from the center in terms of altitude of the observed body above the true horizon. The observer compares the actual altitude of the body as measured by a sextant with this computed altitude, based on a definite *assumed* position, and thus establishes a line of position coincident with or parallel to the computed portion of the circle of equal altitude that passes through the assumed position.

There has been continuous progress in the methods of solving for the line of position. The old methods required from fifteen to twenty minutes for solution, and involved many chances of faulty arithmetic, or mistakes in picking out the numerous arguments from the various tables. To obviate this labor and to obtain speed, air navigators resorted to many ingenious devices, but all involved considerable pre-flight labor in preparing specially computed tables covering various heavenly bodies for the expected period of flight, and in some cases special charts. This is no longer necessary. The navigator may now embark with a nautical almanac, one small book, and no pre-flight worries. Two new methods, invented and developed by naval officers especially for air work, permit the solution of the astronomical triangle in from two to three minutes' time. The latest of these books known as "Hydrographic Office Publication No. 208," is highly accurate and can be used not only to solve for the line of position but also to find direct the latitude at local noon, to identify unknown stars, and to compute great-circle courses and distances.

It should be understood that a single celestial observation does not determine the observer's position, but merely a line. Thus it is only at morning and evening twilight or at night that a "fix" can be obtained from the stars by celo-navigation, unless during the daytime the moon is visible and in favorable position for crossing its "line" with the "sun line." In the morning and late afternoon the sun line of position runs nearly north and south, and thus gives a good indication of longitude at the time of sight. At local noon, the sun being on the meridian, its position line runs due east and west and definitely establishes the latitude. If the morning sun line be moved parallel to itself in the direction of and for a distance equal to the track of the aircraft between the time of the morning sight and the local noon sight, its intersection with the moon line gives a noon position. It is obvious, however, that the actual track of an aircraft between these two sights may be considerably at variance with the track as computed or plotted by dead reckoning, and hence such a position found by "running forward," as it is called, an old line of position is of doubtful value. This, however, is the best that can be done by day at the present time, and it is evident that the radio beacon must be combined with celo-navigation to give the maximum results. The beacon not only solves the very important problem of drift (difficult enough over water by day and even more so by night), but it also establishes a definite line of position. The beacon line is a somewhat thick one, to be sure, but it will serve very well to obtain frequent and rapid "fixes" by the simple process of intersecting it with lines of position obtained by celestial navigation. In case of a forced landing the navigator can report a very accurate position. Thus the beacon and celo-navigation both have an important place in the scheme of future transoceanic air travel, although neither one can take the place of the other, both being essentially complementary to the general scheme of navigation.

Navigation may be said to fall naturally into two main branches, viz.: geo-navigation and celo-navigation. The former embraces the methods and means of determining position with reference solely to the earth and objects on the earth. It comprises what are known as piloting, dead reckoning, and directional radio. Piloting, perhaps better known as "map flying" in aviation, employs visible and plotted landmarks; dead reckoning employs the knowledge of ground speed and direction taken; directional radio may either delimit and mark a course or de-

termine the position, or by combination do both. Celo-navigation, as has been noted, is the branch which, based upon astronomy, enables position to be determined solely from the sun, moon, planets, and stars. We have a variety of navigation methods to choose from, but it is obvious that no single method can cover all classes of flying. Moreover, when we consider how to find the course, which is as much a part of navigation as the determination of position, this requires certain other knowledge depending also on the type of flight. In general, it is usually classed as being in the realm of dead reckoning. Finally, all methods and both general branches of navigation are very closely correlated.

It is often said that an airplane pilot must learn navigation. But we do not demand that Chesapeake Bay fishermen and tugboat captains be finished deep-sea navigators, nor are we surprised if inland-waterway navigators prove incompetent out of sight of land. Undue emphasis on navigation for aviators can therefore only lead to contempt for it on their part, for it is not very difficult to learn map flying and to get about cross-country successfully with only the most sketchy ideas as to the fundamental principles of navigation. It does not matter that the pilot who is thoroughly acquainted and familiar with the art of navigation is *potentially* a more valuable and perhaps safer pilot, for the other chap if he uses good judgment will arrive too.

The Kind and Amount of Navigational Knowledge Required by Aviators

What, then, is the kind and amount of navigating knowledge required in aviation? This depends, obviously, on the type of flying. It is well to remember also that the amount of navigation possible depends to a large extent not only on the type of airplane and the equipment, but also on whether the pilot must fly and navigate alone or whether there is a relief at the controls. A lone pilot frequently has a bad time trying to do both, and easily becomes confused as a result.

Heavier-than-air flying may be classified under three general types: first, transoceanic flights; secondly, flights of shorter length, but involving stretches of water that take the plane out of sight of landmarks ashore; and thirdly, flights over land. Such flying may be either commercial or military in nature, but the principles governing navigational requirements are nearly identical.

Transoceanic flights obviously demand a *navigator* skilled both in geo- and celo-navigation. It is true that some flights have been successfully made without the aid either of directional radio or celestial navigation, but this does not prove anything from a navigational standpoint. Transoceanic flying is still a stunt, and is likely to remain so for some years, but coastwise flights, involving stretches of overwater flying, best illustrated at present by Pan-American Airways, is no stunt. Such flying is a sound and logical forerunner of future commercial overseas flights. It is highly desirable that this type of flight should also be provided with a very skilled navigator aided by directional radio, and for the same reason that boats or amphibians are used, namely, as a factor of safety. Take for example the 110-mile stretch between Key West and Havana. Here there is no question of ability to make a satisfactory landfall, but in case of a forced landing there is a question of reporting the exact position. Since, as previously noted, it is not always possible to obtain a fix at sea by celo-navigation during the day, the radio beacon should be used either in connection with lines of position obtained by celo-navigation or with one or two well-located radio-compass stations to give cross-bearings. Whether we use just the beacon and celo-navigation or a system of directional radio (and this seems the better in these cases), the navigator must be of deep-sea caliber to get best results. It can only be a short time now before planes will run on schedules between the mainland and Bermuda, throughout the ring of West Indian Islands, and from the Canal Zone direct to the States via Cuba. The company that undertakes this without providing proper directional-radio equipment and competent navigators skilled in all forms of navigation, will be headed for an eventual disaster. So much for transoceanic and shorter trans-water flights. There *is* no minimum of navigational knowledge or ability for such types of flights, and this is true, be the weather fair or foul.

When we consider flights made exclusively over land, it is natural to think in terms of the flights that are made daily over our own well-mapped country. Here there is no need for celo-navigation at all. When the weather is fine and visibility is good, we need not even bother a great deal about any kind of navigation so long as we can read a map, while if the visibility is low one can very sensibly take a railroad or perhaps a highway route. Not a year since a lad of eighteen years made two passes at the large Air Corps field near Dayton and finally screwed his courage up and landed, one wing low. The day was fine and clear. He wanted gas and he wanted to know how to get to Troy, Ohio. The day before he had completed his first ten hours' instruction at a Long Island school and then on his first solo flight flown blithely on to Buffalo. He was en route to points west via Troy. He had three gallons of gas left, but the hard-boiled sergeant finally relented and instead of sending him on to the commercial field, gave him some gas and directions to follow the river. We scanned the papers for the next few days, but apparently there were no obsequies held. He got through. His navigation, one might say, was of the rough-and-ready kind, but it seemed to suffice, and apparently there is a great deal of that kind of navigating being done these days. As long as it works, it is all right, and it further appears that that kind of navigation is quite suitable for what might be classed as private cross-country flights from point to point for pleasure or profit. There is a minimum of navigational knowledge, however, for these pilots. They should be good map readers, have an elementary knowledge of the compass, and should either fly in fair weather or faithfully follow the railroads. There is no use in saying that this cannot be done or is unsafe, for the fact is that it is done daily, and, combined with good piloting ability and good judgment, it is not unsafe.

Minimum Navigational Knowledge for Overland Commercial Pilots

The most important flights, though, are scheduled commercial flights over regular airways, and special commercial flights from point to point not over regular airways but in the nature of air taxi service. It is possible for pilots to do such work with only a rudimentary knowledge of geo-navigation and especially if flying only along a regular airway, where daily trips familiarize them to such an extent with the terrain that they can find their way about within the narrow belt of their route as easily as one can navigate around one's bedroom in the dark. Such airplane pilots are comparable exactly to our river- and harbor-boat pilots. The demand of navigational knowledge on the taxi pilot is more exacting, but since this pilot is usually chosen from the staff operating on a regular run, it is proper to set a minimum for all overland commercial pilots.

This minimum should be set, because the pilot who has a comprehensive grasp of navigation is potentially the safest one to fly with, other things being equal; he will average better time and consequently less gas consumption; he will combine judiciously his general navigation knowledge with so-called railroad flying, and will not confine himself to railroads unnecessarily. The minimum for these pilots is everything short of celestial

navigation and the "sailings" of marine dead reckoning. This includes a knowledge of maps, the projections on which they are made, what the courses laid down on them represent, and how distances are measured on them; the true significance and meaning of direction on the earth's surface, of bearings, and how they may be expressed; the theory of the compass, the errors of variation and deviation and how they are found and used; the errors peculiar to the aircraft compass, and how to mount, compensate, and take care of the compass; the problems peculiar to aerial dead reckoning and their graphic solutions, such as the method of course finding to allow for drift in order to make good a desired track, and the method for finding the radius of action from an airdrome; the instruments used in flight, the instrumental aids to navigation, such as the drift indicator, the course solver, earth inductor compass and directional radio; and last but not least, meteorology and weather-map reading, at least to the extent that general weather and wind conditions can be predicted. A pilot having a very thorough grasp of all this has a valuable background of navigational knowledge that on occasion may prove invaluable. As long as he flies solo, he cannot do more today in the average airplane than get his drift by trial and error, fly by map and compass, and figure his ground speed as best he may; there is no room or provision for course solvers, drift and wind computers, or other gadgets, nor leisure to use them. Nevertheless, he is backed by the confidence of knowing what he is doing, and if he gets lost he at least will not cut aimless circles trying to relocate himself. It is much better to fly by compass than by instinct. As a passenger in a two-seater not long ago the author flew by instinct for a spell on a cloudy day, and was soundly berated by the pilot who awoke to find the plane going east when the desired course was west. It is only fair to say that there was no compass in the after cockpit.

In conclusion, instrumental aids and methods have reached a state of development that make air navigation almost as exact in skilful hands as marine navigation, and, the author believes, in any case sufficiently exact. The radio beacon is undoubtedly the outstanding development and improved methods and sextants are next, while many small but vitally important details such as air maps, charts, watches, etc., have been developed to fill a much-needed gap. We have only to use the equipment we now have, and refinement into something better must inevitably follow. As for the theoretical knowledge of navigation that should be stocked in the mental equipment of each type of aircraft pilot, the case is the same.

Discussion

Bradley Jones.[2] The author sums up the various phases of air navigation in a lucid manner and the status of the art is clearly stated. In connection with his comments on a second-setting watch, the desirability of having apparent time aboard the airplane is well put. One usually reads time, however, by noting the position of the hands and not by scanning the figures. Many large street clocks have no numerals, but merely dots at the hour points. A timepiece having a rotatable seconds dial cannot be read without close scrutiny or there is chance of error.

The average hourly difference in the equation of time is 0.56 seconds, so that if a watch is set on the average apparent time for a given day, the error in most cases will not be more than 6 or 7 seconds, even if the rate is not changed. Since at present flights of 24 hours and over are out of the ordinary and suitable preparations must be made for them, the labor of regulating a watch to nearly apparent time for such flights is insignificant. For the first Pacific flight the Army Air Corps set a watch on apparent time by momentarily stopping the escapement. Properly done, this does not injure the mechanism, and the added complication of the second-setting device is avoided.

The artificial horizon for a sextant is still a problem. No one would think of holding a tumbler full to the brim with water while riding in an automobile over a rough road without some of the water spilling. Yet it is a parallel case to attempt to hold a spirit level in an airplane and not have the bubble dancing about. By taking a great number of observations and averaging the results, this mean should theoretically be nearly correct. The camera sextant is designed to do this averaging quickly and easily. For several years the Army Air Corps, having despaired of obtaining an ideal artificial horizon with a single bubble, has been searching for combinations of spirit level and pendulum, spirit level and gyrostat, or pendulum and gyrostat, in which the effect of acceleration on one element is neutralized by the effect of the same acceleration on the other element.

Harold C. Gatty.[3] The need for accurate navigation in the operation of air lines is generally becoming recognized. Aviation has progressed, and paying air lines have been established so rapidly that navigation, or the need of it, has in the past received little attention from air-line operators. Efficient planes have been built, and engines have been improved, to a point where reliability is assured. Good business men are establishing air service on a sound business basis; slipshod methods and guesswork have been eliminated in all but one direction, and that is in the navigation of the plane.

Two pilots are carried on most transport planes. The only apparent excuse for the presence of the extra man is that in the event of the chief pilot dying of heart failure there is someone else capable of taking the controls. It is quite right that the passengers should be protected against all possible accidents, but there is no reason why the assistant pilot should not be actually prepared for other emergencies with regard to the navigation of the plane.

What would we think of a passenger vessel leaving port without an accurately checked compass and the necessary navigational equipment for the determination of the position of the ship by officers having the necessary knowledge? To be sure, it is quite likely that it may reach its destination, but we are not protected for any emergency that may arise.

Time in the air directly affects operating costs, and air-line operators should realize the great advantages of direct flight over railroad courses. Railroad courses may be all right for the man who is cruising for pleasure, but air lines are more concerned with cutting down the time in the air than in sightseeing. How many times in foggy or thick weather will a pilot keep close to the ground in order to recognize known landmarks beneath him, even though he knows full well that there will be no fog at his destination! Supposing, in this case, the pilot is equipped with an accurately checked compass, instruments for determining his position, and the necessary knowledge to make use of them. Would he not climb to a safe altitude above fog and clouds, make a direct course, and eliminate any danger of a crash in a mountain pass or into some unexpected obstruction, due to low-altitude flying? For the purpose of illustration let us assume we are making a flight from Los Angeles to Phoenix. There is a thick fog over Los Angeles and extending over the intervening mountains, but we know definitely that there would be no fog as far inland as Phoenix. The best route for the pilot to take is clearly indicated. Of course, this is one particular case, but there are numerous other instances where similar conditions prevail. It is characteristic of clouds that they form and cling around mountains, and therein lies the cause of an untold number of accidents.

[2] Army Air Corps, Wright Field, Dayton, Ohio.

[3] San Diego, Cal.

If in the air, and he sees the approach of a thunder storm, what does the pilot do? The storm area may be comparatively small, but on the other hand if it should be a line thunder storm, it may have a front extending for several hundred miles. There are two courses open to the pilot—one is to turn and run before the storm until a landing can be made, and the other is to fly through or over it. The higher the pilot flies, the more conspicuous are the tops of the thunderheads, and thus he can pick a corner over the smaller heads. If the top of the storm is so high that it is impossible to fly over it, and it is necessary to go through, the pilot should steer directly through the upper part of the cloud facing the storm.

Without the necessary instruments, and the knowledge of how to use them, the pilot can have no confidence in his ability to determine the course and his position without reference to the ground. Many thousands of miles have been flown by experienced pilots without the knowledge of navigation, just as ships in centuries past found their way to all corners of the globe with very crude navigation, but there is no reason why, from an economic and safety standpoint, these conditions should exist. There is a time in every pilot's life when he wishes that he knew just where he was; when a pilot needs navigation, he needs it badly.

The time-honored methods of marine navigation, entailing tedious calculations, have been found impracticable for use in the air, where speed and simplicity of operation are of prime importance. Great credit is due Lieutenant-Commander P. V. H. Weems for his foresight in realizing the need and for his successful development of a system of navigation which reduces calculation to a minimum and only requires of a student a knowledge of how to add and subtract. This method, though developed for aerial navigation, is equally applicable for marine use. Before outlining these developments, I would like to explain just what we mean by navigation.

There are four methods of navigation: piloting, dead reckoning, radio position finding, and celestial navigation; not one of which by itself will carry the pilot through at all times. A combination of the four methods will produce very accurate results under all conditions

"Piloting" is the method of navigating by known landmarks, or beacons, and though it is practically the only method in common use, it has decided limitations.

If flying over a fog bank or clouds, over unknown territory or at other times when we cannot see the ground, it is necessary to keep an accurate account of the course steered, the air speed, and the time flown on each course, in order to estimate our position. For instance, if we fly on a course due north at an estimated ground speed of 100 m.p.h., at the end of 30 minutes we should be 50 miles north of our point of departure. This is termed dead reckoning. Before dead reckoning can be used, we need a compass that has been compensated and checked for deviations. Air-line operators have given little thought to the importance of the aircraft compass, and it will be found that at the present time the compasses of many transport planes possess unchecked errors of 30 deg. and even more. The compass is the basic instrument of navigation, and as such deserves strict attention. A non-magnetic turntable such as Lieutenant-Commander Weems has devised should and will eventually be part of the standard equipment of every airport, for the compensating and checking of both magnetic and radio aircraft compasses. The weakness of navigation by dead reckoning alone is that one's estimated position depends solely on the accuracy of the account kept of the course and distance made good. Since we have no accurate or continuous means of keeping track of the course and distance made good, the position by dead reckoning is liable to be excessively in error after a few hours' flight. The importance of keeping a record of the dead reckoning cannot be stressed too much. Each time the course or speed is changed, this fact, together with the time, should be noted. In actual practice piloting is combined with dead reckoning, and there should be a careful running record of all possible data pertaining to both methods.

It is only by the knowledge and continued practice of the four methods of navigation during clear weather that we are prepared for bad weather.

In describing in detail the operations for setting a course, we make it seem harder than it really is. The main thing is to be able to change a true course as obtained from our map into a compass course by applying the compass errors, variation and deviation, without making any mistakes. Next, it is very important to have equipment handy for plotting the courses and distance on the map, and to be able to do this quickly and surely. Trying to do this on a board with crude parallel rules and with the map blowing about is very unsatisfactory. On the other hand, with a small drafting machine (or with an aircraft plotter) and with the map slipped under a celluloid sheet, to hold it in position, it becomes an easy matter to plot courses and distances. A convenient-sized board to fill the lap and still permit the use of the stick is about 10 by 16 in. If now we want to cover 600 to 800 miles without changing maps, the scale should be about 2 in. to a degree. This scale would permit fairly accurate work for plotting lines of position, courses, dead reckoning positions, and so on, while at the same time about 500 miles in latitude and about 800 miles in longitude could be included in a convenient-sized board.

Radio position finding is certainly of great value as an auxiliary method of navigation, but it does not, as some people would believe, solve the whole problem of navigation. Transport planes will undoubtedly be equipped with a receiving set and a transmitter, the main uses of which are to communicate with stations and other planes, to summon aid in an emergency, to receive radio beacon signals, to send signals, the bearings of which are picked up by two fixed radio compass stations, the plane's position being radioed back to the plane, and to take bearings of signals from sending stations by means of directional antennae. There are innumerable drawbacks to radio position finding, and disappointing results will be obtained if not used in conjunction with other methods of navigation. It is highly desirable for the plane to carry its own direction finder, for in this way the responsibility for navigating rests upon the shoulders of the pilot, where it undoubtedly should. A plane equipped with a built-in direction finder must head directly for the sending station, in order to get the bearing, yet if it continues to head directly for the station, no allowance is made for drift. In case there is considerable wind, a plane heading directly for the sending station would not travel the shortest route. Radio compasses may be carried either in the plane, and used to take bearings of signals from a known station, or located in a station and used to take bearings on the signals from the plane. In either case, the operation is the same. Bearings taken with a loop antennae or radio compass are subject to two sources of error. First, the metal in the plane may affect the incoming wave, so that the plane must be swung on the ground until signals have been received from all relative directions, and a table of corrections made out for each relative direction of incoming signals. Second, it must be remembered that radio signals follow a great circle course, and therefore, in distance over 50 miles, the direction of the signal is not the actual compass direction of the transmitting station, and a correction must be applied. Another type of radio direction aid is the radio beacon. The directional characteristics of a loop are always applicable to transmission as well as reception, to a limited

extent, and this principle is used in the most successful type of radio beacon yet developed. This type of beacon has been developed to the point where different signals operate lights on the pilot's instrument board, a white light showing as long as he is on the proper path, a green light if he is on the right of it, and a red one if he is to the left. At present the big drawback to the practical use of the radio for navigation is the fact that bearings become inaccurate at long ranges.

The onus of navigating the plane should rest on the pilot, and not upon the reliability of delicate instruments and dependence on people on the ground.

The method and equipment for celestial navigation developed by Lieutenant-Commander Weems enable a pilot to fix his position at night in one minute by simultaneous observation of two stars, by the use of the recently developed Bureau of Standards type sextant, an aerochronometer, rated to Greenwich sidereal (star) time, and Weems' "Star Altitude Curve Book." By placing a transparent sheet, graduated in longitude and latitude, over the curves and running the intersections of the altitudes of two stars, latitude and longitude may be determined without putting pencil to paper. The whole operation can be performed in less than a minute. This night method alone would justify the installation of this equipment in all transport planes. Night flying is becoming more common, and contrary to the average pilot's belief, navigation can be far more accurate at night than during the day. The rapid determination of position by the Weems star-curve method enables drift and ground speed to be calculated without any reference to the ground. Studding the entire country with beacons is both expensive and unnecessary. The most direct route over a lighted airway is not always the shortest. How many times, owing to weather conditions along the route, will a pilot find that by deviating from his course 50 or 100 miles he will not only avoid a strong head wind, but will actually get a tail wind. One of the main objections to beacons is the fact that in clear weather they are not required, while in a condition of fog or thick weather they cannot be seen.

Owing to recent developments by Lieutenant-Commander Weems, celestial navigation in the air may be used day or night, and all calculations in the air are eliminated by pre-computation. The principles of pre-computation have been made use of for many years, but the application of these principles were not entirely practical. The application of pre-computation by the Weems system is performed by the following procedure:

In order to show the practical use of the method for day navigation, let us take for example a flight from Seattle, Washington, to Sitka, Alaska, a distance of 740 miles over a region generally obscured by fog. The course is laid down on a Mercator chart, and found to be N. 40 deg. W. The time of departure is known, and the estimated time of crossing each degree of latitude and the corresponding longitude of the crossings noted. The altitude or angular height of the sun is calculated for those assumed positions, and corresponding times by means of Weems' "Line of Position Book." Lines at right angles to the bearing of the sun may be laid on the chart for the assumed positions, and estimated times at those positions marked on them. Curves of calculated altitude against time are plotted on cross-section paper. All that the pilot requires to do in the air is to take the sextant altitude of the sun, and the Greenwich civil time from his aero-chronometer, and he can, by plotting these on the curves, at once see how many miles toward or away from the sun his line of position is. If the sun be ahead, it will at once give him ground speed, and if abeam it will give him his course. It will not give him his actual position relative to his course unless the sun is abeam, but will give him a line of position relative to the earth's surface. For a great part of the year curves may be pre-computed for the sun and the moon, and at such times the plane's actual position may be obtained. This method is not dependent on taking the observations at specified times. Used by themselves, or in conjunction with radio, pre-computed curves by the Weems system are a valuable aid to aerial navigation. Pre-computation, but with different applications, has been used by Lieutenant Hegenberger and other Army fliers with considerable success. The use of mathematical tables in the air is not very practical, and the writer believes that Lieutenant-Commander Weems' methods are without doubt the solution of the difficulty of using celestial navigation in the air. Flights are becoming of longer duration, and will continue to do so.

The need for navigation is rapidly becoming realized as competition becomes keener and the days of hedge-hopping and railroad courses are near their end. The future will ever be grateful for Lieutenant-Commander Weems' far-sightedness and tireless work in the development of valuable aids to aerial navigation.

V. I. Zelov.[4] The paper covers well the existing status of air navigation, although on account of its purpose and scope, the author correctly does not present construction details of described apparatus.

It is believed that air navigation, successfully applied, requires comparatively considerable knowledge which the average pilot is hardly expected to acquire. Hence, a navigator is required whenever the responsible duty of course plotting or course maintenance is needed. To justify this, an aircraft should be of substantial size, carrying a score or more passengers, or equivalent, from the standpoint of business cargo. It is believed that with the advance of long-distance commercial flights and higher zones of air-travel routing, the present variety of devices will be standardized and their accuracy increased by means purposed to minimize errors of observation and calculation allowances, inherent in unstable aircraft. The majority of present means and devices, discounting their cost, do not appeal to business enterprises. In this direction the Government should contribute to the development of suitable and reliable equipments.

The much-heralded methods of airway illumination appear as a concession, since no absolute and independent means for blind flying or air navigation are available. By following beacons, the aircraft should be considered as ground-bound, limited from the best and most efficient use of favorable properties of its sphere, the air. From a military standpoint more attention should be paid to so-called absolute instruments, based on either magnetic or gyroscopic principles. Military aircraft obviously cannot depend for successful operation or navigation upon an easily confused and vulnerable ground system of beacons, light or radio signals, etc. Besides this, it is believed that independent or self-contained means of air navigation will prove, after all, the most economical and dependable. The less human element, or rather the less humans are involved in the matter, the better. Automatic signals or other radio-guiding arrangements would tend naturally to increase the factor of safety and confidence of the navigator. Properly organized and maintained radio systems offer powerful assistance in commercial flying of peace time, but until there is eternal peace, reliable means to get bearings derived from well-established directional properties of earth magnetism and gyroscope have to be made easily available to a good navigator.

The average pilot, and most of them will be in this class, will do well to know how to follow the indications of modern instruments. These are now reliable, and further improvements are rapidly being introduced into those available for aviation.

[4] Aircraft Control Corp., Philadelphia, Pa.

P. V. H. WEEMS.[5] No longer is it necessary for the pilot to give his attention solely to getting his plane in the air and keeping it there. Even handling the controls in modern planes does not occupy all of the pilot's attention. As actual flying conditions become less difficult, the navigation of the plane becomes relatively more important.

The ideal condition for navigation is in large planes on long flights where the relief pilot can navigate continuously. Under these conditions, using all the means at our disposal, there should be no delay in proceeding directly to the destination under all but the worst weather conditions.

For safe navigation the plane should be equipped with the usual panel instruments, radio, drift and ground-speed indicator, and celestial navigation equipment consisting principally of the sextant and the aero-chronometer. The radio not only affords definite information such as bearings, but it also affords a means of getting weather information and a means of calling for help in time of emergency.

Contrary to common belief, celestial navigation affords the most practicable means of navigation on long flights. Accuracy within the limits of tolerance for air navigation may be obtained from the plane by day and by night with practically the time and effort necessary to take drift observations or to transmit and receive radio information. Positions may be obtained in a minute at night by the use of the latest equipment, and "lines of position" on which the plane is known to be may be found every few seconds during the day. When the moon and sun are in the proper relative positions, positions may be determined during the day within a minute or so.

Efficient navigation within the plane results in (*a*) a saving of time and hence in cost of operation, (*b*) a decrease in the danger inherent in flying, and (*c*) more confidence in flying on the part of the passengers and hence more business to the carrier.

In single-seater planes efficient navigation becomes much more difficult. However, only on stunt flights will one-man planes remain for long periods of time in the air. In these cases a lone pilot may with certain limitations navigate a plane by dead reckoning, by radio, and by celestial navigation. Lieutenant Bromley, now training for a transpacific flight, is planning to do celestial navigation and to have radio.

The fact that air celestial navigation is associated with marine navigation, an old and heretofore difficult science, prevents many airmen from taking up celestial navigation for practical air work. This, combined with the fact that good bubble sextants have not been on the market, has prevented the needed progress in this important phase of aviation. As a matter of fact, advances in marine navigation within the past two years have reduced the time by more than 50 per cent and the labor correspondingly. This work may be still further simplified for air work, and if only there was no connection between sea and air navigation, the airman would doubtless take up celestial navigation with more avidity.

Not only is celestial air navigation practical and possible, but it has been demonstrated repeatedly. It only needs to be popularized, and the high cost of equipment be reduced by quantity production, to make it a valuable asset to aviation.

Some will think that extensive computations are necessary for celestial navigation. However, with proper equipment, the distance the plane is toward or away from the sun may be determined with a sextant and watch observation without putting pencil to paper. At night the latitude and longitude may be determined in a minute with only one subtraction of two times to get the longitude. The latitude is found without any computations whatever. The equipment used successfully by the writer consists principally of:

(1) Bureau of Standards type aircraft sextant
(2) A pair of aerochronometers
(3) The "Line of Position Book"
(4) Star altitude curves
(5) Charts, small drafting machine, pencil, dividers, and Nautical Almanac.

A special supplement to the Nautical Almanac will be published by the Naval Observatory on September 1, 1929, by means of which the moon may be used with as much facility as the sun.

Lest some qualified navigators will question the speed of day navigation, it might be stated that this is a new and special application of the old principle of "pre-computation" which has been used with success by the Army fliers, especially by Lieutenant Hegenberger.

AUTHOR'S CLOSURE

In general the author concurs with the opinions expressed in the discussions. It was his endeavor to stress the fact that the demand of air-navigation knowledge for pilots and the necessity for proper modern equipment depend upon the type of flying engaged in. To his mind the instruments now most needed for safe flying and position finding are better blind-flying instruments and drift indicators. He does not believe that commercial overland flying need ever be concerned about celestial navigation; light beacons and radio, expensive though they may be, are certainly not unnecessary as Mr. Gatty claims, and combined with well-organized weather information should suffice for overland commercial flying. On transwater flights, every known navigational means must be used with the very best of celestial navigation instruments, and it is this type of flying that will demand and get improvements in all branches of air-navigation instruments.

AER-51-26

Recent Developments in Air Transport

By P. G. JOHNSON,[1] SEATTLE, WASH.

The author, after pointing out that there are 21,000 miles of established airways and 1600 airports in the United States, discusses the recent rapid growth of air-mindedness on the part of the public. As an index of this he estimates that 12,000 planes will be built in 1929 as against 622 in 1919, which latter were mostly military craft. He predicts greatly increased employment of planes for mail transportation, their speedy adoption for handling express matter, and their very general use for passenger travel.

TEN years ago a daily round-trip flight of government-owned and -operated mail planes, between Washington, D. C., and New York represented commercial air transport in the United States. Today commercial aviation, statistically expressed, is as follows:

There are approximately 21,000 miles of established airways over which mail-express and passenger planes, operating on regular schedules, will fly in excess of twenty million miles this year. Mail planes, now serving 108 cities in thirty-seven states, will transport more than 3000 tons of letters exclusive of express and passengers, and an estimated load of 300,000 lb. of express. The total mileage of civil flying was 40,000,000 miles in 1928, and that figure will be substantially exceeded this year.

There are 12,000 miles of lighted airways, and one American company, the Boeing System, which flies 46 per cent of its total mileage at night, does more night flying than all the European companies combined.

There are 1600 improved, or semi-improved, airports, the majority municipally owned. The value of existing air terminals is $100,000,000, and this year approximately $200,000,000 will be spent by 1100 airports for land, improvements, equipment, and supplies.

These figures are important because they express facts showing that commercial aviation has passed into the era of extensive operations, and that transportation of mail, express, and passengers by air already forms an important link in our national chain of communication and transportation.

Even more significant is the fact that practically all the development cited above has come about in two years. Commercial aviation progressed more rapidly in 1927 and 1928 than it did between 1903, when the Wright Brothers made the first successful flight with the powered airplane, and 1927. For a decade after the first successful flight, aviation was in the doldrums. It took a world war to hasten the development of the airplane and prove its possibilities, and also to recruit the personnel for peace-time use of the plane. But after the armistice, the aircraft industry paid the penalty exacted by reason of the sudden cessation of buying orders on military account, and, until 1923, the industry was at low ebb.

Then the Government stepped in to play a constructive part. The Department of Commerce assumed the sponsoring and regulation of air traffic and the Army and Navy embarked on a building program calling for 3200 planes over a five-year period. The Post Office Department, which had done a splendid job pioneering with the air mail, expanded its activities, and around the air-mail network this nation began to build its commercial air-transport system. In 1927 the Post Office Department discontinued its operation of the mail routes and private contractors took over the work and put into it the organization ability, initiative, and enthusiasm so characteristic of private enterprise.

Then came that which fanned the growing flame of aviation interest—the Lindbergh flight, followed by other transoceanic and transcontinental trips.

Recent Growth of Air-Mindedness

The public began to become air-minded and suddenly realized that the airplane was the latest and most effective transportation vehicle available in the ceaseless fight against time and space. People wanted to ride in airplanes and they began to send mail and express matter in an increasing volume. Airplane manufacturers and operators capitalized on this interest. Powerful banking groups looked into the future and made funds available for all legitimate expansions.

An index of how suddenly this air-mindedness has come about is seen in the following figures on production of planes in the United States: 1919, 622 planes; 1921, 302 planes; 1923, 587 planes; 1925, 789 planes; 1926, 1186 planes; 1927, 1962 planes; 1928, 4000 planes; and for 1929 an estimated production of 12,000 planes. The production in the early years cited was largely military, and in 1921 practically every plane sold was for Army or Navy use.

Other figures show the recent trends in commercial aviation and point to the future. The air mail carried in 1928 was 2.37 times that transported in 1927, and more striking still was the transportation of practically twice as much mail in the last five months of 1928 as during the first seven months of the year. Planes in commercial use over scheduled routes numbered 128 in 1927 and 227 in 1928, while the total of civil planes increased from 3731 in 1927 to 7800 in 1928.

Thus we see the aircraft industry was lifted from the doldrums by the war and dropped back into lean years after the armistice, with a revival in 1927, followed by the present rapid expansion. We are now in an era of keen competition featured by mergers and consolidations. Efficiency will count much more than it did in the experimental and colorful days of the past. The dominant survivors will be factories and operating companies which are well managed and financed, and fortified with designing and manufacturing staffs capable of keeping pace with the changes which we recognize will come in both the building and operating sides of this industry.

Some of the Definite Trends of the Future

The experience of the past indicates some of the definite trends of the future.

To date, the largest expansion has been in the carrying of mail and passengers, and the majority of lines have carried both on the same planes. However, air-mail loads have so increased and schedules of departures and arrivals are at such inconvenient hours in many cases, that there is a growing tendency to separate mail and passengers.

Different kinds of operations call for different types of planes. The air traveler pays more for transportation than the rail traveler, and he expects schedules and comforts which often cannot be given him when transportation of mail is the prime consideration.

[1] President, Boeing Airplane Co., Boeing Air Transport, Inc., and Pacific Air Transport. Assoc-Mem. A.S.M.E.

Contributed by the Aeronautic Division and presented at the Semi-Annual Meeting, Salt Lake City, Utah, July 1 to 4, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Assistant Postmaster General Glover recently predicted that all first-class mail between certain communities will be carried by air. The Post Office Department averages daily 476 tons of first-class mail which must be given transit handling. So the future of the airplane as a mail transport can be visioned. Mr. Glover also predicted that within two years practically all cities of fifty thousand or more inhabitants will be located on air-mail lanes. He pointed out that the busy man has always been impatient regarding the speed with which his mail is handled, and will naturally demand that all first-class mail be given the speed that air mail now receives in the fast-flying planes.

It is not idle speculation to predict that the airplane companies will build mail planes which will have mail clerks aboard just as railway mail cars do, and that the mail planes will haul the bulk of their cargo between dusk and dawn. The airplane is so speedy that already it eliminates the loss of any business hours in transportation of mail and express between many cities. For instance, between Chicago and New York; between New York and Atlanta, Ga.; between Chicago and Dallas, Texas; between Chicago and Cheyenne, Wyo.; and between San Francisco and Los Angeles and Cheyenne, Wyo. The schedules can so be arranged that major cities within 1200 miles of each other can have their mail moved between dusk and dawn.

The Boeing System recently completed flying its two millionth mile of night flying and on May 1, when a double transcontinental schedule went into effect, planes were flying every hour of the night with mail between New York and San Francisco.

Airplane Transportation of Express

Air transportation must also be reckoned with in the transportation of express. Robert E. M. Cowie, President of the American Railway Express, in a signed article recently expressed his opinion of flying express when he wrote:

> We see the airplane as a builder of more business, basing the conviction on the history of transportation. Express companies were originally regarded as competitors of the railroad. Express tonnage is only a drop in the bucket compared to the volume and value moved in freight cars. Commercial air transport is the logical delivery system of hand-to-mouth buying, the instrument of the rapid turnover which has had so much to do with our prosperity.
>
> The airplane is virtually without limitations. It should open areas to settlement at present far beyond the economic reach of the motor truck and physically impossible to the railroads.
>
> What we need is planes in regular service with a capacity of 20,000 lb. and the ability to carry a pay load of at least five tons. When our air lines are equipped with such a unit, commercial aviation will follow the course of every other transportation system.

In this day of small stocks, quick turnover, little profit, and a growing demand for service—which costs money—competition has become keener and business is reaching out into new and larger trade zones. Air transportation, averaging 100 miles an hour, has already begun to revamp certain long-established distribution and selling methods, just as the automobile and train left their mark on our business structure. Recently the chamber of commerce of a prominent city in the Middle West complained that its banks and wholesale houses were losing long-established trade because competitive cities had direct overnight air-mail express service to commercial centers of the Southwest.

The American Railway Express estimates that approximately $25,000,000 worth of small merchandise leaves New York by express daily. New York City and its environs, said the statement, produce only one-twelfth of the small merchandise of the country. The express company fills up 500 railway express cars every night in New York alone, and in its 28,500 offices the American Railway Express handles approximately 1,000,000 packages a day, and speed is such a requisite that the coast-to-coast cars make faster time than most of the passenger trains. Airplanes of the future will have capacity for large shipments of light-weight emergency express.

But even the most optimistic commercial air transport officials do not claim that the airplane will cut into the freight revenues of the railroads. They believe, however, that the airplane, by speeding up our business structure, will so stimulate industry generally that the railroads will share in the greater prosperity which each faster form of transportation has always brought us.

Current Varied Commercial Uses of Airplanes

In addition to using airplanes operated on regular routes, on scheduled services, to handle their express and to transport their employees, corporations will buy airplanes for the expedition of their own business. Executives are already flying their airplanes in the conduct of their daily affairs. Oil companies, newspapers, manufacturing plants, wholesale houses, and other corporations have their own planes, ranging from single-motored to tri-motored craft. The airplane is used in such a wide variety of pursuits as aerial photography, airplane dusting of crops, forest patrol work, scientific studies, aerial advertising, spotting schools of fish, map making, geographical study, engineering surveys, carrying supplies to inaccessible regions, transporting emergency shipments of factory parts, and in many other ways. These instances indicate the expanding market for airplanes. Each day the air-transport companies hear of specific cases where the airplane has opened up new markets and speeded up business generally, which explains why it is being utilized by business in ever-increasing measure.

The experience of the past two years shows that the passenger side of air transportation can be expanded substantially and quickly. The public is ready to fly. The air-transport companies are prepared to supplement the present services so that, in a few years, major cities in the United States will be connected by air-transport services, and many of them will operate multi-motored planes with a cruising speed of 115 to 135 miles an hour. The public is willing to pay the higher rate charged for air transport.

Increased Passenger Travel by Airplane

The average charge, over the United States, for air travel is 11 cents a mile according to a compilation made by the traffic department of the Boeing system.

If a traveler purchased a ticket for a one-way trip over every line in the United States offering passenger service and operating on a regular schedule, he could travel 12,914 miles. For this air travel he would pay $1427, or 11 cents a mile.

The extra-per-mile charge for airplane travel over rail travel is more mathematical than real, however. The air mileage between cities is generally considerably less than the rail mileage charged for. There is no pullman or chair-car charge on airplanes or taxi fares to and from terminals, as these are included in the airplane ticket. Also, the airplane is three and sometimes four times as fast as train transportation; and if time is money, it is more expensive to travel by train than by plane.

Railroad executives with vision do not regard the airplane as an intruder, and many of the lines sell combination rail-plane tickets. Among these companies are the New York Central, Pennsylvania, Santa Fe, Illinois Central, Chicago & Northwestern, the Milwaukee System, Great Northern, Northern Pacific, Missouri Pacific, and others.

At what mileage air-transport companies can compete for traffic with railroads is a debatable question. European authorities, a year ago, thought 300 miles was the minimum, but Germany is proving that this figure is too high. There, with the aid of a federal subsidy which enables them to quote mileage rates quite comparable to rail tariffs, one German company has hauled

56,000 passengers in one year, or one-tenth of the first-class rail passengers of the German lines, and their average air haul was only 93 miles.

At the present time transport companies in this country find it difficult to secure sufficient passenger lists on routes less than 300 miles long. But the American's inborn desire for speed will probably assert itself when commercial aviation is a little older, when the companies have brought their passenger service to high efficiency, when airports are closer in, and when the public becomes a little more air-minded. In the future air-transport companies will not limit their operations to arbitrary distances, but will adjust the service to meet the demand, irrespective of the length of haul.

Passenger travel by airplane is certain to increase because the public embraces each form of faster transportation. Airplane travel is speedy, comfortable, and interesting, and the operators are bending every energy to make it as safe as any form of mechanical transportation.

The public pays an extra fare on faster trains like the Twentieth Century and the Broadway Limited. Speed is expensive, but the travelers are willing to foot the bill, especially when the airplane is three times as fast as rail transport. A plane with a cruising speed of 90 miles an hour is already becoming slow to some confirmed air travelers, and the airplanes of the future will undoubtedly be more speedy than any of those now flown on commercial routes.

Airplane engineers are planning larger, faster, and more comfortable transports.

The safety factor is increasing each year through improved equipment, more and better airports, more experienced pilots, better weather reporting, lighting and marking of airways, the directive radio, the radiophone, and other aids.

The manufacture and operation of airplanes is not merely a matter of mechanics, but of "humanics." To give the airplane its rightful place in our national system of communication, transportation, and distribution calls for vision and initiative, but the recent developments in air transport indicate clearly that we are making rapid progress toward our goal.

Author's Closure

The question has been asked, Will improvements in structural design ever overcome the inability of an airplane to fly through rough air without the jerky rising and falling caused by sudden contact with downdrafts or rising currents and what aerodynamical improvements have contributed to the stability achieved in modern airplane construction?

There is no possibility of building an aircraft which will not respond to the action of convection currents and to other aerological phenomena such as are encountered when flying at an altitude where two wind currents of different directions cross one above the other. The air is just as full of waves of various kinds as the ocean, and even the largest steamships occasionally run into conditions which will make them pitch and roll almost as badly as a small craft in less disturbed water.

There are two conditions which tend to minimize the effect of similar disturbances, these conditions being high speed and weight. An extremely fast airplane is affected less by rough air than a slow one, and a heavier airplane has so much inertia that it takes larger disturbances to change its direction quickly than will similarly affect a lighter one.

Wing loading has some effect also; but inasmuch as high wing loading is generally associated with high speed, these two might be classed in the same manner.

We cannot hope to eliminate the effects of rough air entirely. There are no aerodynamical improvements upon which one can place a finger and point them out as contributing specifically to the stability achieved in modern airplane construction. The ability to make an airplane stable is a result of long experience in design and flight testing; and, as a result of this experience, the aeronautical engineering profession has been able to devise certain empirical methods of calculation which permit the attainment of the desired amount of stability in design with a reasonable amount of probable error.

In aircraft of radical design, these empirical determinations are of questionable value, which is one reason why the development of aircraft must proceed by slow and easy stages. It is best to try the effect of one change in design and determine the limits within which our calculations will give us reasonable results.

Another question is, Does the size of an airplane have anything to do with stability?

The size of the airplane has nothing to do with the characteristic of stability. Stability is determined by the proper distribution of wing surface, center of gravity, dihedral angle, horizontal tail-surface area, vertical fin area, and the position of the thrust line of the motors with respect to the center of gravity. By a proper juggling of these factors, it is possible to obtain any degree of stability, providing time is available to make necessary calculations and tests. I would rather judge from the nature of the question that the word "stability," in this case, means the ability of the airplane to ride through bumps without severe disturbance.

Another question raised was, Does muffling an airplane engine necessarily result in appreciable loss of power due to back pressure and is a muffled airplane motor an improvement that can be reasonably expected to appear in the immediate future on regular passenger lines?

The loss of power incidental to muffling an airplane engine depends entirely on the amount of restriction which the muffler places on the exhaust system. Pratt & Whitney Aircraft Company is insistent that the back pressure in the exhaust system not exceed $\frac{1}{2}$ in. of mercury, and a muffler which would meet this condition would necessarily be so large and heavy as to preclude its use.

Even with the engine completely muffled, there is still the propeller, and propeller noises are of such intensity to make the muffling of the engine almost valueless. We have found that, with the proper design of exhaust manifolds, the separate explosions of the engine can be almost completely smoothed out into a steady hum, with the vibrations brought so low as to be entirely unobjectionable. As a consequence, no muffler which has been developed to date appears to us to offer any advantages. Propeller noises are of such a high frequency that these cause most of the trouble for the passenger. The only solution for this is apparently a slow-speed propeller.

The European engineers do not agree as to which is the most objectionable from the standpoint of noise: a geared engine with a slow-speed propeller or the direct drive with the high-speed propeller (see Third Guggenheim Foundation Report, December, 1928).

The author has been asked if sleeping accommodations are a feasible improvement that might be expected to appear generally in planes operated over long-haul or night routes within the next year?

There is much argument among operators as to whether sleeping accommodations will be provided on night planes. Unquestionably, the traveling public will eventually demand such accommodations. At the present time, however, the cubic feet of space per passenger is getting so large, even without sleeping accommodations, as to make carrying of passengers very uneconomical in view of the rates which can be charged. The provision of sleeping accommodations will make the re-

quirements of space per passenger even greater, and is a condition which cannot be met properly at the present time.

There is no doubt that the equivalent of Pullman accommodations will make their appearance eventually, but hardly within the next year, even though there is much talk and advertising matter put out with this end in view.

The serving of meals aboard passenger aircraft is a problem akin to that of the provision of sleeping berths. Equipment necessary for serving extensive meals together with the personnel necessary will represent a large item of non-paying load. Furthermore, the commercial transport with a range of more than six hours will not be economical because of the large amount of fuel which it is necessary to carry in order to obtain this endurance, and the pay load per horsepower is proportionately decreased.

Assuming that stops will be made every three or four hours, there is no justification for serving meals aboard. The exception to this will be a run which covers the four hours in the middle of the day, in which case it would be necessary to provide the passengers with lunches, which probably would be prepared ahead of time and carried on the run. This would eliminate the necessity for any extensive extra equipment in the plane itself.

If planes are carrying both mail and passengers, there would be objection to stops of sufficient length to permit the passengers to eat a meal because this would interfere with the mail schedule. It is believed that the tendency now is to segregate mail and passengers in order to relieve the mail pilot of the responsibility he feels when passengers are aboard. Probably, mail will be carried in passenger planes in the future only in an emergency, when the mail can be carried on the passenger schedule to a better advantage than leaving it for the next regular mail trip.

Another question is, What are some of the causes for delays in delivery of air mail to destination and how are these obstacles being overcome?

On rare occasions air mail is longer in transit than mail sent entirely by rail because of operating difficulties. In cases where the distance to be traveled is very short a handicap is placed on the air mail in that the advantage to be gained is so very slight as to be easily lost by minor delays. On air mail traveling longer distances the margin of advance possible is greater, and consequently minor delays may be absorbed and still place the air-mail service at an advantage over train service. Even on longer distance hauls there are sometimes cases where the train mail beats the air mail due to circumstances which are difficult to overcome, but which it will be possible to overcome.

When a plane is forced down at some remote point where train service is very infrequent and the local conditions are such as to make prompt transportation of the mail to a railroad center difficult, an important train connection may be missed and another not be available for a number of hours. A protracted delay in departure of the plane might in such a case permit the train to arrive at destination ahead of the air mail.

On long-haul mail it is believed this condition can be overcome by furnishing pilots with a schedule of train-departure time and destination, to apply to each railroad station in the vicinity of regular and emergency landing fields in terrritory through which they fly, and keeping this schedule corrected as changes in train schedules are made from time to time, and by specifying certain deadlines beyond which mail down at a specific point may not be held beyond train departure. This arrangement will make it possible for the mail to be dispatched by rail from the point where the ship is down, and if the weather or mechanical difficulty which interfered with the flight is overcome in time to enable the ship to overtake the train at some point further along the line, the mail may again be picked up and sent forward by plane. Otherwise it can be carried to the first point on the line where a plane is stationed and from which weather conditions will permit the flight to be continued, or delivered to destination by train without losing the time which had been gained up to the time the flight was interrupted.

The author had in mind as an auxiliary to the foregoing arrangement the plane entering into contracts with responsible parties in the vicinity of emergency fields, who would be under agreement to promptly call for and transport the mail to the nearest railroad station whenever required and thus eliminate any delay which might be encountered by the necessity of the pilot hunting up some one to handle the transportation. The operations department advises me that this feature of the case has already been taken care of. The preparation of the pilots' schedules referred to has already been started and will be completed just as soon as up-to-date Railway Mail Service schedules are received, which are needed before the work can be finished.

The arrangement outlined will enable us to realize our aim of being able to guarantee to the mailing public that the case will be unusual indeed when it will be possible for train mail to beat air mail.

AER-51-27

The Railroads and Passenger Air Transport

By C. E. McCULLOUGH,[1] WASHINGTON, D. C.

LINKING rail and air transport is an expression now commonly used to indicate the coordination of rail lines with commercial airways. It expresses, in a few words, the progressive action of the railroads in forging a new link in the chain of ever-improving transportation throughout the United States. It is most appropriate that the railroads of the United States should enter the commercial aviation field. They were the chief factors in the development of this country, through providing and constantly improving our transportation facilities.

Rapid transportation for goods as well as persons has been necessary for railroads to progress. It is generally recognized that without the railroads the United States could never have reached its present peak of industrial and commercial dominance and leadership in human progress during the comparatively few years which have brought us to the present day and age. The railroads realize that further development in transportation of any form will be helpful to the future of our country.

The development of the electric interurban car lines, and later the startling growth of the automobile and motor-propelled vehicles for the public highways, were looked upon by some railroads as threatening dangerous competition. But as time went on, it was soon demonstrated that any improvement in transportation, in any form beneficial to the public interests, aided the growth and prosperity of practically every line of business.

The railroads lost some travel and some freight shipments to the new forms of transportation which had grown up and thrived, but a careful analysis shows that these losses were more than made up by the increase in new classes of travel and shipments of new commodities and manufactured articles, resulting from the ensuing general prosperity and welfare of the country.

It has now become apparent to every thinking man that inevitably there must be in our scheme of life a constant improvement in all transportation facilities and in the development of new forms of transportation. Less than a century ago the battle for supremacy between canals and railroads was fought out. Men are still living who can recall it. Stage-coach service as a means of passenger travel, particularly in the West, survived into the present country. In 1850, a comparatively recent period as history measures time, by using the rail lines which had then been developed in the East and the overland stage routes in the West, it was possible to cross the continent in twenty-four days, which was thought to be a notable feat. The extension of the rail lines to the Pacific coast and the successive improvements which have been effected in their service now make it possible to go from ocean to ocean by train in a little less than four and one-half days, enjoying the luxury and comfort of the highest class American limited passenger-train service. The day is now upon us, however, when that time is to be still further shortened by the coordinating of rail service with the newest form of transportation, the airplane.

The desire for speed is not a mania, as it is too frequently called, neither are the persons who have striven, are still striving, and always will be striving in the future, to break speed records, in one manner or another, in one kind of vehicle or another, speed maniacs, who are merely seeking thrills or notoriety, or both. They may be rash, courageous, foolish, or adventurous in the eyes of many, but they are, nevertheless, pioneers. The very nature and progress of our civilization demand speed, and more speed, in transportation and communication. Faster railroad trains, both freight and passenger, faster automobiles and motor vehicles, more rapid means of communication, and the development of the long-distance telephone and the radio, all have brought the far corners of our country closer together. As we still progress still further, these far corners must be brought still closer together.

Possibilities of airplanes are being recognized. Progress cannot be stopped; we must keep abreast of it, or forfeit our place to others in the race. Hence the plane is being harnessed to the iron horse, and the Pennsylvania Railroad has taken the first steps toward linking rail and air transport. These first steps are through the means of coordinated rail and air service, in connection with Transcontinental Air Transport, Inc., for an ocean-to-ocean service which will make possible the trip across the continent in forty-eight hours, instead of four and one-half days or twenty-four days.

Air transport will be organized along lines quite similar to that of the larger railroads. For example, in addition to the executive officers, such as president, vice-president, and general manager, there will be a general superintendent and division superintendents, constituting the operating department. Pilots will receive orders from the division superintendent. The field manager can be likened, in railroad comparison, to a combination of master mechanic and station master. The traffic department will be in charge of a general traffic manager, and for purposes of convenient administration, the country has been divided into three regions, with a traffic manager in charge of each. The eastern traffic manager will be located in New York City, the central traffic manager in St. Louis, Missouri, and the western traffic manager in Los Angeles, California. These traffic managers will have under their jurisdiction certain prescribed territories, and men in charge of certain specific traffic work, with the titles of division traffic agents, traffic agents, and passenger representatives, whose duties will be the sale of this new and more rapid mode of transportation to the traveling and shipping public.

In addition to the pilot and assistant pilot, the crew of each plane will include a representative who will be known as a courier, that title having been selected as indicative of his duties, he being an attendant accompanying each trip for the purpose of being generally helpful to passengers, and giving them information of value and interest.

The railroads prospered, and the public benefited, as the modern luxurious Pullman cars were built and steadily improved, as dining cars gradually supplanted the old twenty- or thirty-minute train stop for meals, and as the modern day coach grew in comfort and up-to-date conveniences; likewise, as safety appliances were invented and adopted by the railroads, such as the airbrake, automatic signals, heavy steel rails, steel cars, and others too numerous to mention here, so the public confidence in railroad transportation grew steadily. Where only a generation or so ago it was considered a noteworthy adventure to make a long railroad trip, demanding quick advice to one's friends or relatives of the safe completion of the journey, now a railroad trip of hundreds or thousands of miles is undertaken on short notice and in a most matter-of-fact way.

[1] General Passenger Agent, Pennsylvania Railroad, Washington, D. C.

Presented at the Third National Aeronautic Meeting, St. Louis, Mo., May 27 to 30, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

If commercial aviation and the coordinated rail and plane service is to be sold to the public, there must be a sound basis for instilling into the minds of prospective air travelers the fact that they can travel safely and comfortably, as well as speedily, in regularly scheduled commercial airplanes.

Severe or unfavorable weather is perhaps the greatest problem in organizing safe air transportation. Weather cannot be regulated, but precautions can be taken to avoid unfavorable weather conditions. The route of transcontinental rail-air service has been laid out through country where normal conditions are most favorable to flying. The train-by-night and plane-by-day idea was adopted with the view of using rail through the country least favorable for flying. In addition to these things, a most elaborate system of weather reporting and communications has been installed.

Regular United States Weather Bureau reports will of course be available and used, but in addition there will be a complete installation of regular Weather Bureau instruments in charge of expert meteorologists at all of the principal airports or landing fields across the continent. Twice daily two hundred United States Weather Bureau reports will be received at these stations, and weather maps drawn and studied. These particular reports will be augmented by a mid-day report from all observers. The United States Weather Bureau observations will of course cover the entire United States and provide general weather information, while the mid-day report will cover the territory traversed by the airplanes, and consequently furnish more concentrated data.

Observers will be stationed at seventy-two observation points, in addition to the airports and landing fields mentioned, these stations being not only on the airway across the country, about fifty miles apart, but on either side, off the route, about one hundred miles apart, and about seventy-five miles from the line of flight. As a further evidence of the linking of rail and air transport, most of these observers will be railroad operators at stations on the Pennsylvania and the Santa Fe Railroads; these operators or agents being not only equipped with the necessary instruments, but trained especially in making weather observations.

In order to provide for the prompt dissemination of these weather observations and reports, as well as the dispatching of planes and the necessary interchange of general information, a very complete communication system had to be installed. Naturally, the most modern methods are necessary; hence the network of telegraph, teletype, and radio which has been adopted. Seventy-two weather observers will make their observations when scheduled and send them by railroad telegraph to the railroad station operators in the cities where the fully equipped airports or landing fields are located. The railroad station operators at these cities will then relay the messages by teletype, especially adapted teletype machines having been installed in these offices. The main fields, having automatically and instantaneously received the observers' reports by teletype, then add their observations, and after careful checking and study, and comparison with United States Weather Bureau reports, they will be placed in the hands of the pilots before their departure.

Any important information received later, of a nature to cause a change of the course, will be sent by radio, through voice transmission, to the pilot while in flight. Radio, by voice transmission, or by code should conditions make voice transmission difficult or undesirable, will be used only between a ground station and a plane, or sometimes between two planes in flight. It will not be used for communication between two ground stations. The teletype system has been adopted for communication between ground stations where the telegraph or telephone is not used.

As an additional feature, for the convenience of passengers in flight, arrangements have been made through a hook-up with the American Telephone and Telegraph Company, so that in an emergency passengers can communicate quickly with their offices or homes, by either telephone or telegraph. This service will of course be restricted to the extent that it shall not interfere with the use of the radio for plane dispatching and operating.

Among other things, to insure the public of the safest possible air travel, only thoroughly trained pilots will be employed. They will fly at comfortable altitudes, going into the higher altitudes only to avoid rough air. The planes will take off and land easily. There will be no needlessly steep banking after taking off or when preparing to land. While this is not necessarily dangerous, it is perhaps disconcerting to passengers who have never flown before, or who are of a nervous temperament.

Only safe loads will be carried. The motors and all equipment will be inspected thoroughly and frequently with the same care as are railroad trains. No taking of chances with the safety or lives of passengers will be permitted at any time or in any way.

With a fully organized airway, the arrival, departure, speed, and handling of airplanes will be as carefully regulated and controlled as in the operation of railroad trains.

The future success, development, and progress of commercial aviation depend largely on the reliability with which operations are handled and the public informed. By this means only can the confidence of the public be won in this new form of transportation.

Discussion

STUART F. AUER.[2] Within the brief span of twenty-five years aviation has grown from the status of a dangerous novelty to an economic position with an influence far reaching both in scope and effect. It stands today where the railroad stood fifty years ago and where the automobile stood twenty years back. In the early days, because of mechanical imperfections and lack of aerodynamic knowledge, accidents were frequent. From the public point of view every accomplished flight was a marvel, and every accident was an occasion for an outburst. It is only natural, therefore, that under such circumstances the management of insurance companies was hesitant to assume the risks incident to aviation. The hazards of flying, until recently, were too great to attract much insurance capital. Many factors contributed to this condition of affairs.

First, in the early stages, a large percentage of airplane accidents resulted in the death of the occupants. In case that 50 per cent or more of the accidents attendant upon flying ended in death (and earlier statistics show such to have been the case), the company's loss would have been greater by far than the possible premium return.

Second, a large percentage of those not killed suffered severe injuries, which resulted in long periods of total disability or permanent partial disability which would have developed losses far in excess of any possible premium income.

Third, in surface transportation like railroads, steamships, buses, trucks, trolley cars, etc., travel was on a two-dimensional surface. In aviation, however, a third dimension is added, the hazards of which could not well be calculated because there was no background of previous experience. Prior to the Air Commerce Act no agency was charged with the investigation or recording of civil air accidents, and no reliable information was available upon which to base statistics.

In the year 1927 there occurred 200 reported accidents in which 164 persons lost their lives and 149 were injured, including both

[2] President, Auer, Inc., Milwaukee, Wis.

pilots and passengers. Of the 200 accidents, 34 occurred with licensed planes, 11 licensed pilots and 22 passengers being killed. The others were charged to unlicensed craft.

In scheduled flying over definite air routes there were six fatal accidents, six pilots and one passenger being killed. The other fatalities were in the course of miscellaneous flying, experimentation, contests, races, oceanic flights, etc. Deaths in the "experimental" classification accounted to 24 and are not properly chargeable to aeronautics as a means of public or private transport.

Thus the same Department of Commerce figures which show that aviation, under certain conditions, is extremely hazardous, also show that under other conditions it is extremely safe. For, in 1928, out of a total of 10,472,024 miles flown by commercial planes on a regular schedule (air-transport classification) there were but nine fatal accidents, in which nine pilots and thirteen passengers were killed. Available figures for the same year show 1062 accidents in all classes of flying, including air-transport classification, resulting in 215 deaths and 168 injuries as against the 200 accidents for all classes of flying, with 164 deaths and 149 injured, for 1927.

Although the pilots licensed for 1928 showed an increase of 150 per cent over 1927, the accidents increased over 500 per cent, probably as a result of the large number of inexperienced men taking up flying, yet the percentage of fatalities shows a marked decline as follows: In 1927 80 per cent of all the accidents resulted in fatalities, whereas in 1928 less than 21 per cent of all accidents resulted in fatalities, and there were only 19 more people injured in 1928 than in 1927.

The normal death rate in the United States is 11.4 persons per thousand of population. Deaths from airplane flights are but 0.024. Thus, it may be seen that, under certain conditions the pilot is safer in his plane than on the ground.

At first, insurance companies would not insure any perils of the air, and it was some years before they had sufficient information to estimate the rate for insuring the average careful pilot who was not participating in so-called stunt flying. The first policies were issued to such pilots on the basis of their previous records. Later it was recognized that if these pilots were a safe risk, their passengers were also, and insurance was extended to passengers under the same conditions.

Still later, available statistics made possible the study of flights about the airports, from which a rate was estimated to cover field hops of not more than a 25-mile radius, and issued for a definite period of time, usually less than half an hour.

Until quite recently aviation insurance has been in a truly pioneer state. However, with more reliable aircraft statistics, this condition is rapidly passing away, and more progressive companies are already working on comprehensive policies along the lines already in use in other fields of transportation.

Such insurance, of course, is divided in various classes. There are policies for pilots and for passengers, graded of course as to the length of flight. Recently policies are provided for student fliers, the status of whom has not yet been thoroughly determined. Some classify them as fliers, others as passengers. The maximum policy in any class is, at present, $5000. This is for pilots and passengers. Student policies are usually for $2500 or less.

The most recent passenger-accident policy is sold on the following basis: For each $1000 of insurance a premium is charged on the number of miles of flying away from the base airport; 50 cents for a trip of 200 miles or less; 75 cents for 500 miles; $1 for 1000 miles, and $1.50 to any point in the United States in excess of 1000 miles. Insurance of this form parallels very closely the type of insurance issued with railroad tickets and is now optional to passengers.

It is either automatic or optional, and is issued in accordance with the desires of the operator. If he wants automatic insurance of this type to be in force upon the purchase of tickets, he can secure such insurance. On the other hand, if he wishes it optional, with the passenger, he can secure this form also.

Group student-accident policies are a somewhat newer development, and are intended to meet the growing demand for protection by thousands who are learning to fly. Such a policy covers accidents during flight instruction, solo flights, or accidents to the ground during instruction, as in mechanics, repair, etc. The rate of such insurance is $20 for the first $1000 coverage, $17.50 for the second $1000, and $15 per thousand dollars of coverage for the next $500, making a total of $45 premium for the coverage of $2500 which is the maximum allowed.

This policy is good for one year or the length of stay in school within the limit of 12 months, after which a new policy must be taken out. It does not, however, cover any other form of accident away from the airport. Such a policy is non-cancellable to students to whom it has already been issued, and is open to new students provided 25 per cent of the class agree to take the coverage. The non-cancellable clause in this type of insurance has made it very popular.

This covers in a general way various classes of accident insurance written, and while it is impossible at present to underwrite all aircraft personnel or passengers as a group, indications are that, with the present rapid development of aircraft mechanics, safety measures, and additional statistical information, etc., such insurance may be available in the future.

Author's Closure

Referring to the comment of Mr. Auer, permit me to submit the following more definite description of the insurance arrangements of the Transcontinental Air Transport, Inc.:

The safety of air travel as it is offered by the regular operators using a fixed and definite schedule is further indicated by the fact that an insurance company whose experience is large in the transportation field has issued a blanket life insurance policy covering passengers while on planes of the Transcontinental Air Transport Company. This policy protects each passenger individually in the amount of $5000. This protection is included in the cost of the ticket. Passengers may secure additional protection through the purchase of accident insurance which is available at all Transcontinental Air Transport ticket offices and at most railroad ticket offices.

Installing and Servicing Aircraft Instruments

By JOHN D. PEACE, JR.,[1] BROOKLYN, N. Y.

Careful installation of instruments in airplanes is most essential in order that they function properly, and remain free from trouble. The author describes details of installation that have proved satisfactory for the principal types, and points out certain things that should be avoided.

Service work on instruments is divided into two classes, periodic overhauling and inspection, and adjustments done at service stations. Engineering service to the airplane builder is considered a very important part of the instrument manufacturer's duties as it insures proper installation of the product.

THREE essentials must be considered in the installation of instruments on aircraft. First, the method and conditions of installation, so that the instrument will function properly; second, the workmanship and detail which will insure that vibration and other factors will not cause an otherwise properly installed instrument to cease to function due to breakage of tubes and the like; and third, that the installation is arranged so that the instrument can be removed quickly and conveniently for servicing without having to remove an oil tank, the whole instrument board, or two or three other instruments. The responsibility for properly observing all these conditions rests primarily with the aircraft manufacturer together with the instrument company, whose business it is to see that the plane manufacturer is supplied with the necessary data and cooperation. Unfortunately the rapid increase in production in the last two years has at times made it inconvenient for the airplane company to assign a first-class man to the work of installations alone, not only as regards instruments, but with respect to numerous other accessories as well. Fortunately this situation has been or is rapidly being corrected in most of the larger companies where project engineers are giving considerable attention to the whole subject of the workmanship and quality of their product. The instrument manufacturer is working continually toward putting more instructive data in the hands of these project engineers and the designers.

Taken alphabetically, the first instrument is the air-speed indicator which is installed on all but the cheaper ships. This instrument is essentially a pressure gage calibrated in units of speed which measures the pressure difference created in a pitot and a static tube caused by the passage of the plane through the air. The indicator itself is mounted on the instrument board, the main consideration being that it should not be subjected to excessive and possibly destructive vibration. The pitot-static combination should be mounted where it will receive an undisturbed flow of air, and not be within the propeller wash or within the high- or low-pressure areas adjacent to a wing. There remains only the connection between these two units which is usually made with copper tubing of $^3/_{16}$ in. outside diameter, using a soldered cone and a nut at the joints. Aluminum tube is sometimes used to save weight which, however, requires the use of rubber tubing for connections unless Parker-type fittings are employed. There should, of course, be no leaks in the tubing. While this condition may be observed at the time of installation, it often happens that rubber tubing will deteriorate at some inaccessible joint within a wing, a long unsupported length may crack after continued vibration, or chafing against some structural or other member may cause a leak which will destroy the proper functioning of the instrument.

It is rather disconcerting to have to open up a wing to repair a poor rubber joint which was there just because there happened to be a piece of tubing left over at the factory which was not long enough to use without joining it to another piece. Lastly, the tubing should be arranged so as to minimize the possibility of water getting into the lines, and especially to the instrument. To accomplish this, there should be a definite rise of at least three to four inches from the pitot and static openings. The lines should then progress continuously downward from the high point to a point in the fuselage, preferably two to three feet below the level of the indicator. At this point the line from the wing should come into the stem of a T. The line from the instrument should come to the top of the T while the bottom should have a removable cap to facilitate drainage.

The altimeter installation is probably the simplest of any aircraft instrument. Roughly speaking, it involves merely its mounting on an instrument board. The advent of the cabin plane, however, introduced in certain cases a new condition. Certain ships used or do use the instrument board as part of the structure or fire wall separating the engine compartment from the cabin or cockpit. The old type of altimeter, with vent holes in the back of the case, was then subjected to the barometric pressure corresponding to the altitude of the ship plus a pitot pressure in the engine compartment due to the movement of the ship through the air. Thus an altimeter, reading zero when the plane was at rest on the ground, would register minus 100 to 200 ft. at the moment of takeoff, and would not come back to zero until the ship was 100 to 200 ft. above the ground. The error introduced would also vary with the speed of the ship so that the instrument readings were more or less unreliable except as approximations. Experiments showed that sufficient leakage could be provided around the glass to make the old vent holes at the rear unnecessary. This procedure automatically caused the altimeter to read pressures corresponding to the cabin instead of the engine compartment. Like any other instrument, the altimeter should not receive excessive vibration.

The installation of a climb indicator is almost as simple as that of an altimeter, for it involves merely the mounting of the indicator, its thermally insulated tank, and the connection of the two with a tube which is supplied with the instrument. Since its operation depends on rate of change of barometric pressure which is generally quite small, it is important that the instrument receive the true barometric pressure corresponding to the altitude of the plane, and not receive pressure changes due to other causes than changes of altitude. Where the instrument is mounted on an instrument board so that it receives engine-compartment pressure, it is necessary to connect it to a static line to the cockpit or cabin. If this is not done, changes in speed of the ship will cause climb or descent readings though the altitude of the plane is not changing. In some high-wing cabin monoplanes, pulling up sharply from level flight apparently caused an increased pressure in the cabin, especially with windows open, which would cause a momentary descent indication before the instrument showed a climb. This can be cured by venting the instrument to the rear of the fuselage or to the static line of the air-speed indicator.

The magnetic compass has probably been poorly installed more often than any other instrument. The earth's magnetic field is rather weak, and unfortunately the compass responds to

[1] Pioneer Instrument Co., Brooklyn, N. Y.

Presented at the Third National Meeting of the A.S.M.E. Aeronautic Division, St. Louis, Mo., May 27 to 30, 1929.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the influence of any magnetic force present rather than responding to the earth alone, so that often one is confronted with quite a problem. In cabin ships with the pilot close to the motor, magnetos, generators, and electric starters on the rear of an engine, make things rather hard for the compass. There are two rules to follow. First, the compass should be placed in a location as far from magnetic disturbances as possible and second, as convenient as possible for the pilots observation. Often the two conditions conflict materially so that the best location may be a compromise of the two. As a general statement, a location which introduces more than 30 deg. maximum deviation before compensation should not be used. The compass should always be compensated and excessive vibrations should be avoided. The earth-inductor compass usually permits of a very advantageous location of the generator in the rear of the ship away from the motors. The indicator of this compass, which is a sensitive galvanometer, should be kept as free from vibration as possible.

Practically nothing need be said of the engine instruments except the tachometer. The tachometer shaft should be run as straight as possible without sharp bends. Shafts which bind or which have a number of sharp bends may cause a fluctuation in the instrument.

The turn-and-bank indicator rarely presents any trouble. A venturi tube which is mounted in the slipstream provides the power for operating the gyro wheel of this instrument. Failure of the instrument to operate can usually be traced to a poor location of the venturi tube. The general practice on mail planes at the present time is to mount the venturi somewhere on the exhaust pipe to prevent ice formation which might cause the instrument to cease working.

The service work on instruments may be divided into two classes, periodic air-line service, and occasional service as rendered at a service depot. Almost from the start the National Air Transport has had an instrument department which has made a careful study of the instrument problems on their lines, and has endeavored to keep their instruments in good working order at all times. Whenever a plane is in the shop for overhaul, all instruments are tested, not only to see whether or not they operate but also for accuracy, sensitivity, friction, etc. When the plane is checked out of the shop as being ready for operation, the instruments are all in first-class condition. This work is always done whether or not the pilot reports a faulty instrument. A plan worked out by National Air Transport some time ago is being adopted at the present time on several new ships. This consists in the main of mounting all of the flight instruments on a small demountable panel on the instrument board proper. This small panel can then be removed easily from the ship for testing during motor overhaul, and a spare can be carried on hand for replacement in a ship during an emergency. The overhaul of instruments consists of checking for calibration and friction, oiling, and replacing minor parts where necessary. As the need for them arises, service depots are being established which will make it possible for an individual to have any necessary work done on instruments. This will include the testing or checking of any instrument, minor repairs, compensating compasses, and all other details incidental to the proper maintenance of aircraft instruments.

Engineering service to a manufacturer is very important from the standpoint of insuring the proper installation of the product. This work includes the selection of proper locations for compasses and pitot tubes, advice as to types of instruments most adaptable to a customer's plane, provision for proper clearances, and the design of instrument boards. It may involve several visits to a factory to see that all the details of an installation are carried out properly. To generally improve their installations a number of companies have already sent men to spend some time at an instrument factory, and with the service department to improve their knowledge of the instruments which they place in a plane.

The past year has been the first in which there has been any amount of aircraft instrument servicing on a commercial basis. Each of the air lines has established or is arranging to establish this service for themselves. To the air line it is vital that their instruments function properly. This will undoubtedly be followed by service stations all over the country which will take care of the private individual in a manner similar to the automobile service station of today.

Discussion

W. G. Brombacher.[2] This paper calls attention to an important, and up to the present, a much neglected aspect of aircraft instruments. The conditions under which aircraft instruments operate are so severe that considerable care must be taken in their installation in order to obtain the most favorable operating conditions, and further, owing to this fact, more servicing is also found necessary.

The installation problems of the instruments ordinarily installed on aircraft have been fully presented by Mr. Peace. One additional point might be mentioned. If the aircraft operator for any reason is interested in obtaining the air speed accurately, a calibration of the completely installed pitot-static air-speed indicator must be made over a speed course or its equivalent. This is due to the fact that flow of air around the pitot-static tubes now commonly used is subject to interference from the structure of the aircraft. In order to eliminate this interference special pitot-static tubes must be used, and precautions observed which are impractical in the ordinary operation of aircraft. It is suggested as a possible requirement that the completely installed air-speed indicator of every individual ship be calibrated over a speed course at two speeds, one near the stalling speed and the other at the cruising speed. The results of this calibration should in some way be made available to the pilot, preferably by marking it permanently on the dial of the indicator.

The need for servicing aircraft instruments is similar to that now followed in servicing the speedometers of automobiles, service stations for which are maintained by manufacturers in every large city. Largely owing to the severe conditions of use, aircraft instruments are in frequent need of minor repairs, and often require adjustment in order to maintain their accuracy. As has been pointed out by the author of the paper, a start has been made by a few of the larger operating companies in organizing instrument-maintenance units. The organization of such units will be accelerated no doubt by the emphasis which is now being placed on "blind" or instrument flying during which complete dependence must be placed upon a certain group of instruments.

Author's Closure

The discussion calls attention to the fact that in order to obtain an accurate calibration of the air-speed indicator, it is necessary to run a plane over a speed course. While this is true as regards absolute accuracy, it is hardly necessary to go through such a procedure in the case of a production series of airplanes. Such tests would be of value on the first one or two of a production series in order to determine a good location of the pitot-static tube.

Dr. Brombacher also calls attention to the fact that not all aircraft operators can employ an instrument man among their personnel. To take care of this situation, there are already being established a number of service stations at strategic points throughout the country, which will be able to take care of any required service.

AER-51-29

Some Aerological Principles Applying to Airship Design and Operation

By F. W. REICHELDERFER,[1] LAKEHURST, N. J.

In this paper the author discusses some of the problems of wind structure and of vertical air currents. Data are presented on local wind fluctuations of great frequency, on less-frequent, wide-spread wind shifts, and on local vertical air movements. The discussion is not primarily of strong winds and gales as a navigational problem affecting cruising radius, but of those properties of wind structure which may be obstacles to air navigation because of the excessive forces which they may exert on airship structures.

THE physical properties of the atmosphere, especially its composition, distribution of pressure and temperature, and the average changes in these properties as they relate to airship design and operation are well known through the science of aerostatics. The forces relating to movements of powered aircraft through the air are treated in aerodynamics. In general, both of these sciences, in order to present their material systematically, regard the atmospheric elements as continuous phenomena, and overlook the marked discontinuities which occur; or, if they consider these abrupt variations in physical properties of the air with time and place, they treat them in their average form. In reality, however, the atmosphere rarely conforms to an average behavior. Its changes are not usually systematic in any simple manner. This characteristic is well demonstrated in the fickleness of the weather.

Rapid changes occur in practically all of the so-called weather elements—pressure, temperature, humidity, wind, clouds, and so on. All have their influence on every-day airship operations. The most capricious weather element, and the one which is most interesting in its possible influence on all branches of aeronautics, is the wind. The subject of wind structure, referring to the character of horizontal wind flow and sharp discontinuities therein, and to local vertical air flow in clear air and in thunderstorms where the most violent vertical air movements are found, is of importance to all types of aircraft, but it has special applications to lighter-than-air craft. This subject, while not so important during the experimental stage of lighter-than-air development, becomes increasingly important as commercial airship operation approaches.

Airships operating under commercial requirements will encounter wind conditions which ships under experimental operation could avoid. Reference here is not primarily to strong winds and gales as a navigational problem affecting cruising radius, but to those properties of wind structure which may be obstacles to air navigation because of the excessive forces which they may exert on airship structures.

Just now, it is important to find out what actually goes on in horizontal and vertical air movements. Some of the problems of wind structure and structure of vertical air currents have been attacked with some success from the theoretical and mathematical side, but in most cases it has been impossible so far to express as exact mathematical functions the large number of variables entering into atmospheric processes. (See reference A, and further references contained therein.) The data presented here pertain to (1) local wind fluctuations of great frequency (gusts); (2) less-frequent, wide-spread wind shifts (squall lines, discontinuities between air masses); (3) local vertical air movements.

(1) It is common observation that the wind blows in gusts. The speed of the wind, whether a gentle breeze or a gale, varies greatly from second to second. The wind direction, likewise, changes from moment to moment, swinging irregularly to one side or the other of the mean direction. The records of wind-recording instruments show that there is no simple periodicity about these fluctuations. For practical purposes they appear largely "accidental."

Fig. 1 shows a portion of a record of wind direction and wind speed at the naval air station, Lakehurst, N. J. It illustrates the irregularity of the wind. The lower graph gives wind speed,

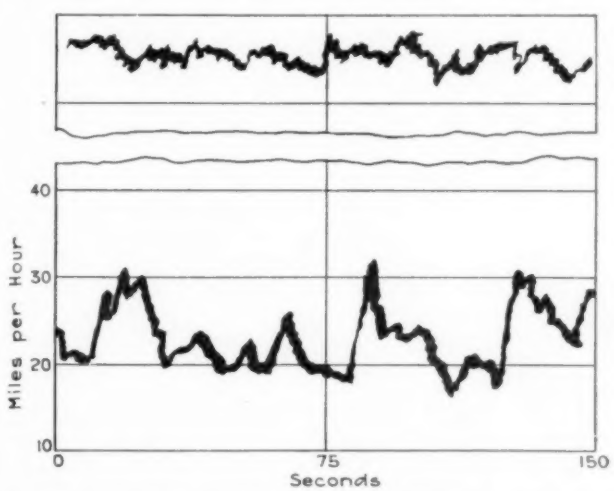

FIG. 1 GRAPHICAL RECORD OF GROUND WIND TAKEN BY AN ANEMOBIAGRAPH OF THE DINES PRESSURE-TUBE TYPE

each small ordinate representing two miles per hour (2.93 ft. per sec.). The upper graph gives wind direction, each ordinate corresponding to 20 deg., angular measure. The heavy ordinate, just below which most of the graph lies, is northeast (45 deg.). Direction and speed are plotted against time, the time interval between each vertical graduation being 75 sec. In Table 1 values are given for direction and speed of the wind during the 20 seconds beginning with the vertical line to the left in Fig. 1, and also for the 72, 73, and 74 seconds.

This example represents the usual character of the wind. It was taken at random. It shows the rapid changes in direction and speed which the ground wind passes through continually even over flat, unobstructed country. This record was made by an anemobiagraph of the Dines pressure-tube type. Doubtless this instrument fails to record some of the sharper and briefer fluctuations in wind speed and direction. Measurements by hot-wire anemometer show the existence of these more rapid fluctuations. Although there is some uncertainty as to the degree of accuracy of measurements of natural wind by hot-wire anemometer, owing to difficulties of exposure and instrumental errors, there is little doubt that this instrument is de-

[1] Lieutenant U.S.N., Lakehurst, N. J.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

cidedly more sensitive than the anemometers commonly used for gust study. It appears to be a close approach to expressing the actual turbulence of wind flow near the ground. These very rapid fluctuations are tabulated, not because they are at present of direct practical value to airships, but because they are of interest in the study of wind structure.

TABLE 1 WIND FLUCTUATIONS, DINES ANEMOGRAPH

Wind (seconds)	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	72	73	74
Direction (deg.)	60	62	55	60	50	52	51	50	49	43	43	50	49	44	61	59	59	59	72	65	67	90	35
Speed (m.p.h.)	23	23	22	21	20	19	20	20	20	21	20	19	18	20	22	26	28	23	28	30	19	18	18

TABLE 2 WIND FLUCTUATIONS, HOT-WIRE ANEMOMETER (REF. B)

Time interval	Character	Velocity fluctuations within time interval shown at left	Accompanying vertical fluctuations
0.5 sec.	Intensity above avg.	31 to 37 to 31 to 42 m.p.h.	Up to 16° incl.
0.5 sec.	Intensity above avg.	26 to 42 m.p.h.	+10 to −16 to +13
5.0 sec.	Wind "surge"	29–41–29–31–46–31 m.p.h.	+16 to −18 (1 s.)
0.3 sec.	Strong gust	26 to 46 m.p.h.	+16 to −16

The maximum wind acceleration measured by the hot-wire anemometer (ref. B) was at the rate of 24 meters per second per second (54 m.p.h. per sec.). The maximum change in wind direction was at the rate of 180 deg. per sec. It should be noted that the fluctuations did not actually pass completely over the maximum ranges mentioned, but that the fluctuations over a fraction of a second were at the rates stated. Further, fluctuations of this order of magnitude were not sustained. The element either returned quickly to about its mean value or went beyond toward the opposite extreme. These very large but transitory fluctuations from the "mean wind" are of little significance in airship design and operation. The cycle is passed before its maximum phase has exerted sufficient force to cause serious strains in any portion of the ship.

It is the fluctuation in wind speed or direction, or both simultaneously, which is sustained for several seconds that is a factor in airship handling. If the wind were steady in flow, it could blow with rather high velocities without having much effect in ground handling or in riding at the mast. It would be possible to estimate its effect and make provision for meeting it. With wide and sustained fluctuations in velocity and direction at irregular time intervals, however, it is difficult to provide handling lines and mooring devices which will meet the changing forces in strong winds. At the mast, airships have without difficulty ridden out strong winds. When the average wind speed is 35 or 40 m.p.h., and there are gusts up to 55 or 60 m.p.h., with the maximum value sustained for 5 or 10 sec., and at the same time a sustained change in wind direction, the forces exerted by the wind cause undesirable strains in the ship. Again, a sudden marked change in wind direction even though unaccompanied by an increase in wind speed may, if the speed averages around 50 m.p.h., produce large strains. This fact is not surprising when one considers the dimensions involved. When a ship 800 ft. long is moored to a mast so that its tail swings freely, the tail describes a circle about 5000 ft. in circumference. If there is a wind shift of 45 deg., the tail must move through an arc of about 600 ft. to place the nose directly into the wind. It requires appreciable time to overcome the initial inertia of the ship, and move it through the required distance, and during this time the wind exerts considerable forces against the side of the ship.

Most wind gusts fall well within the allowable limits of direction and velocity fluctuations, but occasionally there are winds with gusts which approach critical values. Some of the largest values obtained in gust records at Lakehurst are given in Table 3. These apply to fluctuations in gusts in the same general wind stream and not to the more violent wind shifts between air masses of different origin and density.

It is unlikely that gusts retain their individual form for very long periods of time or over considerable distances. An individual gust is constantly changing in form. There is little definite information about their usual dimensions in space and their rates of travel. They appear to travel for short distances at approximately the speed of the mean wind. Data at hand indicate that some gusts extend several hundred feet in the direction perpendicular to their line of travel. The height to which a strong surface gust ordinarily reaches is unknown. The approximate dimension of a gust in the direction of its travel can be computed on the assumption that it travels at the speed of the mean wind.

Using the first example in Table 3, in which the gust was of 90 seconds duration, and then returned to the mean value or slightly below, the front to rear dimension of the gust would be about one mile. The examples given do not, it is likely, mark the limit of intensity of gusts within the same wind stream (as distinguished from the gusts in wind shifts to be mentioned later). It is for the purpose of obtaining more information on the usual dimensions of gusts and their circulation and propagation that the gust measurements at Lakehurst, Cardington, and other places are being carried on. This information will apply in design of ground-handling equipment and methods.

Gustiness in the surface wind is largely the turbulence caused by the friction between the wind and the ground. This cause is aided during the day by convection resulting from the heating of the ground. The temperature distribution in the particular air mass constituting the wind is a factor in gustiness. If it is a north wind and is bringing colder air, the lagging of the surface layer will permit the cold air to come in more rapidly aloft, and result in instability due to the relatively greater density of the layers above. This leads to the breaking through of the air from above, giving the bursts or "surges" of downward gusts which characterize a cold north wind. A south wind, on the other hand, is usually less gusty in velocity because it brings warmer air aloft more rapidly than at the surface and results in thermal stratification and stability. There are a few other characteristics of gusts which may be referred to very briefly. An ocean wind is usually less gusty than a continental wind. The wind is less gusty at night than during the day, not only because of the absence of convection which would increase the mixing and turbulence, but also because a temperature inversion is often built up by radiation from the ground, thus increasing the vertical stability of the air.

As is to be expected from consideration of the causes of gustiness, no simple periodicity or regular structure is apparent either in wind-direction fluctuations or in wind-speed changes. It has been suggested by some meteorologists that air layers of different velocity generate a cylindrical motion in the air in their

TABLE 3 WIND CHANGES IN GUSTS AT LAKEHURST

Mean wind	Wind-speed change (m.p.h.)	Time interval	Rate, ft./sec.	Sustained speed and interval	Accompanying change in direction	Time interval of direction change
40 m.p.h.	27–45	4 sec.	7	40–45 for 90 sec.	veer 30°[1]	2 sec.
35 m.p.h.	24–44	6 sec.	5	40–45 for 75 sec.	v. 20° at end	3 sec.
35 m.p.h.	32–50	3 sec.	7	40–45 for 45 sec.	30° and held 2 sec.	1 sec. (30 sec. after crest)
35 m.p.h.	31–49	2 sec.	14	40 m.p.h. for 65 sec.	20° gradual	60 sec.
30 to 35 m.p.h.	20–42, then	10 sec.	3	40 m.p.h. for 180 sec.	N and NE, 35°	5 sec.
	42–29, then	12 sec.	1.5	40 m.p.h. for 180 sec.	backing, then	2 sec.
	29–36, then	3 sec.	3	40 m.p.h. for 180 sec.	10° veer, then	15 sec.
	36–34, then	3 sec.	1	40 m.p.h. for 180 sec.	45° veer, then	10 sec.
	34–55	7 sec.	4	40 m.p.h. for 180 sec.	steady 2 sec., then 45° back	... ...

([1] 30° veer momentarily)

boundary zones and that part of this motion is transmitted in gusts. There is apparent a very rough regularity of recurrence in direction and velocity changes in gusts. It varies in different winds, and from place to place. Computations of average variations as regards intensity and frequency give results of about the same order for different regions. Thus, gust measurements in Europe (ref. C) as well as in the United States show that the magnitude of the crests and lulls varies in rough proportion to the average wind speed. The variation is roughly 50 per cent of the mean wind. If the mean is 30 m.p.h., the gust peaks reach, on the average, 40 or 50 m.p.h., and the lulls, 10 or 15 m.p.h. The frequency of well-marked cycles (from one marked peak to the next) in wind speed is roughly 30 to 50 cycles per hour. Marked fluctuations in wind direction, usually in the form of an abrupt and momentary swing of 15 deg. or more from the previous direction, followed by a partial or complete return to the previous direction, occur with a frequency of three to six per minute, on the average. There are usually minor fluctuations in direction which average as many as forty or fifty per minute. These average values, obtained from Dines anemobiagraphs, are relative only. As stated before, the more sensitive hot-wire anemometer shows many sharp and momentary fluctuations not shown by the ordinary anemometer or anemobiagraph. The increase in wind speed in a gust often comes in surges, usually in the form of one or two momentary interruptions to the rise. Sometimes the surges take the form of double crests. Fig. 1 shows that there are numerous ripples superimposed on the larger waves. A characteristic which is often important in airship handling is the tendency for the wind after a gale to pass through three or four large cycles in mean wind speed and direction, each cycle covering 30 to 60 min., with the cycles gradually decreasing in amplitude. Another characteristic which is regularly used in airship docking and undocking is the well-defined sunset lull which occurs on most clear days. The wind decrease at sunset often remains through the night, but frequently the sunset lull is followed by an increase. The averages of wind velocity on clear days show a slight tendency for the wind to lull at sunrise also, but this lull is much more uncertain and ill-defined than the sunset lull.

The foregoing tables apply to surface winds. There is very little available in direct measurements of the gustiness at usual flying altitudes, that is, altitudes above 1000 ft. There are great difficulties in exposing gust-measuring instruments at high altitudes. It is known that gustiness in a general wind stream decreases rapidly with altitude, and practically disappears at a few hundred feet above flat country. Over mountainous country, surface gustiness in strong winds may extend to 1000 ft. or more above the ground. The vertical extent of the wind shifts between different air masses is referred to in Table 5. Turbulence having the effects of gusts is produced at high altitudes by thunderstorms. These two causes of turbulence aloft—namely, general wind shifts and violent convection as in thunderstorms—are by far the most important in producing sharp discontinuities at flying altitudes. Other causes of turbulence aloft, such as waves at the horizontal boundary between two air layers of different velocity, and interruption of air flow by rough terrain, usually have no appreciable effect other than to make the air "rough" for aircraft.

Some of the gustiest winds at Lakehurst, as regards changes in direction, occur when the station lies on the boundary between southerly winds associated with the general pressure gradient, and the southeast sea breeze. The boundary is often sharp, and the two wind currents sometimes blow side by side over the same locality for an hour or more. There are usually large temperature and humidity differences between the two currents, making the boundary turbulent. The instability of the air along this surface of discontinuity makes very rough going for aircraft. The surface wind speed under these conditions rarely becomes strong, seldom over 20 or 25 m.p.h., but the direction often swings through an arc of 135 deg. to 180 deg. within one or two seconds as a bulge, from first one air mass and then the other, passes over a given point. Usually the extremes of these direction fluctuations are held only momentarily, followed by a return to within 50 deg. or 60 deg. of the mean wind, but it is not infrequent to have an abrupt shift under these conditions in which 45 deg. to 90 deg. of the change is not momentary. The wind often continues in the new direction for several minutes.

(2) The sea breeze boundary effect has been described because it illustrates on a small scale the atmospheric distribution which gives rise to some of the most violent gusts to be encountered; namely, the gusts which occur at the boundary between general air masses of different density, usually the boundary between a warm, moist, and therefore relatively light air mass moving as a south or southwest wind, and a cold, dry, and therefore denser air mass moving as a northwest or north wind. These are the conditions commonly associated with a well-defined V-shaped "low" on the weather map. The warm southerly wind lies in front (eastward) of the trough line, and the cold northerly wind, just behind the trough. Under favorable conditions the cold northerly wind under-runs the warm southerly with the boundary so sharp as to give a wind shift from southwest to northwest within a very few seconds, and an accompanying velocity increase from 10 or 15 m.p.h. to 50 or 60 m.p.h., and occasionally to 75 m.p.h. or more within four or five seconds. The mass of cold air sweeps over a locality like a wall of water. These are the conditions which give the abrupt changes in temperature of 20 deg. to 40 deg. experienced occasionally in the United States. Usually such a violent under-running is accompanied by convection which leads to thunderstorms, and the violence of the wind shift between air masses is sometimes increased by the squall wind. There are lows in which this abrupt wind-shift line extends for hundreds of miles along the trough with severe wind squalls and thunderstorms over most of this distance. It sweeps across the country in a direction approximately at right angles to its length. This is a line squall. Frequently, in the summer time, a "heat" thunderstorm develops until it covers 500 sq. mi. or more and produces a wind shift which is an air-mass boundary wind shift on a small scale. The thunderstorm develops a cold-air mass on the ground in the region of heavy rainfall. This cold air under-runs the warm air in front of the storm producing a sharp surface of discontinuity and changes in wind direction and velocity quite as intense as those in a general wind-shift line. Viewed from a single point on the ground it may have all the appearances and produce all the effects of a general line squall, except that the wind often returns to its southerly or other

TABLE 4 WIND SHIFTS IN THUNDERSTORMS

Type	Change in wind speed (m.p.h.)	Time interval	Accompanying change in direction	Time int.	Remarks
Thundersquall	5 to 24, then stdy. 1–2 min., then 24–37	5 sec. 1–2 min. 5 s. or ls.	135° 45° return 90° return to 1st dir. 2 min. later, 135° op.	5 sec. 1–2 min. 5 sec.	Avg. wind speed 20 to 25 m.p.h.

previous direction, after the local thunderstorm has passed.

The cold air in the rear of a trough sometimes over-runs the warm southerly current instead of under-running it. In such case the resulting instability soon produces convection and thunderstorms.

Table 4 lists some of the violent wind changes which have been observed in connection with wind-shift lines, both line squalls and local thunderstorms. These data refer only to effects in the horizontal wind and not to the vertical currents in thunderstorms. While the violent effects of a local thunderstorm may frequently be avoided by detouring, the line squall of similar violence sometimes extends for long distances, making it impracticable to detour and necessitating use of some other means to avoid it.

The conditions described by the data in Table 4 are not infrequent. Wind shifts of this order of intensity occur once or twice a year in most portions of the United States. Many regions have them several times a year. Such shifts are not peculiar to the United States. Some of the examples are from European weather records. Most regions of the globe experience wind shifts either from line squalls or from thunderstorms, or both.

An interesting feature of the first example is that it occurred at night when the sky had been generally clear until the squall cloud arrived, and that the wind shifted through 270 deg. within a period of eight minutes. This occurred at Lakehurst. The last example, which occurred near Washington, D. C., is interesting in that this very violent thunderstorm came more than two hours before the line squall and general wind shift. The winds in the storm were extremely violent, and attained their full force within a very few seconds after the first burst of the storm. It is not implied that these data represent the most abrupt changes that occur in wind speed and direction. The most violent local wind conditions are those found in tornadoes. From the average diameter of these storms, their rate of travel, and wind speeds which are without doubt often in excess of 200 m.p.h., it is readily computed that a point directly on the line of travel must experience a wind increase from 30 m.p.h. or less up to 200 m.p.h. or more, and a complete reversal of wind direction within 15 sec.

The shifts in the surface wind, as tabulated, are of particular interest in connection with ground handling and mooring. Such shifts as these often extend to considerable altitude, and are therefore also of importance to airships in flight. Accurate data are scarce, but the observations in Table 5 give some indication of the vertical extent of wind-shift surfaces.

TABLE 5 WIND SHIFTS ALOFT (REFS. D AND E)

Wind shift	Wind speed before shift	Wind speed after shift	Minimum altitude to which shift was observed to extend	
E.S.E. to W.S.W., abruptly	30 m.p.h.	30 m.p.h.	3000 ft.	Both of these shifts were abrupt, probably less than 1 min.
S.S.W. to N.W.	33 m.p.h.	33 to 55	2500 ft.	

(3) While the shifts in horizontal air currents are important, they are not, in some respects, as important as the vertical currents associated with violent convectional phenomena. A sharp wind discontinuity imposes unusual forces on an airship, whether exerted laterally as in a wind-shift surface or vertically as in the convectional current of a thunderstorm, but the vertical current necessitates in addition that the ship be prevented from going too far aloft or too far downward. Direct measurements of vertical currents are difficult to obtain. There are numerous indirect measurements which demonstrate that vertical currents, especially ascending currents, may attain very high velocities.

The thunderstorm cannot be considered in detail here. The processes involved have been described elsewhere (ref. F). It is interesting to note, however, that saturated air ascending from 2000 or 3000 ft. to approximately 10,000 ft. would by virtue of its latent heat become "potentially" about 20 deg. warmer than the surrounding air at that level providing the temperature gradient is adiabatic. Under favorable conditions the thermal energy produced is available for formation of violent ascensional currents within the cloud. The thermodynamics of convectional processes is discussed briefly in reference A. Table 6 gives some of the observed and estimated vertical speeds of ascending and descending air currents.

A larger number of cases showing measurements of ascensional currents obtained like those in the table, more or less accidentally, could be listed. Circumstances indicate that these measurements do not represent extreme values. It is highly improbable that the balloons and recording instruments which supplied these measurements got into the most violent vertical currents. There is a mass of data indirectly substantiating the conclusion that the velocities listed are not infrequent in thunderstorms.

It is important to know something about the boundary of vertical currents typified by the foregoing examples. The airship designer needs to know whether the change from air without vertical motion to air with the excessive ascensional speeds mentioned is gradual or whether it occurs within 1000 ft., for example; also, whether the transition zone is turbulent or not; also, whether ascending and descending currents of considerable speed can exist in such proximity as to place the nose of an airship in the descending current while the tail is still in the ascending current, or vice versa. Information on this subject is far from complete.

An indication is afforded by the sharpness of boundary surface between air masses which give abrupt shifts in horizontal wind. If the second example in Table 5 is considered as a 90-deg. shift, from southwest to northwest, in which the average speed of each wind current is 30 m.p.h., giving an "easting" of about 21 m.p.h., and the interval between the full force of the two currents is 30 sec., the width of the boundary zone is 900 ft. or less. It is to be noted further that the two currents with respect to each other are blowing in opposite directions, instead of perpendicular to each other as it appears from a point on the ground, and that an airship passing directly across the boundary would experience a change in wind from south, 21 m.p.h., to north, 21 m.p.h., in a distance of 900 ft.

Evidence that similar sharp boundaries are found between vertical currents, especially under thunderstorm conditions, is given by observations of the behavior of cloud wisps in a line squall and of the circulation of the squall cloud in a thunderstorm. The squall cloud forms occasionally between the ascending and descending air near the front of the thunderstorm. Observations of the dimensions of squall clouds have shown that the distance between the strong ascending and the marked descending currents is often less than 1000 ft. This conclusion is substantiated by the experiences of aircraft which have been caught in this portion of a severe thunderstorm.

Another aspect of the study of wind discontinuities is the subject of means for identifying and locating intense discontinuities. There is, of course, no sharp division between the mild and visible

TABLE 6 VERTICAL CURRENTS IN THUNDERSTORMS

Type of current	Speed, met./s.	Speed, ft./s.	Source of estimate
Thunderstorm ascending	5	16	Aerograph on box kite which broke away
Thunderstorm ascending	8	26	Pilot balloon by range finder
Thunderstorm ascending	8	26	"End" velocity of largest raindrop
Thunderstorm ascending	10	33	Manned balloon
Thunderstorm ascending	16	53	Velocity required to support hailstone 2 cm. in diameter
Thunderstorm ascending	24	78	Velocity required to support hailstone 4 cm. in diameter
Thunderstorm descending	3	10	.....
Thunderstorm descending	5	16	.....

convectional current encountered as a "bump" on almost any clear summer day, and the very strong uprush of air in an intense thunderstorm. A light ascensional current of a meter per second may grow into a current rising at five to ten meters per second, still without clouds to indicate its presence. If a cloud is formed, and develops first into a shower, then into a thunderstorm with hail, the vertical currents within the cloud may reach the high speeds given in Table 6. Again, a thunderstorm associated with a suitable barometric depression may merge into a tornado with its extremely violent wind conditions. Obviously, aircraft of all kinds must avoid these extreme conditions as an ocean vessel avoids a derelict or an iceberg.

Cloud appearance is a rough indication of the presence and intensity of violent wind shifts. The more ugly the cloud appearance, and the greater the electrical activity in a thunderstorm, the more violent the wind conditions, as a general rule. Visible indications are not always reliable, however. Under certain conditions, ascending currents of five or more meters per second and wind shifts as violent as those given in Table 4 are unattended by clouds. Two other general methods of identification are available. They are both indirect. First, the use of the daily weather map to recognize atmospheric conditions which give rise to wind discontinuities. Second, the use of instruments which give an indication of violent conditions at a distance.

There is not space here to discuss in detail the use of the weather map in forecasting wind shifts and thunderstorm conditions. The comparatively recent development of methods of forecasting based upon air-mass analysis, rather than upon an objective survey of high and low areas on the map, opens the way to more definite and detailed information of storm structure of fundamental importance in airship operation. A single example is given to illustrate the aerological principles underlying this method. In winter and spring it is not unusual for a bulge of warm equatorial air from the Gulf of Mexico to ride up over a mass of cold northerly air overlying the southern states. This usually causes formation of an ill-defined but heavy rain-producing low. If the temperature-lapse rate of the southerly air exceeds the adiabatic rate for saturated air, thunderstorms develop, once condensation gets well under way. In such case, the turbulence of the thunderstorm is usually confined to the upper layers because the wedge of cold northerly surface air forms a barrier to the penetration of the thunderstorm circulation to the surface. An airship can, therefore, avoid the thunderstorm condition by keeping close to the surface, well within the cold wedge. An analysis of air-mass distribution on the weather map including upper air maps makes it possible to recognize this storm structure when it occurs. The procedure referred to here has been employed on one occasion for a storm of this type by the airship *Los Angeles*.

Three general types of instruments employing different principles for identifying severe thunderstorms or conditions giving rise to them are described briefly. All are still in the experimental stage. The first is use of a meteorograph or aerograph to obtain temperatures and humidities of air strata aloft. These, together with upper-wind data obtained by pilot balloon, are used to determine the thermodynamic structure of the air at a given time and place. This enables one to draw conclusions as to whether conditions are favorable for thunderstorm development (ref. H).

A second type of instrument for identifying severe thunderstorms is one which measures the potential gradient of the atmosphere. The gradient in the vicinity of a thunderstorm is usually very steep and distorted. To some extent, the electrical activity of a storm is proportional to the intensity of its vertical circulation. This instrument, like an electrometer in principle, makes it possible to determine when the gradient exceeds a certain critical value. The possibilities of this type of instrument are uncertain. The electrostatic effects of a thunderstorm probably do not extend to great distances from the storm, and the instrument, if successful at all, would be indicative only at close range.

The third type of instrument is the ceraunograph, or lightning and static indicator, which makes use of the electromagnetic effects of the thunderstorm. It is well known that "static" from a thunderstorm may be heard in radio receivers many miles away. A type of static indicator now under test at Lakehurst and Anacostia utilizes two fixed-loop antennae placed at right angles, each with its own receiver connected with the plates of a cathode-ray oscillograph. The deflection of the oscillograph beam gives not only a measure of the intensity and the form of the waves intercepted by the loops, but also the line of direction on which the wave is traveling. Simultaneous bearings from the instruments, one at Lakehurst, the other at Anacostia, make it possible to find the location of the static disturbance, and thus to locate a violent and isolated thunderstorm. This instrument has been used with success in England. Incomplete tests in this country indicate that it will find important applications in airship operations of the future.

The Selection of an Airplane Engine

By LT.-COMDR. J. M. SHOEMAKER,[1] U. S. NAVY

The author states that the commonly accepted fundamental requirements of an aircraft engine are: minimum weight per horsepower; maximum dependability, durability, and economy; minimum cost; and maximum ease of maintenance. He discusses the relative importance of these requirements, from the point of view of the airplane designer, in the power plants of various types of airplanes, and adds to them another requirement, namely, the consideration of an airplane engine as an integral part of an airplane.

THE fundamental requirements of an aircraft engine have been enumerated many times. The commonly accepted requirements, set down without reference to their relative importance, are:

1 Minimum weight per horsepower
2 Maximum dependability
3 Maximum durability
4 Maximum economy
5 Minimum cost
6 Maximum ease of maintenance.

The author proposes to discuss the fundamental aircraft-engine requirements as to their relative importance in the power plants of various types of airplanes, and to amplify the foregoing list of requirements by the consideration of an airplane engine as an integral part of an airplane.

It is appropriate to define and discuss briefly the fundamental aircraft-engine requirements from the point of view of the airplane designer.

Minimum Weight per Horsepower

Up to the present time, the development of aircraft engines has been measured in terms of "pounds per horsepower." The specific weight of an airplane engine is one determinant of the gross weight of the airplane. The heavier the engine for a given power, the greater the wing area needed to support it. Greater wing area means heavier airplane structure, which requires more power for a desired performance. Considering the aircraft power plant as a whole, the engine must be charged with the weight due to the cooling system, necessary engine accessories, and propeller. From this viewpoint the air-cooled engine has a decided advantage over a water-cooled engine, as has the high-speed engine with its small propeller over a slow-turning or reduction-geared engine with its large, heavy propeller. Other requirements, as will be pointed out later, may operate to make the case against the heavy engine less conclusive.

Maximum Dependability

All heavier-than-air craft, depending as they do upon propeller thrust to overcome the force of gravity, must have power plants which are as nearly perfect as possible as regards dependability. Here again the power plant must be considered as a whole. Fuel- and lubricating-oil tanks and pipes, ignition, and cooling-system dependability are chargeable to the airplane power plant. Not only must the engine function perfectly throughout every flight, but the whole power-plant installation must be simple and rugged enough to obviate failures in the air. The water-cooled engine, with its cooling system, is again placed at a disadvantage as regards simplicity, and the extra plumbing involved must be carefully designed and maintained to insure dependability.

There has been a great deal of discussion among engine and plane builders as to the responsibility for power-plant failures outside of the engine itself. At present the engine manufacturer considers himself responsible for abnormal fuel or oil consumption and ignition and engine failures; the propeller manufacturer takes the responsibility for propeller failures; and the airplane manufacturer is blamed for any failure of engine mount, plumbing, or tanks. Failures which are due to excessive engine vibration should be charged to the engine, as should failures due to complicated plumbing (fuel, oil, or water) required by some engines because of poorly designed pumps and outlets.

Maximum Durability

Aircraft-engine durability is measured by the operating hours between overhauls. The durability of an airplane's power plant can be measured by that of the engine, as the other components of the power plant should all be more durable than the engine.

Maximum Economy

Specific fuel consumption, next to weight per horsepower, is probably the most important determinant of the efficiency of an aircraft engine. Most conventional engines are equal as regards specific fuel economy, although some of the less efficient designs of air-cooled engines require an abnormal fuel consumption for sufficient cooling. The impending entrance of an air-cooled Diesel engine into the family of successful aircraft engines requires more attention to specific fuel consumption as a component of specific engine weight. In other words, it may be highly desirable to consider the specific weight of an aircraft engine as installed as the sum of pounds per horsepower of complete engine with cooling system plus specific fuel consumption (multiplied by intended duration of flight).

It is somewhat of a problem to choose the percentage of engine maximum brake horsepower at which to compare specific fuel consumptions. The nature of the service expected of the airplane power plant varies widely with different types of airplanes. Military airplanes and commercial planes operating under large loads per horsepower must pay particular attention to fuel consumption at or near full power. Lightly loaded planes, on the other hand, will normally fly with the engines well throttled, and the specific fuel consumption under these conditions is of particular interest. Since the fuel-consumption curves of most engines are of approximately the same shape, it is believed that the specific fuel consumption at 60 per cent of full power on the propeller load curve (at which point r.p.m. = 0.843 of full-power r.p.m.) is probably as good a point for comparison as any.

A study of the power curves for various engines indicates that the full-power specific fuel consumption varies from 0.55 to 0.60 lb. per b.hp-hr., but that most of the engines now in service have a specific fuel consumption of 0.50 lb. per b.hp-hr. at 60 per cent of full power on the propeller load curve.

When a successful Diesel aircraft engine is available, it will probably have a fuel consumption in the neighborhood of 0.40 lb. per b.hp-hr. at 60 per cent power. If air cooled, such an engine will probably weigh about 3 lb. per hp. Comparing it

---

[1] Chief, Power-Plant Section, Bureau of Aeronautics, Washington, D. C.

Presented at the Third National Meeting of the A.S.M.E. Aeronautic Division, St. Louis, Mo., May 27 to 30, 1929.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

with existing air-cooled engines of 1.5 lb. per hp., we find that for flights of less than 15 hours the conventional air-cooled engine will have a lower weight of engine plus fuel. That is, an engine weight of 1.5 lb. per hp. plus a fuel consumption of 0.50 lb. per hp-hr. will be less than the Diesel weight of 3.0 lb. per hp. plus a fuel consumption of 0.40 lb. per hp-hr. until 15 hours has elapsed. Beyond 15 hours, the advantage is all with the Diesel.

Minimum Cost

The cost of an aircraft engine requires definition. Do we mean first cost, or first cost plus maintenance cost? In any airplane, power-plant dependability is of paramount importance. Dependability may be achieved by a combination of light weight with excellence of design, materials, and workmanship, or it may be obtained by a less refined design manufactured of cheaper but heavier materials. The first cost of the latter engine may be less, but the engine will undoubtedly have a higher specific weight and probably no better dependability, durability, or ease of maintenance.

The first cost of an engine is of course greatly affected by the rate of production. This being so, the popularity of an engine model will be the final determinant of price, and an engine which most closely meets all the other fundamental requirements will be deservedly popular and can be manufactured in sufficient quantity to insure minimum cost.

Maximum Ease of Maintenance

Ease of maintenance calls for simplicity of design and accessibility of the moving parts. Ease of maintenance is interlocked with durability. If, despite its complexity of design and relative inaccessibility of parts, an engine runs for several hundred hours between overhauls, ease of maintenance fades into comparative insignificance.

In addition to the above requirements, the author would like to present for consideration a requirement which, for want of a better name, he has called "maximum effective thrust per horsepower." This requirement has to do with the effective thrust available in an aircraft power plant.

An aircraft engine's direct output is Brake Horsepower, while the output of the airplane power plant (which includes the propeller) is Thrust Horsepower. The thrust horsepower developed is, of course, dependent on the efficiency of the propeller used. The propeller should be so designed as to deliver the maximum thrust horsepower possible with the given conditions. For purposes of comparison, it is assumed that this is the case—that all the aircraft-power-plant types discussed have the most efficient propellers possible.

Aircraft-engine design affects the effective thrust horsepower in two ways, directly and indirectly. The direct effect is the speed of rotation at which the engine develops its power. The efficiency of a propeller increases with V/ND, where V = speed of advance of the aircraft, N = speed of rotation of the propeller, and D = propeller diameter. Hence, a high-speed propeller is less efficient than a slower-turning propeller in the same aircraft. (The slow-speed propeller will be of slightly greater diameter, but the effect of change in r.p.m. will be much greater and hence the latter will have much more effect on propeller efficiency.) A high-speed direct-drive propeller may also suffer a loss of efficiency due to excessive propeller tip speed. There is very little definite information as to the tip speed beyond which propeller efficiency falls off, but we have not been far wrong in assuming that it is in the neighborhood of 900 ft. per sec.

We see that the effect of high crankshaft speeds is to lower thrust horsepower directly due to its effect on propeller V/ND and on propeller tip speed. Consequently, with high-speed engines it is necessary to incorporate reduction gearing between the crankshaft and the propeller shaft in order to reduce propeller speeds. This reduction gearing is an additional complication owing to its possible reduction of engine durability, dependability, and ease of maintenance and increase in engine weight per horsepower and engine cost. In addition, the transmission of engine b.hp. through gearing to the propeller shaft involves a slight loss in power, although this does not amount to more than one or two per cent.

Until recently, American practice in the use of reduction gears was to employ a 2:1 reduction ratio. The latest ideas as to the choice of the proper reduction-gear ratio take into account the increase in propeller diameter and propeller weight due to reduction gearing. The disadvantage of increased propeller weight is self-evident. Not only does increase in propeller diameter, while maintaining the same ground (or structure) propeller-tip clearance, require additional weight of structure, but the added length of supporting structure increases the parasite resistance of the aircraft. For these reasons the latest practice in regard to reduction-gear ratios is to choose one which will give a V/ND in excess of 0.007, where V = m.p.h., N = r.p.m., and D = propeller diameter in feet, and a propeller tip speed not greater than 900 ft. per sec. Working to these values will give a propeller efficiency somewhere near the maximum, and yet will insure that propeller diameter and weight are held to a minimum.

The indirect effect of engine design on the effective thrust horsepower of an aircraft power plant is the drag (air resistance) of the engine as installed. The thrust of the propeller overcomes the drag of an aircraft, of which drag that due to the engine is an important component. So if the engine is of such a shape or size that its inherent air resistance is high, the effective thrust is proportionately diminished. One of the drawbacks of the radial engine is its high drag. This can be cut to a minimum by totally enclosing the engine with cowling, but with an increase in weight of structure and an evident sacrifice of visibility (in a single-engine tractor installation).

The two factors—direct and indirect—which influence the effective thrust per horsepower of an aircraft engine are themselves conflicting. An engine which is designed to develop a certain b.hp. at high r.p.m. will be smaller and lighter than a larger-displacement, slower-turning engine of the same horsepower, and its air resistance in flight should be less. The high-speed engine will probably require reduction gearing for the purpose of obtaining reasonable propeller characteristics, and this will add to the power-plant weight and complication, and in air-cooled engines will call for additional care to insure proper cylinder and oil cooling.

The author has devoted a great deal of space to the subject of the effective thrust horsepower of an aircraft engine, for the reason that, though important, it has been very little discussed or considered in engine design. Builders of several well-known engines place emphasis on their small frontal area, but as pointed out above, this is only a part of the subject.

Discussion

Henry L. Brownback.[2] The selection of an airplane engine will naturally vary with the service for which it is being selected. I think that we might divide the different services as military, air-mail and passenger lines, training of pilots, privately owned small planes.

I am somewhat surprised upon returning to this country to see the tremendous stress being placed upon the manufacture of aircraft for established runs, which market must always have a very definite limit as opposed to privately owned planes, the

[2] Brownback Motor Laboratories, Inc., Pottstown, Pa. Assoc. Mem. A.S.M.E.

market for which will eventually be extremely large. In fact, in certain quarters there seems to be an unspoken doubt that this market will materialize for some time to come.

There is no doubt that, with the exhaustion of the large supply of OX engines which permitted small planes to be turned out at normally fictitious values and the subsequent rise in price of small planes, the market will decline sharply until small planes are developed for smaller powers and engines suitable for quantity production are developed and placed on the market. Naturally these new engines will cost more than the OX as they must carry, not only the burden of cost of production, but development, advertising, sales, and general overhead costs, and a fair profit as well.

Engines for military small combat planes are a limited market possibility and a highly specialized product, which will probably be manufactured by a limited range of companies, but the large bomber engines can be made interchangeably, with certain detail differences, with commercial engines.

While this class of engine has weight limitations where long flights are desired, reliability and long life are essential. When one considers that engines in this class consume their weight in fuel and oil in approximately four hours' running, it will be seen that a slight increase in weight to gain other necessary and desirable qualities is not prohibitive.

In these engines, especially those having large cylinder bores, one of the determining factors in selection should be that of absence of localized high temperatures. While the European air lines have been remarkably free from accidents, due no doubt to excellent ground service and very conservative operation by the pilots, the same engines in military service have given a great deal of trouble from crash fires, due to the engines running from autoignition after the spark had been cut in preparation for the crash or even fires due to high volatile coming into contact with highly heated metal surfaces.

Another point to be carefully considered in the operation of aircraft in countries having high normal temperatures is the ability of the engine to operate on a stable fuel which can be transported over the desert and stored in tanks or the fuel wing tanks of the airplane without distilling off the highly volatile fractions, or in case of mechanical mixtures of several fuels, the more volatile constituents, leaving a poor grade of fuel to be fed to an engine which is not suited to operating on this grade of fuel and suffers accordingly.

While most English and American companies have jumped into high-speed engines which certainly give a higher power output per cubic inch, per pound weight, and per dollar cost, the French and the Germans have stuck to the wise course of the low-speed engine.

Lubrication and valve difficulties seem to increase with the square of the speed beyond a certain point, and while this is of secondary importance in a combat machine it is of primary importance in commercial and privately owned planes. I am frankly dubious of speeds in excess of 1700 to 1800 r.p.m. in the present stage of the art.

While both here and abroad there are murmurings about Diesel engines, they have not yet reached the stage of practical opposition. When they do, there will be certain things to be considered, such as the universal distribution of a suitable and uniform grade of fuel, a means of rapidly filtering this fuel, and the perfection of filling apparatus and handling apparatus so that none of it will be spilled upon or reach the plane in liquid form. Gasoline will evaporate if spilled, but fuel oil makes an awful mess.

Something outside of this discussion but interesting is the experience of one of the large European operators over a very long run. His business was falling off due to airsickness which could not be accounted for by rough air. It happened that the chief engineer of this company had a friend in the oil business, and to please this friend he substituted mineral-oil lubrication for castor on several trips. When the monthly survey was made, it was noticed that the airsickness rate for these trips was very low. The company now uses mineral-oil lubrication exclusively.

The cowling of radial engines has killed one of the arguments against this type of engine very effectively. The modern radial engine is a post-war development based upon an analysis of conditions, and to my mind it represents, up to certain sizes, the ideal cylinder arrangement. The vertical engine in small sizes is somewhat analogous to the OX situation as the original small four-in-line engines were designed to use up a vast store of war material and then continued to take advantage of the tremendous sales effort expended to sell the first engines.

In Europe I have laid out several radials and line engines, but all of the factors so favored the latter type that we always finished up by building it. The prospective buyer of the small plane will soon size his purchase largely on a viewpoint of ease of servicing.

As the number of planes increases there will be a corresponding decrease in the quality of available mechanics, and the servicing will be done by men approximating the average garage "grease monkey;" and when that time comes it will be necessary to have engines which can be renewed rather than repaired. If this were not so in the motor-car business, the service problem would be insurmountable.

With the advent of the cabin plane the engine designer is faced with the elimination of mechanical noise. The day is coming very rapidly when the public will not buy an engine which makes a horrible mechanical clatter to be carried by the metal portions of the plane to the cabin and the ears of the passengers; for noise, especially clashing noise, is very tiring.

The same thing holds true of rigid engine mounts, and the study of placing rubber or other shock-absorbing materials in the engine mount is well worth while.

Robert Insley.[3] While no news to those few aircraft designers who have had time and inclination to think beyond pounds and square feet, Commander Shoemaker's aircraft-engine requirement of "maximum thrust per horsepower" should be of considerable value to those aeronautical engineers who evaluate all engines in terms of "pounds per horsepower." Some such concise statement has been sorely needed since this aeronautical pandemonium made it possible for technical schools to make full-fledged chief aeronautical engineers out of high-school students in four years. The number of responsible engineers in the industry who consistently disregard the general purpose of the aircraft power plant and bless or condemn it for single more-or-less important characteristics is appalling.

I should like to believe that in his remarks Commander Shoemaker intended to convey the impression that the intrinsic weight of the power plant per se is becoming less important among the other requirements. Unfortunately each of the requirements of the aircraft engine conflicts with one or more of the others, but the only one which seems to conflict with all of the others is the requirement of minimum weight per horsepower. In the past, when all creditable designs were of military origin, when there was small commercial demand and little competition, cost was all but disregarded. Weight and performance were paramount considerations, with dependability close behind, and economy, durability, accessibility, and low cost desirable but by no means essential characteristics. In commercial operations economy, low cost, and durability assume more important positions. Dependability cannot be sacrificed, and it seems not unlikely that low weight per horsepower will have to yield place that the other

[3] Chief Engineer, Aeronautical Division, Continental Motors Corporation, Detroit, Mich.

characteristic may be improved. Also, as Commander Shoemaker explained, the intelligent application of the maximum-thrust requirement often will result in the selection of other than the engine with the lowest weight-horsepower ratio. For each particular installation the probable operating conditions will determine the relative importance of the various engine requirements, and the increasing variety of commercial applications of aircraft make the engine designer's task more difficult, because each new application arranges the engine requirements in a new order of importance.

Commander Shoemaker's remarks about the Diesel engine are particularly opportune. While the Diesel engine bids fair to play an important part in the development of aviation, there is no advantage in fooling ourselves about its probable blessings.

It seems to me that there is one more aircraft-engine requirement which in the past has been relatively unimportant but will take on rapidly increasing importance as air travel becomes more general, and that is "maximum comfort for passengers." A short flight in almost any of our passenger-carrying airplanes is convincing evidence that to advance passenger transport by air beyond the novelty or emergency stage there is much to be done for the comfort of the passenger, chiefly as regards noise and vibration. In few of our passenger-carrying airplanes is normal conversation possible in flight, and in many the vibration resulting from engine vibration or exhaust or propeller pulsations is distinctly uncomfortable. Engine noise, engine vibration, exhaust pulsations, and propeller noise all can be reduced enormously, but to do so we may have to rearrange some of our other engine requirements.

Author's Closure

Both Mr. Brownback and Mr. Insley have pointed out the advisability of judging engines as regards their freedom from mechanical noise. This subject was not discussed by the writer, due to the fact that the vibration and noise in an airplane arise from so many causes. Vibration may be largely due to the airplane structure. Noise in an airplane may be due to the plane itself, and particularly to the propeller, as well as to the exhaust pulsations and valve tappet and gear clatter of the engine. Propeller noise is a function of propeller-tip speed, which in turn depends on the rotative speed of the propeller. The question of propeller-tip speeds was discussed in the paper, but I might add that the lower the tip speed the less the propeller noise.

Mr. Brownback discusses the various classes of aircraft engines and their relative fuel requirements. He is referred to an article entitled, "The Problem of Engine Fuel Requirements," which appeared in *Aviation* of June 29, 1929, wherein the author set forth his views on that subject.

AER-51-31

Methods Used in Training Pilots for Commercial Flying

Three Papers Discussing Modern Flight-Training Courses and Advanced Methods Used at Flying Schools

The authors of these papers advocate use of more systematic methods for training pilots. Longer courses at flying schools with better and more uniform flight instruction will help materially for schools to discharge their duty to the aeronautical industry and to the flying public.

Greater safety in the operation of aircraft and a reduction of accidents are results that are being sought. More instruction and more varied experience for pilots before they enter the industry will do much to lessen the hazards of flying. Increased stabilization of the industry will come from providing a definite, satisfactory source of pilots and thus assure the public that satisfactory facilities are available for flight training.

Flying Schools and Flight Training

By CLARENCE M. YOUNG,[1] WASHINGTON, D. C.

THE FIRST natural division of flying schools and flight training might well be that of military schools and commercial schools. The efficiency and adequacy of the military school is unquestioned, therefore, the type of work done and the purpose of such flight training can be passed over with only a reference thereto. Before discussing the commercial schools as such, it should be pointed out, that until the last year the majority of the commercial pilots were men who had military training, that is to say, the largest source of trained pilots was from ex-service men who had had training in military schools, either during the war or since. On account of this available supply, the matter of the well organized commercial school and the demand for this phase of work has been slower in making its appearance on a large scale than other phases of commercial aviation. This is no longer true. The demand for pilots now far exceeds this source of supply. It also follows that for this reason, the commercial training which has been done and the commercial flying schools which have been operating have been inadequate both as to the amount and quality of instruction given. In addition, there has been a lack of uniformity in courses of instruction given by civilian schools.

During the first half of 1928, 17.69 per cent of all accidents in commercial aviation have been during the earlier solo stages of student instruction. This figure dropped to 9.65 per cent during the second half of 1928, but this is partially due to the fact, that there was a larger amount of other commercial operations during the second half of 1928 than there was during the first half.

For example, a group of 390 airplane accidents analyzes as follows: 76 involved pilots with less than 50 hours' flying time; 21 involved pilots having between 50 and 100 hours; 17 involved pilots having 100 to 150 hours; 20 involved pilots having between 150 to 200 hours; and 13 involved pilots having 200 to 250 hours' flying time, etc. This indicates, in the absence of adequate instruction, that three times as many accidents occur in the first 50 hours of a pilot's experience than in any other successive 50 hours.

As another example: Although, during the year 1928, 70 per cent of all pilots licensed were transport pilots, less than 20 per cent of accidents and fatalities involved pilots of this grade.

Again, as still another example: Only 9 pilots out of a total of 161 were involved in fatal accidents in 1928, while operating as part of a scheduled airway under an organized operation system. During this period, the scheduled airways did over 20 per cent of the total commercial flying, and approximately one-third of it was done at night. Further, in all the 9 cases referred to, weather was a contributing factor. This shows that properly trained pilots and properly maintained equipment, efficiently organized and operated, decidedly decreases the hazard of aeronautical operation. As a final illustration, the findings of the Aircraft Accident Board show that 12.64 per cent of the accidents in 1928 were due to errors of judgment on the part of the pilots, 29.80 per cent were due to poor technique, and a total of 55.79 per cent were chargeable to some class of pilot's error.

In the face of these figures, it is perfectly evident that anything which can be done to improve flying schools or flight training should correspondingly increase the safety of operation of aircraft and decrease accidents in the aviation industry.

The framers of the Air Commerce Act of 1926 had no more knowledge or idea of the tremendous development that has taken place in commercial aviation in the past two years than any one else. It is, consequently, remarkable that they covered the regulation of the industry as well as they did. The omission concerning the regulation of civilian flying schools has been corrected by the amendment to the Air Commerce Act approved February 28, 1929. This amendment states that the Secretary of Commerce shall, by regulation, provide for the examination and rating of civilian schools giving instruction in flying as to the adequacy of the course of instruction, the suitability and airworthiness of the equipment, and the competency of the instructors. The examinations and ratings thus provided for are made only upon the request of the owners or representatives of the air navigation facilities or schools.

The civilian schools now in operation can hardly be criticized for inadequacy of their courses of instruction. In fact, they are rather to be commended for the progress which they have made in this rapidly developing industry. Part of the inadequacy in flight training was undoubtedly due to the public demand and the popular idea that it was only necessary to get enough dual instruction to be able to solo an airplane in order to become a competent pilot. This is, as we all know, and as the past two years of commercial operation have shown, a distinct fallacy. If definite standards can be agreed upon, established and maintained, the present condition can largely be overcome.

Considerable pressure has been brought to bear upon the Department of Commerce to set up requirements for the regulation

---

[1] Director of Aeronautics, Department of Commerce, Washington, D. C.

Presented at the Third National Aeronautic Meeting, St. Louis, Mo., May 27 to 30, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

of schools even before the amendment to the Air Commerce Act was passed; that is to say, public opinion now makes it imperative that steps be taken in this direction.

The school supplement to the Air Commerce Regulations, setting up these standards, following a conference with school representatives from the industry, has been formulated and is now available. It is expected that these regulations will result in the accomplishment of the following:

1 Better and more uniform flight instruction
2 Greater safety in the operation of aircraft and fewer accidents, due to pilots having had more instruction and a more varied experience before entering the industry
3 Increased stabilization of the industry by providing a definite, satisfactory source of pilots
4 Stabilization of the schools themselves by encouraging them to give a more complete course under the privileges granted to approved schools
5 Assurance to the public of satisfactory approved facilities for obtaining flight training.

A distinct attempt will be made to accomplish these results by means of rating and approval of schools which are qualified to give adequate flight training in accordance with the standards set up in the regulations just referred to.

The regulations prescribe for the rating and approval of schools under three separate headings; that is, (1) suitability of equipment, (2) adequacy of the course of instruction, and (3) competency of the instructors.

Under suitability of equipment, provision is made for a minimum-sized field for safe flying instruction purposes and hangar and shop facilities sufficient to maintain the airplanes in an airworthy condition.

A restriction is stipulated concerning the total number of planes permitted to operate for flying instruction purposes from a given field, that is, 10 planes per 100 acres. The restriction is also made as to the number of students that can be enrolled for each plane available for flying instruction purposes. Further provision of adequate classroom and ground-course facilities is required.

Under the heading of adequacy of the course of instruction, provision is made for time limits of the course which are established in order to assure a regularity of procedure of instruction.

The school is required to maintain individual records of each student, showing the progress through the course. Students' examination grades are to be made a part of this record. Schools are required to submit an outline of all courses to the Department of Commerce for its approval. The school is required to maintain a standard of instruction to assure that 9 out of 10 graduates who apply for license satisfactorily pass the Department's tests. Schools are required to give the students instruction in the recovery from stalls and spins prior to a first solo. The minimum curricula requirements are set up for both the flying courses and the ground courses. Under these minimum curricula requirements, the school is encouraged to give the student advanced instruction and check time by granting the graduates of the school the privilege to credit a portion of their dual and check time toward their solo-flying experience required for Department of Commerce license.

Under competency of instructors, provision is made for the licensing of flying instructors and ground instructors. The ground instructor will be required to pass examinations in the subject matter of the course he proposes to teach. The flying instructor will be examined as to his capability as a flying instructor, both by flight test and by a practical and theoretical examination on the explanation of flight maneuvers. The net result of this school rating should be, that an approved school with competent instructors, with sufficient suitable equipment, and with definite standard curricula, both in flying courses and ground courses, should be capable of graduating a class of pilots with guaranteed ability. This applies particularly to the schools for advanced grades of license.

At present schools will be approved as private-pilots' schools, limited-commercial-pilots' schools, and transport-pilots' schools. Students who desire to enter the aviation industry as a profession or vocation should unquestionably attend a limited-commercial-pilots' school or a transport-pilots' school. This would give them sufficient time for advanced instruction and experience on various types of airplanes as required in these courses, which should certainly qualify them better for their future work than is the case under the present civilian flying school condition.

In conclusion, our present situation might be likened to the fable of Daedalus and Icarus. Icarus, youthful enthusiast, overconfident but without experience, soared his way toward the sun on his almost untried wings, but, on account of his lack of experience, met with grief; whereas Daedalus, the older and more experienced of the two, realized and prepared himself for the emergencies which experience taught him might be encountered. Thus, today, the embryo pilot with few solo hours, unaware of the pitfalls in aviation as our statistics have shown, certainly encounters difficulty; whereas, if his period of training were of longer duration, under more competent instructors, and with a greater variety of experience, he would graduate better equipped to meet the emergency situations which all pilots encounter sooner or later in their experience.

Modern Flight Instruction

By TEX RANKIN,[1] PORTLAND, OREGON

FLIGHT instruction has undergone a number of changes and improvements since 1927. Practically all the better schools in the United States are giving a minimum of twenty-hours' flight instruction, ten of which are dual and ten solo hours. In the opinion of the author, most of these schools will adopt a minimum of fifty hours within the next two years, so regardless of whether a man wishes to fly for pleasure or for profit, he should have the complete flying course as well as a complete ground course.

The average twenty-hour course costs approximately $500 including the ground course, and the average fifty-hour course costs approximately $1200 including the ground course. There is a difference of $700 between the two which can be charged off under the heading of "Life Insurance." For the additional thirty-hours' flying instruction that the student receives for the additional $700, he will be assured of 150 per cent more aeronautical education, than he had at the expiration of twenty hours. Therefore, his chances of having an accident, in which he may damage an airplane or injure himself, have been lessened a great deal.

As far as can be learned by the author at the present time, not a single graduate of the fifty-hour flying course has had an accident, in which the pilot or an airplane has been injured. This is out of a total of thirty-six graduates of the fifty-hour course during the past two years.

It is necessary to give students a certain amount of stunt work, to assist in developing the feel of the ship and to insure confidence in their ability to fly the ship in an ordinary position. The student should be taught, in a practical way, accidental means of getting into spins and how to come out of them and,

[1] President and Chief Instructor, Rankin School of Flying, Portland, Oregon.

of course, how to avoid them. A number of solo students and embryo flyers have been killed by accidental spins, simply because they did not know how to avoid them and how to get the plane out of an accidental spin after they once got into it. The author recently investigated an accident in which a solo student pilot was killed. It is believed from testimony of eye-witnesses, that the pilot attempted to turn, using a 45 deg. bank and when he came back to center with the stick, he failed to center the rudder. This caused the nose to go down sharply, and apparently, an attempt was made to get the nose up by pulling back on the stick rather than by using the top rudder, which put the ship into a spin. Due to the student pilot's lack of knowledge concerning accidental spins, he attempted to hold the stick back, in an effort to get the nose up and consequently spun into the ground.

Learning to fly a ship and land it with a dead engine is another accomplishment that should be taught to students regardless of whether they are taking a twenty-hour course or a two hundred-hour transport course, for they will, undoubtedly, some day have engine trouble if they fly long enough. Dead-motor landings are actually more of a mental hazard than a real hazard. As soon as students become accustomed to flying without hearing the familiar sound of the engine, they will have little difficulty in making successful dead-motor landings. During the first few dead-motor landings that a student makes, the sight of a motionless propeller, in front of him, creates a mental condition in the student's mind that will upset his nervous system and reasoning powers completely and will cause him to make a poor landing or even to crash were an instructor not with him. The author has found it best not to permit students to make dead motor landing solo, until they can land a ship with a dead engine just as well as they can with the engine idling.

Simulated forced landings in strange fields should be featured in every good course and the student should have an opportunity to get close enough to the ground, to know actually whether he would make a good landing or not, before the instructor opens the throttle again. Of course in the case of a good field, it is a good plan to permit the student actually to make landings on that field.

In every good course, students should be given the opportunity of doing a great deal of taxiing around on the field. They should taxi down-wind, up-wind, and side-wind in a strong, brisk breeze as well as being able to taxi in a calm. Taxiing a plane is extremely difficult and it will improve the student's handling of the ship in the air a great deal. Taxiing down-wind is considerably different than taxiing up-wind and should be explained thoroughly to the student. The author has been on large metropolitan airports and has observed many students trying to taxi down-wind in the same manner in which they would taxi up-wind.

In the advanced course, a student should receive considerable cross-country flying, both as pilot and as navigator. He should receive night flying and a few hours of blind flying, in which he must depend entirely upon his instruments. The more blind flying the author does, the more he is convinced that this type of flying should be featured in every good fifty-hour flying course and also, at least a few lessons of it given, even in the twenty-hour course, not in an effort to teach the twenty-hour student in three or four lessons, that he can fly through a fog with instruments, but to convince him in three or four lessons that it is an utter impossibility for him to do so. Blind flying is a very deep subject and is as yet purely experimental. It is entirely different than ordinary flying and the old-time pilot that tries to fly blind by "feel" will find that he will have to learn almost to fly over again in order to fly entirely by instruments. It is necessary to sit in the cockpit, just the same as an engineer sits before his instruments in the hold of a large steamer. He must give no thought to the feel of the ship, but place confidence in the instruments and believe in them entirely. It is the opinion of the author after talking with Martin Jensen, winner of second place in the Dole flight to Hawaii, that the majority of the planes that were lost on the Hawaii flight, were lost because the pilots had more confidence in their "feel" of the ship than they did in their instruments. Mr. Jensen told the author that he went into two spins and barely got out before he struck the water, before he could believe in his instruments. He also stated that he had no further difficulty, after he devoted his attention to the instruments and quit trying to fly by the feel. Therefore, it appears that blind flying is a subject that demands a great deal of serious thought by the flying schools and pilots of the country at the present time.

Up to the present time, practically all of the schools have been using OX-5 motors in commercial planes capable of carrying two passengers and the pilot for instruction purposes. Each school found that the fuselage is entirely too wide to give the student the visibility he should have in taking off and landing. Therefore, it appears that one of the principal needs of flying schools at the present time is a good training plane that is built only for that purpose. Several manufacturers have recently turned their attention to this matter and undoubtedly before another year rolls by, we will see many types of training planes on the market at a reasonable price.

In the interests of safety, some type of collapsible-control stick should be placed in the student's cockpit of each training plane. One of the best developments along this line that the author has had the good fortune to see, is the Davis stick, which was invented by Mr. Davis after his son, an instructor, was killed by a student freezing on the control.

Instruction should be confined to private airports and municipal airports where no transport planes were coming and going, with the possibility of collision in mid-air. The Aeronautical Chamber of Commerce of America has done some very wonderful and constructive work in assisting the Department of Commerce in developing flying school regulations.

Modern Flying School Practices

By OLIVER L. PARKS,[1] ST. LOUIS, MO.

UNDER the old dispensation in flying instruction, there was a certain amount of grimly humorous formality attending the business of sending a student forth on his first solo flight. Old timers liked to picture the first flight alone as an event of great importance, which it was, but also as an event of danger. "You do or you do not," they would tell their students before they sent them off and frequently the latter alternative was accompanied by a significant gesture, expressive of an airplane crash. Frequently, too, the more hardened instructors would send their students off on their first flight with the admonition, "Now go out and kill yourself."

Times have changed since those days, and the first solo flight of the young student is now as safe as the first trip of the novice automobile driver through the city's traffic by himself. It is still an event in the young flier's life but a vast improvement in training methods has shorn it of its danger. The change in the attitude of the instructor toward the first solo flight of the student is indicative of the entirely new condition in the business of teaching young men to fly.

[1] Vice-President and General Manager of Parks Air College, Inc., and Parks Aircraft, Inc., St. Louis, Mo.

Flying instruction has, until the last year or two, been a laggard in the swiftly growing aeronautical industry. The design of airplanes and methods of instruction have improved as aviation grew, but until the need for well-trained pilots became acute, the method of making flyers, particularly in the civilian schools, was a very haphazard, hit-or-miss proposition. The consequence is, that a large proportion of the experienced flyers operating in the United States are graduates of the service flying schools, particularly the army school, which has consistently given a well regimented and thoroughly systematized course of instruction. It is the adoption of this careful system of teaching the young men to fly which distinguishes the forward-looking commercial flying school of today from the school, let us say, of two years ago.

Possibly, the lack of suitable airports and the use of obsolescent military airplanes were partially responsible for the early methods of teaching in civilian flying schools. Then, too, the heritage of recklessness, that was left from the wartime days, may have had something to do with the methods by which young men were fitted for wings. In any event, the method of operation was roughly as follows:

The student arrived at the flying school full of ambition to become a flyer, signed up and was turned over to a pilot for instruction. Perhaps there were three or four pilots. If that was true, there were three or four methods of flying instruction in use. The instructor explained the workings of the controls, took the student aloft and gave a brief lesson. On following days, other lessons were given, until finally the student was able to take off and land the ship with ordinary student facility. If the instructor was extraordinarily careful, he told something about recovering from a spin and showed how to sideslip the ship for landings in tight fields. In most cases, however, the instructor was anxious to solo his student as quickly as possible in as much as he was paid a flat rate per student for instruction so that the student was, probably, sent off on a solo flight with the absolute minimum of instruction. If he succeeded in getting back on the field, all well and good. If he did not, it meant only a loss of a few dollars to the flying school since the ship was an old Jenny or a Standard, at the best, easily repaired, if the damage was slight, and capable of being junked without much loss, if the damage was great.

From that point on flying was largely self taught. Day by day the student took the air for solo flights, learning much by experience but getting into many dangerous positions as he tried out one maneuver after another. Here was one of the great dangers of early commercial flying instruction. The student was led to believe, that he had to learn only by experience and a certain amount of venturesomeness was necessary for the development of a well trained pilot.

Frequently the effort of self instruction paid its dividends in accidents with airplane injuries and fatalities. It was rarely that any student reached one hundred hours of flying under such methods of instruction, without cracking up at least one airplane. That first crash came to be regarded by flyers almost as a matter of course in the education of the student pilot.

At the end of fifty hours' instruction, however, the student found himself fairly well able to handle an airplane but from then on up until four hundred or five hundred hours, he frequently found himself in flying scrapes, from which he did not know how to extricate himself. In such contingencies he took the way out that seemed best from former experience and if it worked, all was well. If it did not he had just another crash.

At the time of entrance in the flying school, the student was told that a certain amount of Ground-School instruction would be given. After a few days at school he found that ground-school classes were occasional affairs. Probably one of the pilots was also ground-school instructor and on rainy days and other times when there was no flying, it was his custom to call the class together in the hangar or storeroom and lecture it on engines, aerodynamics, theory of flight, and other subjects that should go into the make-up of a good pilot. Possibly these lectures were competently given and, certainly, they were interesting to the young student. Their great failure, however, lay in the fact that they were given on no set system and on no established schedule. The consequence was that while some students drew a fairly complete course in ground school instruction, others had only a hodge-podge of aeronautical knowledge and lacked the academic background that every pilot should have.

The old system of commercial flying school instruction was dangerous, wasteful, and inefficient. It was foreordained that it would have to pass away, if instruction was to keep pace with the progress of the other phases of the aeronautical industry. A great change in flying-school instruction began more than a year ago when the more progressive schools perceived the fault in their system, saw how successful the army school was in turning out good pilots, and decided that in the interest of good business, as well as safety, it was necessary to improve methods.

The course in the commercial flying school, with which the author is connected, includes a system for organization routine and instruction so that no matter which pilot instructor takes charge of the student for flight instruction the student learns the same things in the same way. The instructor assigns the student to a definite flying period as, for example, from 9.30 a.m. to 10.00 a.m. daily and immediately the student's name is posted on the flight board under the name of his instructor and under the proper flight period.

On the day of arrival or the following day, he has his first hop. It begins with a lecture by the instructor as he and his student stand beside the ship. The pilot explains the workings of the controls, the use of flying instruments and the general theory of flight of an airplane. Every effort is made to make flying appear to the student as a normal activity for which almost any normal man is fitted.

The first flight is usually brief, not more than fifteen minutes. It is followed by successive flights, which increase in duration to half an hour and later to an hour. In each of them, the pilot is consistently watchful of the instruction of his student, attacking the problem of teaching him, according to the set schedule of instruction upon which the pilots and general manager have agreed as the best form of teaching.

Uniformity of flight instruction is obtained. The instruction plan is sufficiently flexible to allow the pilot to vary his methods somewhat with the needs of individuals. While system is necessary in the teaching of flying as it is in the teaching of any other activity, there is also a frequent need for variation in special cases, just as there is in the teaching of other branches.

Early flight instruction proceeds through straight flying, landings and takeoffs. At this point many of the older schools would set their students to solo, but before classes reach that stage, they are also taught how to recover from tail spins and how to sideslip, so that if they are suddenly confronted with the necessity of either recovering from a spin, or of landing on a small field, they are able to do so with the minimum of danger.

The average flying student solos in from seven to ten hours of instruction. His first solo flight is given quite casually, so that the student will suffer from no unnerving apprehension when he takes off and every effort is made to convince the student he is taking a very ordinary step.

The first flight is to fix in the student's mind the conviction that he can fly an airplane by himself. Immediately after the

solo hop, he is sent back to the dual instruction stage, where he remains for several hours longer while his instructor polishes off the rough features of his flying. This feature of instruction enables checking up of flying faults, which unquestionably would bring students to grief were they allowed to continue in them.

After twenty hours of dual instruction, the student is sent over to the solo stage. Here he flies alone daily but the pilot now in charge of his activities is still watchful for the faults that are bound to crop up in the first fifty hours of flying. The student is checked in his air work every day so that when he completes the fifty hours of instruction included in the primary and advanced flying courses, he has had a total of about twenty-five hours of solo flying and twenty-five hours of dual flying.

During his flight instruction, the student is also going through a course of instruction on the ground. Every day from three to six p.m., Saturdays excepted, he spends in the class rooms which are equipped with lecture chairs, blackboards, maps, globes, and the specific paraphernalia needed for instruction purposes. Every instructor takes his class through the same course of study and except for the phraseology of the instructors the lectures are identical.

The course covers theory of flight, meteorology, aerodynamics, theory of engines, carburetion, ignition, and navigation. The instruction in navigation and meteorology, incidentally, is sufficiently thorough to qualify students for the Transport Pilot written examination in those subjects. The ground school course runs for nine weeks with a written examination every Friday. The last three weeks is spent in the line shop in actual repair work upon the twenty-four airplanes which comprise the instruction fleet. This work is carried on under the careful supervision of licensed-airplane and engine mechanics.

Carefully systematized instruction is also carried out for airplane and engine mechanics. The course runs for seventeen weeks with classes held from 8.30 a.m. until 4.30 p.m. daily. A carefully laid out curriculum is followed. Class-room work and actual practice in the shop are combined. In the school for aerial photography, a course including details of photography, from the operation of the hand camera up to the making of aerial mosaics has been laid out. The course is practically taught and covers far more ground than would be possible under a hit-or-miss schedule taught without careful planning.

Only by systematic methods can any flying school hope to discharge its duty to the aeronautical industry and to the flying public. Undoubtedly, the methods now in use will be modified and improved. The Aeronautical Chamber of Commerce, by prescribing certain restrictions for flying schools, is doing admirable work in that direction.

Discussion

HARVEY H. HOLLAND.[2] These three papers cover very briefly one of the most important phases of aeronautical development. There is no single phase in the development of aeronautics which is more vital to the future of the industry than a high standard in the training of airplane pilots, especially those who propose to qualify as transport pilots.

The future development of the industry will be vitally affected by the standards which are adopted and maintained by the numerous flying schools which are rapidly springing into existence. It is gratifying to observe the trend toward the maintenance of high standards which is emphasized in these three papers.

Mr. Young's paper expresses clearly the necessity for the correct regulation of training schools by the Department of Commerce and the advantages to be derived therefrom. The new regulation requiring stalls and spins before allowing the student to solo is very important, and a few forced landings should also of course be required before the student ventures forth upon his own resources.

The subject of psychology is one of the important considerations in flight instruction that often is neglected and one in which the desired results are difficult to obtain. The proper function of the flying instructor is to lead the student, step by step, into the proper methods which he eventually will adopt involuntarily and habitually at the correct moment.

There has been an effort to standardize methods of instruction in the Army Air Corps by first training the instructor in the proper procedure of handling the student. Instruction in flying can be compared in a limited way to teaching a student to drive an automobile. Personalities often clash, and patience and consideration must be the rule.

It is believed that the tendency will be toward the attainment of higher standards in ground instruction, especially for those students who propose to enter the industry professionally.

AER-51-32

Radial Versus In-Line Engines

By GLENN D. ANGLE,[1] CINCINNATI, OHIO

In this paper the author, after recounting the history of the two types of engine under consideration, sets forth at some length reasons why the in-line type has been revived. Following this he compares the two types as regards such features of primary importance to the airplane manufacturer as weight per horsepower, cost, smoothness of operation, installation, visibility, cooling, and head resistance. He concludes that the radial engine is inherently superior on the basis of weight per horsepower, smoothness of operation, installation, service, and cooling. It also promises to excel in the matter of low manufacturing costs. The upright in-line engine, by virtue of its smaller frontal dimensions, is possibly better for visibility in some installations, although this advantage becomes of little consequence in certain types of airplanes. The inverted in-line type obviously excels in visibility, in almost any installation. The comparative resistance or drag of the radial and the in-line engine, however, is still a matter of opinion.

ENGINE development is of necessity a slow and expensive procedure, consequently engine production has not kept pace with the rapid growth of the aircraft industry. Because of the present increasing demand for airplanes of various types, there is a sellers' market in engines, a situation which may continue for some time. It is true that several new aircraft engines are being placed on the market, but it is hardly to be expected that this will greatly alter the situation for many months at least. Some of these engines are still to be more fully developed before it is really safe and advisable for their manufacturers to go into an extensive production program. There are even instances where the personnel of the organization attempting to market an engine have had little or no previous experience, and are merely copying other engines, including their mistakes. This is certainly an unhealthy condition, and it may reflect most unfavorably upon the industry if it continues. Still, it undoubtedly will continue as long as we have this sellers' market, and aircraft manufacturers will persist in selecting the engine for their ship on the basis of availability more than upon suitability.

Constructive criticism and accurate detailed reports on engine performance are always welcomed by the engine manufacturers who sincerely desire to improve their product. Unfortunately not all airplane manufacturers can spare the time or sufficiently appreciate the variety of problems involved in the development of aircraft engines to realize the importance of rendering this assistance. It is believed, therefore, that a better understanding of the engines available and a closer relationship between the airplane and engine manufacturer will do much to bring about better and safer airplanes upon which the successful growth of this new industry depends.

Discussion of the radial versus the in-line engine, is a subject of vital interest at the present moment, particularly among the aircraft manufacturers who are producing a sport or light commercial and training ship of approximately 100 hp. or less. Both types of engines are now available, and although some airplane manufacturers seem to have developed a marked preference for one or the other, it is apparently based upon some particular feature, and not the result of a thorough comparative study. The author was particularly impressed by this fact during recent discussions of the subject with a number of airplane engineers and manufacturers in the attempt to obtain material for this paper. For instance, among the few who preferred the in-line engine, the small frontal area seemed to be the only feature which could be referred to with any degree of certainty; while a few thought possibly the in-line engine could be produced at a lower cost than the radial, yet there were no cost figures or data of any kind at hand from which to draw such a conclusion. It would seem, therefore, that a comparative study might clarify the situation, or at least encourage investigations on such points as may still be regarded as doubtful.

History of the Two Types of Engine

But before entering into a discussion of the two types of engines under consideration, let us briefly review their history. Both types are older than the airplane itself, and it is rather interesting to study their rise or fall in popularity during the various stages of aircraft development.

The engine responsible for the first successful flight of man was, as we all know, a four-cylinder vertical or in-line type. The Wright Brothers followed a logical course in developing an engine of a type concerning which there was considerable information. Other constructors followed similar lines, taking the automobile engine in principle and general arrangement, and proceeded to refine and change its design in order to meet more fully the special requirements for use in aircraft.

However, most of these early four-in-line types were water-cooled, as the records show among the four-cycle engines a total of 99 different models as against 10 which were air-cooled. Of the two-cycle engines, ten were water-cooled and two were air-cooled. Besides being fewer in the number used, the air-cooled engines were on the whole inferior, mainly because of the lack of knowledge existing at the time relative to air-cooled cylinders.

The four-in-line types gradually gave way to the six-in-line, rotaries, and radials in the matter of popularity. There were several obvious reasons for this, among which perhaps one of the most important was the demand for higher power outputs, which experience had shown were impracticable with this type. There was also a need for engines with a lower weight per horsepower, the four-in-line never having shown to much advantage on this score. Vibration was a source of trouble, and it was desired either to eliminate or reduce it as much as possible. The inertia forces in the four-cylinder in-line engine are inherently unbalanced. Furthermore, attempts to dampen the fluctuations of torque on some of these early engines by the addition of a flywheel only added weight to an already heavy engine, and did not produce the improvement expected. In the early days of flying, then, the four-in-line engine had been found to be inherently heavy and rough, limited to relative low outputs, and was consequently abandoned for aircraft use.

On the other hand, the radial engine has, due more or less to the lack of design precedence, undergone a most arduous course of development. It has evidently survived a disappointing series of experiences only because of the inherent outstanding possibilities which the type possessed. Credit for originating the radial is generally given to Forrest, who built an engine of this type in the year 1888. However, the credit for the first radial aircraft engine goes to the late Charles M. Manly, who built a five-cylinder water-cooled engine for Professor Langley's experi-

---

Presented at the Third National Aeronautic Meeting of the A.S.M.E. St. Louis, Mo., May 27 to 30, 1929.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

mental airplane. This was a most remarkable contribution for the year 1901, and undoubtedly would have received greater acclaim if the Langley experiments had not met with such bitter disappointments.

Little attention was given to the radial engine until Anzani in France began building this type, following the construction of some fan types, one of which was used by Blériot in his flight across the English Channel in July, 1909. Aside from the Salmson engines, practically all of the early radial engines were air-cooled. None of these engines were noted for any degree of reliability, particularly if based on present day standards. Besides failures of valves, pistons, and the like, resulting from lack of air-cooling experience and unsuitable materials, the radial engine had several other common troubles. The crankpin-bearing loads were seldom, if ever, analyzed, and many failures resulted from overloading. Gas distribution was another problem that apparently was never satisfactorily solved. Yet the type offered sufficient advantages to inspire these early engine builders to carry on this development work.

It was during the war, when lighter and more powerful engines were in demand, that the first real scientific work in the development of air-cooled radial engines was undertaken. The British Government conducted a series of interesting investigations, the results of which have been invaluable in the development of the modern radial engine. Contracts were given to certain British firms by the Air Ministry for the construction of engines for military use. Following the war, the United States Army and Navy encouraged similar developments by placing contracts with some of the leading engine manufacturers, as well as conducting research work in their own laboratories. In due fairness, then, the development of the modern air-cooled radial engine must be credited mainly to the military services.

Commercial aviation, if the term may be used, was struggling along the best it could, using war-surplus engines and trusting faithfully in the future. The air-cooled radial developed for military use was still too expensive to be universally adopted, although as the war-surplus stock of engines was becoming gradually depleted, many began looking forward to this type as the logical possibility for commercial airplanes. Public interest in aviation was stimulated suddenly by a succession of long flights, particularly those made across the Atlantic Ocean, and with this came recognition of the fact that the radial air-cooled engine was perhaps the most reliable and best-suited type of power plant for commercial aircraft so far developed.

However, during this period of growing aeronautical interest, radial-type engines of lower horsepower were actually being developed in this country. It was nearly five years ago when the first strictly commercial engine was started, and there have been possibly 15 or 20 others designed since. Practically every one was an air-cooled radial. This indicates one of two things; that the designers were convinced of the advantages of the radial type, or were influenced by the popularity given it by the larger military engines.

Our last reference to the in-line type engines was that, for certain justifiable reasons, it had been abandoned for aircraft use. Why, then, has it been revived? If the facts were not known, one might be led to believe that some one had recently discovered some new and promising feature in this type that heretofore had escaped attention. However, this revival came as a result of rather unusual circumstances, and an attempt will be made to explain briefly from such reports as it has been possible to gather.

Why the In-Line Engine Has Been Revived

Great Britain had many trained flying men at the end of the World War, and was confronted with the problem of keeping these men in training, as well as training new men, in order to maintain a reserve flying force. It is understood that it was impossible to provide airplanes and equipment, as has been done by the U. S. Army Air Corps, so encouragement was given in the form of subsidies to the light-plane clubs. However, these subsidies were apparently contingent upon using equipment furnished by one of the government departments, the engines being built originally from salvaged or excess stocks of parts, and were of the four-in-line types, doubtless from necessity. This was indeed an economical measure, and we therefore cannot judge from the limited information at hand if there were any other reasons for choosing the in-line type of engine.

Recently the author read the following which is typical of some of the arguments for the in-line type of engine: "That insurance rates in England were very materially higher on commercial or flying-club airplanes with radial engines than on similar machines equipped with upright in-line engines, owing to the fact that a landing-gear collapse or mild crash does not result in wiping off cylinders from an upright engine, as it does the lower cylinders in the case of a radial." Such a mild argument might be taken seriously, if one did not understand these forced conditions under which the modern in-line was developed. Far greater damage can be done to the lower crankcase of an in-line engine than to the lower cylinders of a radial in event of a landing-gear collapse or mild crash. To substantiate this opinion, consider the condition of a certain radial engine which crashed into the ground at full throttle from approximately one hundred feet following the failure of the wing. The propeller was wiped off close to the hub, only four or five fins were broken on the two cylinders which had dug deep into the ground, and the crankshaft was sprung less than three thousandths of an inch, otherwise the engine was in perfect condition. Obviously there should be points of comparison between the two types of engines of far greater importance than the effects of a mild crash.

During the forced use of the four-in-line engine in Great Britain, it could reasonably be expected that a number of important or spectacular flights would be made. A list of these flights was given in some of the advertisements appearing in practically every current aeronautical magazine. If one were not familiar with light-plane performances or did not take the time to investigate the records, it would be only natural to assume that all the important flights had been made with the in-line engine. However, this is hardly the case as a more complete list of important light-plane performances will show.

Included in a list of officially recognized records of light planes, which was obtained from the National Aeronautic Association, the ones made by airplanes powered with in-line type engines are:

1 *Class C.* First category, two-seater, altitude record of 19,862 ft. made with D. H. Moth and 85-hp. Gypsy engine.
2 *Class C.* First category, two-seater, speed for 100 kilometers held in Germany by Gypsy 100-hp. engine, 119 m.p.h.
3 *Class C.* Third category, speed for 100 kilometers held in England by D. H. Moth 32, special Gypsy engine, 130 hp., speed 186.47 m.p.h.

Recognized records with radial engines are:

1 *Class C.* First category, two-seater, distance record over closed circuit, Avia using a Walter 60-hp. engine, distance 932 miles.
2 *Class C.* Third category, distance closed circuit, Walter 60-hp. engine, distance 1553 miles.
3 *Class C.* Third category, distance air line, Walter 60-hp. engine, distance 1249 miles.
4 *Class C.* Third category, altitude record 22,250 ft. held by Germany Baumer with Wright 60-hp. engine.

The radial engine, then, holds four officially recognized records, while the in-line engine is credited with three. It is believed that the first two records referred to in connection with the in-line engine have been broken unofficially in this country by

airplanes which use radial engines. At any rate there are airplanes capable of doing so. It is interesting to note that the American manufacturers of light planes have not as yet gone in for breaking records, but the author ventures to predict that during 1929 most of these records will be brought to this country, and the airplanes will probably be powered with radial engines.

Time will not permit listing all of the remarkable flights made with light planes using both in-line and radial engines. The flights of Lady Heath, Lady Bailey, and Bert Hinckler using in-line engines were especially brilliant. Those of Miss Bobbie Trout, Maryse Sebastie, and Mauler and Baud, in which radial engines were used, are equally spectacular. It may be interesting to know that the flight of Mauler and Baud from Paris to Cape Town and return, under the direction of the Paramount Film Co., is the outstanding flight through Africa in a light plane.

Nevertheless, through wide publicity, it has been possible to negotiate American manufacturing rights to help supply this present market; and even some American manufacturers, in their anxiety to get into the engine business, have suddenly taken up the in-line engine. What these engines will show in service is yet to be seen, as to date there are not enough in actual use in this country to form a definite opinion. The average American pilot forms his own opinion of the equipment he uses, and he can probably tell more regarding it a year from today.

The manufacturers of small radial engines have also boosted their products, and, quite frequently perhaps, a trifle more than actual conditions warranted. They seem to have taken for granted, however, that since practically all of the really outstanding flights of recent months have been made with radial air-cooled engines, there is no further need to boost this particular type of engine for the benefit of their present and future customers. But it appears that these manufacturers must continually parade engineering facts and performance figures of the radial engine before a fickle public, if they are going to meet the competition which the in-line propagandists are presenting. To illustrate, the following is quoted from a pamphlet published and distributed by a brokerage house which is offering the public stock in a company manufacturing an in-line engine. "Leading aeronautical engineers have stated that the day of the radial motor has about passed and that the in-line engine is most satisfactory for aviation, and the in-line motor that is at the same time air-cooled is now considered the acme in airplane motive power." This may be an excellent argument to encourage stock sales, but the author doubts very much if any one who could be classed as a leading aeronautical engineer would make such a positive statement, and surely not without including a few words of explanation.

The question of the suitability of either the radial or the in-line air-cooled engine for the lighter types of aircraft, can be determined only by investigations conducted along sound engineering lines. The opinion of one or more can have no great bearing on this question, because if personal opinions could settle the issue now, the radial engine would undoubtedly poll the larger vote, receptive subjects to in-line-engine propaganda notwithstanding. Neither will airplane-performance figures give us a solution, unless tests are conducted under comparable conditions. The advocates of both types of engines may justly point with pride to a number of noteworthy performances, but facts devoid of sales arguments are needed before a decision can be rendered.

Comparison of Various Important Features of the Two Engine Types

Let us now compare the two types of engines as regards features of primary importance to the airplane manufacturer. These features are weight per horsepower, cost, smoothness of operation, installation, service, visibility, cooling, and head resistance, all of which will be treated in the order named.

Weight per Horsepower. One needs only to study casually the radial and in-line engine to form an opinion of how the two compare for weight. It is quite unlikely that, for a given output and with similar standards of construction, a four-in-line engine could ever be built for the same or less weight than a corresponding radial engine of five or seven cylinders. In fact, the lightest in-line engines today generally show higher weight-per-horsepower values than the heaviest radials in their class.

The actual weights of existing engines of both types will not be included, but it may be of interest to mention that in-line engines of four cylinders are 20 per cent or more heavier than corresponding radials, and this in spite of no small advantage which the in-line engine possesses in the reduced weight of its cylinders. The weight of the bare engines is interesting, of course, from a design standpoint, but the weight completely installed is the figure of most importance. The author has been unable to obtain any accurate figures on the differences in weight between two such installations, but it is perfectly obvious that no reduction of any consequence could be expected, and it is more than likely that the long engine bearers, cowling, and extra air scoops would add more weight than the usual radial engine installation.

Cost. The loss determinate of all features under consideration is the question of cost. Naturally manufacturing cost figures of the various engines are not obtainable, and the present list or selling price is no criterion. Moreover, if actual cost figures were available, we should still be unable to draw a conclusion, unless the design, type of construction, and quality of workmanship and materials employed were much alike. The matter mainly resolves itself into the question of which type of engine can be purchased by the airplane manufacturer at the lowest price, assuming, of course, everything else to be equal. There will be no attempt here to prove that which it is only possible to determine through time and manufacturing experience, but in passing it may be well to refer briefly to a few of the more obvious features affecting the cost of production.

For a given type of cylinder construction, the four-in-line engine holds a distinct advantage, in that it has one or three less cylinders than the average radial of approximately the same horsepower. On the other hand, the crankshaft, crankcase, and associated parts are of larger dimensions, and it is naturally to be expected that both the material and machining costs will be higher. There are also several bearings for the crankshaft and camshaft in the in-line type that are not required in the radial engine. The assembly cost of any engine depends largely upon the design and type of construction, but experience so far indicates that a simple radial engine should require less time to assemble than an equally simplified four-in-line type.

A point has been raised that, since the in-line aircraft engine so closely resembles the automobile engine, high-speed-production machine-tool equipment can be employed. This is with particular reference to the crankcase, crankshaft, camshaft, and associated parts, which is undoubtedly a real factor to consider. It is believed that the use of this equipment should effect some saving in jigs and fixtures, as compared to those designed to fit standard machines, but the actual machining time would be nearly the same. Practically all standard machines are employed at present in the production of radial-engine parts, and it is not easy to predict how much saving would be possible on a large-production basis with machine-tool equipment especially designed for the purpose.

Smoothness of Operation. Nothing is so annoying to the senses of the airplane pilot or passenger as a rough engine. Any

engine which is not functioning properly, or has been fitted with an unbalanced or out-of-pitch propeller, can develop a considerable degree of vibration. These remarks, therefore, will be mostly confined to the inherent sources of vibration in the two types of engines under consideration during normal operating conditions.

The four-cylinder in-line engine, as previously stated, is not balanced for inertia. These unbalanced forces vary directly as the weight of the reciprocating parts and as the square of the engine speed. Modern engines employ higher speeds than the early four-in-line engines, which were considered so rough, therefore the fact must be recognized that the reduction in weight of the reciprocating parts in the modern four-in-line type has been of real consequence. This is the result of using aluminum-alloy pistons and forged duralumin connecting rods. Nevertheless the four-in-line engine will always be subject to some vibration from unbalanced inertia forces, regardless of any degree of refinement.

On the other hand, the single-crank radial engine of five or more cylinders can be quite nicely balanced, since the resultant of the primary inertia forces and the centrifugal force of the rotating masses are directed along the throw of the crankshaft. No regard need be taken of the secondary inertia forces except to avoid rough periods at idling, cruising, or full-throttle speeds. This can be accomplished for any given type of mounting by a slight variation in the size of the crankshaft counterweights. For all practical considerations, then, the radial engine is in nearly perfect inertia balance.

The radial engine of five or seven cylinders has some margin of advantage over the four-in-line engine in the matter of evenness of torque, due to the added cylinders. Also the radial engines to which we are referring should not become nearly so rough as the four-in-line engine in the event that one cylinder fails to fire or function properly. Crankshaft torsional deflections are of no consequence whatsoever in the short, rigid shaft of the single-row radial, while the vibrations from this source may become both noticeable and destructive in the four-in-line engine unless the crankshaft is especially rigid.

All radial engines cannot be less prone to vibrate than the four-in-line just because the type is inherently in better balance. Full advantage must be taken of the characteristics which the type offers, and when this is actually done the radial will unquestionably operate with less roughness than a four-in-line. We must not judge a type by one or more good or bad representatives.

Opinions as regards the smoothness of some of the modern four-in-line engines have been obtained from a number of pilots who have flown them. Naturally these opinions varied considerably, and several reported that the engines were not so rough as they expected them to be. This leads to the conclusion that all four-in-line engines are not objectionably rough, yet in no instance did any one venture the opinion that these engines were endowed with any inherent characteristics which would distinguish them for smoother operation than that of the radial engine.

Installation. There is really no feature quite so appealing to the average airplane designer as a simple engine installation. The author has actually encountered instances where the possibilities of a simple installation practically overshadowed all other features of the engine.

It appears that, in this particular feature, the radial engine holds the advantage by a considerable margin. In fact, simple installation has always been referred to as one of the outstanding features of the radial type, and comparisons, whenever drawn, have been with reference to the style of mounting required for the in-line type of engine.

Usually, with the modern welded steel-tubing construction, it is required only to provide forward extensions welded to and supporting a ring of the proper diameter. This ring has welded to it clips or brackets to receive studs in the engine crankcase. Aside from connecting engine controls and fuel and oil lines, it is only necessary to attach a few nuts, and the radial engine is installed. The ordinary cowling can be simple and of light weight, besides requiring only a few minutes for attachment.

The in-line engine, on the other hand, requires members extending the length of the crankcase, to form what is usually referred to as the engine bed. These members obviously need considerable bracing, because of the distance which they extend forward of the fuselage. The cowling required to enclose the engine is greater by far than the amount required for the radial engine, and seldom can the controls and other connections be arranged in such a simple manner. Briefly, there is hardly a single phase of installation in which the in-line can be shown to excel.

Service. Comparisons between the radial and in-line types of engine as to their possibilities for maintenance and service will be confined to the more obvious points of difference between the two. Naturally the more detailed questions of service depend upon the individual design and the type of construction employed.

With overhead valves operated through rocker arms and push rods common to both types of engine, there is really not much difference in the problem of service on cylinders. This is practically true of all units which can be readily removed and repaired without disturbing other parts of the engine. But in drawing comparisons with reference to the crankshaft and connecting rods there is a rather marked difference.

The radial engine, which uses articulated-type connecting rods, has but one crankpin bearing, while the in-line type under consideration has four. Burned-out crankpin bearings are not a common source of trouble in either type, yet the possibilities are four to one, and this is also the probable average ratio of the amount of work to be done on these bearings at the regular overhaul periods.

Ball or roller bearings are usually mounted on the main journals of a radial-engine crankshaft, and besides requiring no special fitting, are in only rare instances known to fail. Should replacement be necessary, it can be accomplished with both accuracy and speed. The four-in-line-engine crankshaft is usually carried in five plain bearings, with a ball bearing to carry the propeller thrust. If the ball bearing is arranged to carry radial loads as well, it is extremely difficult to maintain alignment with the plain bearings whenever take-up on account of wear in the latter bearings is found to be necessary. There are five possible sources of a burned-out main bearing in case of a failure in the lubricating system, none of which exist in the average radial engine. When a bearing burns out or must be replaced on account of wear, it is often necessary to fit all new bearings and line-ream them in place, in order to obtain a first-class job. Neither can one fail to take into account, with these long oil passages, the greater possibility of a clogged line, which invariably results in a bearing failure.

There are no apparent differences between the radial and the in-line engine when considered in connection with top overhauling and making routine adjustments, but if the trouble to be corrected is of a more serious nature, the radial-type engine will generally show to advantage. Very few major replacements can be made on an in-line engine unless it is taken into a repair shop, while some radial engines can be almost completely overhauled without being entirely removed from the airplane. This is a point worth considering, especially in a case where the airplane might possibly be grounded at a point some distance from a repair station.

No doubt dozens of points in contrast of lesser importance could be cited, but this really does not seem necessary, since the advantages of the radial engine from a service viewpoint are quite apparent.

Visibility. The general form of the in-line engine is conducive to excellent visibility, but in the particular power class which we have under consideration, the gain in this feature is possibly not as great as one might at first imagine. The upright in-line engine leaves an area for unobstructed vision forward, on either side of the cylinders, which is partly or wholly blocked when using a radial engine. The amount of obstructed vision, and the nature of its effects, depends upon the overall diameter of the radial engine and the seating arrangement in the airplane.

It is perfectly obvious that the diameter of any radial engine should be as small as possible in order to permit good forward visibility, and also to reduce head resistance to a minimum. Apparently some designers have not given this matter the attention it deserves, and consequently their engines do not compare favorably with the in-line type. But when the outside diameter of the radial engine of approximately 100 hp. or less does not greatly exceed 35 in., there are never any complaints about obstructed vision upon the part of those who use them. It is therefore rather doubtful if any great benefit would be derived by a slight increase in forward vision, which can be assumed for the moment would be gained by the use of an in-line engine.

The seating arrangement, however, must be taken into account. The pilot's seat, in airplanes using the in-line engine, is usually farther to the rear than in similar airplanes equipped with a radial engine. This is to balance a heavier engine whose center of gravity is located at a greater distance forward from the rear of the engine. In this position the pilot undoubtedly needs all the forward vision which the in-line engine affords, and therefore the ultimate gain in visibility resulting from reduced frontal area is questionable as compared to installations of the radial engines of small diameter.

The four-in-line engine, when mounted in an inverted position, really offers better visibility than either the upright four-in-line or radial engines, and moreover gives a higher line of thrust. In the author's opinion, this is the only arrangement which permits four-cylinder in-line engines to enjoy fully the few advantages which they possess. But up to this time the development has been slow, due to problems of inlet manifold design and distribution. One firm in Europe has spent over a year on these problems, and, according to latest reports, has not yet reached a solution. The author cannot, for obvious reasons, venture an opinion regarding the engineering phase of this situation.

The inverted four-in-line engine, when more fully developed, may be preferred to one designed for use in an upright position for reasons just given, but it otherwise offers no further advantages as compared to the radial type of corresponding output.

Cooling. It would be necessary to treat extensively several phases of air cooling in order to compare fully the cooling advantages of the several radial and in-line types of engine. Time will only permit mentioning some of the important contrasting features.

The radial cylinder arrangement is practically ideal from a cooling standpoint, in that an equal amount of air is directed against each cylinder. This also holds true with almost any type of symmetrical cowling that may be employed. When using well-designed cylinders it is unnecessary to provide baffles and deflectors to force the air in directions contrary to its general line of flow. Briefly, then, all cylinders of the engine share about alike in the cooling blast available under any set of conditions.

The air blast for cooling the in-line type of engine must be deflected at nearly right angles to the direction of flight. This requires a more or less complicated system of air scoops, baffles, and deflectors if anything like equal distribution of cooling air is to be made available for the cylinders. The correct size and shape of these parts making up the cooling system can only be approached after considerable experimentation. Another problem entering into the design is the arrangement of inlet manifold and exhaust pipes, so as not to interfere seriously with the free flow of cooling air around and between the cylinders. In a completed installation the in-line air-cooled engine is obviously made quite inaccessible.

The question which perhaps is of most interest is the comparative effectiveness of the two cooling systems. No accurate test results have been made available from which conclusions can be drawn. It would seem that the advocates of the in-line type of air-cooled engine would do well to present some data on the subject for the benefit of those who seriously doubt the effectiveness of their cooling system. The author has been unable to find any information which would lead to the belief that the cooling of the in-line type would in any way be comparable to that of the radial engine, and this appears to be the consensus of opinion among those who have really given the matter serious thought. It seems to be generally accepted, that the cylinders of an in-line engine do not operate at uniform temperatures. Perhaps this can be overcome by the proper use of deflectors, and if so, something should be done about it right away, and the proof of the accomplishment properly presented in order to relieve existing doubts. There are numerous reports of stuck pistons due to overheating, and one cannot deduce from such reports that the cooling is either uniform or adequate. The author has been reliably informed that last year at the Concours des Avions Legers in France, the only two airplanes powered with in-line engines to finish had cylinders and pistons changed almost every night during the tour, and this despite the fact that the engines were lubricated by a blended castor oil. For the heavy stunt work of this meet, some of these ships were powered with an air-cooled radial engine, and also the radial engines in the tour finished without repairs.

With the exception of a few spectacular flights of which we read and hear so much, the greater part of the flying with the in-line engine has been done about airdromes in England. In this country greater distances are flown, and it will be rather interesting to follow the success of the in-line-engine cooling system under more grueling conditions.

For the present, at least, it must be concluded that the radial engine, with its cylinders uniformly exposed to the cooling air, maintains a distinct cooling advantage over the four-in-line engine employing air scoops and deflectors of uncertain effectiveness.

Head Resistance. The small frontal area of the in-line engine appears to be its one outstanding feature, and we are naturally quite interested to know how much this actually reduces the head resistance. However, not too much importance should be attached to this phase of the comparison of radial and in-line engines, because speed in light planes is really secondary to other features, such as proper cooling and reliability.

The radial engine apparently offers considerable head resistance, the amount of which depends, of course, upon the speed of the airplane, the size and shape of the engine, and the manner in which it is cowled. It is believed that too frequently comparisons are carelessly drawn between the radial and the in-line engine on the basis of frontal area alone. If this in itself were a determining factor, how then could it be possible to develop our fastest military pursuit ship around a large radial engine? It is not intended to hold any brief here for the extremely large radial engine, but only a few of these installations need be con-

sidered to realize that comparisons cannot be correctly drawn on engine size alone.

Two radial engines of different design, but having approximately the same frontal dimensions, might reduce to quite different equivalent flat-plate areas. Therefore, how can one safely judge the resistance characteristics of an in-line engine by merely drawing comparisons with other engines on the basis of frontal dimensions? The drag or resistance can be measured only by placing full-scale models in the wind tunnel, and the author's opinion is that we may all be surprised when we learn how much resistance is developed by the air scoops and deflectors in turning the cooling air at approximately right angles to its normal direction of flow. It is sincerely hoped that the National Advisory Committee for Aeronautics, or some similar institution, will soon undertake an investigation of this kind. Whatever advantage in reduced drag that the in-line engine may enjoy by virtue of its small frontal area can be attained only with a narrow fuselage and a tandem seating arrangement. Even then it is not always possible to provide the best streamline forms. Many are of the opinion that side-by-side is the best arrangement for a two-seater airplane, both for instruction and private flying. If installed in an airplane of the latter type, the in-line engine must sacrifice any advantage that may be due to small frontal area, because a better streamline form can be developed about a larger nose.

Although reliable conclusions cannot be drawn at this time regarding the effects of small frontal area, its importance can be greatly overrated. One may assume for the moment that the in-line engine holds a fair margin of advantage in reduced drag over the usual radial-engine installation, in which the greater part of the cylinders are exposed to the slipstream. However, when these cylinders are enclosed by a cowling of the correct streamline form, it is necessary to regard comparisons in quite a different light.

Investigations conducted by the National Advisory Committee for Aeronautics disclosed some remarkable reductions in drag with an annular streamline form of cowling which completely surrounded the radial engine. This is generally referred to as the N.A.C.A. type of cowling, and several manufacturers have already adopted it with much success. The reports of these investigations have been carefully studied by the majority of aircraft engineers, and there is no need to even review the data.

Some engineers are rather reluctant to admit the advantages of the N.A.C.A. cowling, claiming instead that actual results fall short of the wind-tunnel investigations, and the engines are not properly cooled. If the cowling was improperly designed it could readily hinder the cooling efficiency of the engine. Moreover, the reduction in drag might fall short of the laboratory results if the installation was not correctly made.

Actual results in flight, however, have pretty well proved the advantages of the N.A.C.A. type of cowling applied to radial air-cooled engines. The maximum sea-level speed of the Curtiss AT-5-A airplane, powered by a Wright "Whirlwind" J-5 engine, was increased from 118 m.p.h. with the original cowling to 137 m.p.h. with complete N.A.C.A. cowling, a gain of 19 m.p.h. or 16 per cent. The Lockheed "Air Express," powered with a Pratt and Whitney "Wasp" engine, had its speed increased from 159 to 175 m.p.h. by the application of the N.A.C.A. cowling. This increase was accomplished with the same propeller and propeller setting, an increase of 75 r.p.m. of the engine being noted, and the cooling of the engine was reported satisfactory.

Such improvements in performance should remove doubts as to the effectiveness of the N.A.C.A. type of cowling. Moreover, it leaves us with still greater doubt in our minds as to the actual reduction in drag resulting from the smaller frontal area of the in-line type engine. The gain in speed by the use of the N.A.C.A. type of cowling is largely the result of reduced drag on the fuselage. While impinging along the airplane fuselage, this disturbed air flow caused by exposed cylinders apparently sets up considerable resistance, and therefore it is wondered if the cooling air leaving the in-line-engine cowling is not causing an even greater degree of drag. Wind-tunnel tests on full-scale models should tell the real facts.

Conclusions

The comparisons of the radial and in-line engine, which have just been made, are neither complete in themselves nor do they represent all the points upon which the two may be compared. An attempt has been made to treat the most important engineering features of the two types as completely as the limited time and data available would permit. As stated in the beginning, it is not expected that many of these questions will be brought to convincing conclusions, but it is sincerely hoped that they will at least encourage an analytical trend of thought on the subject. One hears so many amusing discussions pro and con these days, that it seems doubly important to confine investigations to the more fundamental characteristics.

It is desired to bring attention to the fact that these comparisons have been drawn on the basis of types without reference to any particular engine of either group. Moreover one should not, in all due fairness, compare a good radial with a poor in-line engine, nor a good in-line engine with a poor radial. With a view into the future we are perhaps more interested in the inherent possibilities of each type than we are in existing engines. We are now at a critical stage in aircraft development when problems of this nature should be given more than passing consideration.

From the views expressed, it appears that the radial engine is inherently superior on the basis of weight per horsepower, smoothness of operation, installation, service, and cooling. It also promises to excel in the matter of low manufacturing costs. The upright in-line engine, by virtue of its smaller frontal dimensions, is possibly better for visibility in some installations, although this advantage becomes of little consequence in certain types of airplanes. The inverted in-line type obviously excels in visibility in almost any installation. The comparative resistance or drag of the radial and the in-line engine is still a matter of opinion, and it is hoped that some investigations will be undertaken soon to settle the variety of ideas which now exist.

Discussion

H. L. Brownback.[2] This paper is particularly timely as aviation has reached a critical stage. A few years ago the industry was starved for money, with none in sight. Now companies are formed and merged, and their stocks played with for months, making and losing fortunes before they are even organized to produce. With these conditions prevailing, much of the advertising and quasi-scientific magazine articles originate in the advertising agencies of stock-selling concerns and in company sales organizations, rather than in the better-qualified technical departments. When the writer first entered aviation in 1912, the same malady in a milder form was epidemic, but the money was lacking to complete the "Florida boom" of today.

As the author points out, there is a sellers' market. Everybody who believes himself capable of producing an airplane and

[2] V. P. and Gen. Mgr., Brownback Motor Lab. Inc., Norristown, Pa. Assoc-Mem. A.S.M.E.

getting backing is "going to it" and crying for engines, and in less numbers the same thing is happening in the engine industry. There is one case in which a carpenter who turned garage man in the boom days of the motor car, is now selling himself at so much per share as a second Ford. In building his engine he has had no drawings. He simply took the pattern of a crankcase of some one else's motor, explained a few changes, then showed his mechanics some one else's cam crankshaft and connecting-rod layout, and ordered them to make something like that to fit the case as shown on the patternmaker's layout board which he kept as a drawing. Money was found for a beautiful little plant which is now going into production. This is only one case which has come to the writer's attention; perhaps there are many.

In considering radial versus in-line engines, if the discussion is to be confined largely to small engines, the desirability of either type will depend largely upon the points desired in the airplane.

In carrying mails, in contests, and in emergency flight, speed is of prime importance. In carrying passengers it has great importance, but in ordinary pleasure flying and aerial touring it is decidedly secondary to cost, ease of maintenance and repair, ease of inspection, ease of replacement, and comfort.

In very small airplanes, say, of the two- and three-passenger type which will use from 60 to 150 hp., at least two of the passengers will want to sit side by side and be protected, even though this be done at the cost of some visibility. This year, next year, and maybe for a few years to come, people in decreasing numbers will be willing to sit, swathed like mummies, far apart in the blast of air, noise, gas, and smoke in order to get air transport, but as time goes on and air travel becomes an ordinary means of transport, comfort and companionship in flight will supersede speed as the primary factor in determining the purchase of aircraft.

No one today will build a motor car having the comforts of the average present-day tandem airplane, and try to sell it to the public in competition with the small runabout or coupe; and one can well imagine the situation the average husband or beau would find himself in if he were to drive up to the house of the feminine half of the combination and say, "Here it is, let's ride in it."

These side-by-side protected airplanes are going to be more stub-nosed than the tandem plane, and with their general adoption the major talking point for the in-line engine will be blasted when it is compared with the radial type. Thirteen years with all kinds of engines, here and in France, has taught a lot of lessons, not the least of which is the realization that the pilot, when he crosses wide stretches of water, forests, deserts, mountains, etc., is staking his life on his confidence in the ability and integrity of the engineers who have designed his engine and the manufacturers who have built it, and it is up to us to keep faith.

At present the writer is interested in a radial project and an in-line project, so these remarks are in a way unprejudiced. About six months ago the design of a 55-hp. engine was started and the matter was approached in an open frame of mind. Two engines were laid out, one in-line and one radial, and they were analyzed. Today the designs for the radial are being finished. Why?

Any structure has a foundation, and upon the integrity of the foundation the life of the whole structure rests. The foundation of a gasoline engine with separate cylinders is the crankcase. The radial permits a short cylindrical or hemispherical crankcase enormously strong, with bearings accurately aligned, all parts flanged together, which is suspended in its mount in such a manner that distortion of the mount will not affect it, and can be made very light. The in-line engine on the other hand must have numerous crankshaft bearings accurately aligned and maintained in line by the crankcase structure. The case is generally long and mounted on a frail structure which it must help support rather than be supported by it. That means weight.

If the whole structure be gone through—the size and weight of the crankshaft of the in-line vs. the radial engine, the camshaft and its bearings vs. the floating cam ring of the radial, etc.—it will be found that were the in-line motor to be built with the same factors of safety as the radial, with the same compression ratio, and turned at the same r.p.m., it would be very considerably heavier. A glance by any experienced engineer at two of the three in-line engines offered generally on the American market, will instantly show the comparative flimsiness of the cam followers, rocker mounts, etc., of the two light ones, and the high total weight of the heaviest, as compared to the radial.

Furthermore it is the writer's belief that the high r.p m , that is to say, more than 1900–1950 with small engines and 1750 with medium-sized engines, are undesirable in private-ownership aviation, and the high rated speeds of the in-line engine in order to cut pounds per hp. are very apparent.

One feature criticized in the radial engine has been the connecting-rod structure. There are several solutions to the problem. One is use of the slipper-type rod which, if properly designed, gives good results up to five cylinders per crankpin, and the other is a mathematical solution of the articulated rod worked out and patented some years ago by A. Anzani, the father of the modern radial engine, with whom the writer was closely associated for some years. Mr. Anzani's scheme gives the same stroke on all rods. He also worked out a very ingenious rod for the big two-row 20-cylinder water-cooled radial which developed 840 hp. at 1400 r.p.m., and would develop more than 1000 hp. at 1600 r.p.m., which had large bearing surface on the knuckle pins, and yet was light and compact.

As to head resistance, the radial has more frontal area, but what is the resistance of the air conduits necessary to keep No. 3 cylinder cool on an in-line job, when climbing at full throttle, and what is the extra installation cost, the liability to damage of all of the sheet-metal work when the engine is being serviced, and the additional weight? An installation drawing of a well-known English in-line engine calls for cowling having $^{3}/_{8}$-in. passages between long sheets of sheet metal, which makes the engine appear somewhat burglar proof, and does not look as though it would remain efficient if handled roughly. Another thing: "It takes a pound to fly a pound," so every pound of unnecessary weight added means very approximately an additional pound of airplane structure, and as every 20 lb. means 1 wide-open or 1.2 cruising hp., it doesn't take much time to consume more hp. than a little additional head resistance will consume. Furthermore, because of its ease of installation and reliability, even in typical hay-wire installations, the radial has suffered a handicap until lately by just being hung on the nose of the fuselage, often totally uncovered. Judicious cowling will give good head resistance and temperature characteristics, while if one desires the last ounce of speed, the engine can be totally cowled and be no harder to get at than the in-line, but easier if a swing mount is used, and will have better temperature characteristics and little or no more penetration resistance.

One large maker of in-line engines modestly advertises that his engine powers the majority of light planes and made the light airplane possible, and produces an imposing performance record. That is sheer advertising "bunk." In the first place, several other countries, especially the United States and France, produce large numbers of planes of under 100 hp. Today most of the world's planes of under 100 hp. are powered by war-surplus OX-5 engines, and most of those powered by new-production motors carry radials. Last year France and Germany turned out immense numbers of low-power radial and low-

power air-cooled in-line engines, while in the United States the Department of Commerce bulletin of May 24, 1929, gives the 1928 production as: Engines under 150 hp., new-production radial 621; and all other types, 11.

As for records, a rival of the company mentioned and of the same nationality states in an advertisement: "The house of XYZ holds six of the seven international records now standing to the credit of . . . . . (Country) . . . . . of which three were gained by the XYZ, the only . . . . (Nationality) . . . . . light aero engine to hold world's records." All of the other world's light records are held by radials, one being endurance of 24 hours 37 minutes with but 40 hp., and as for the rest they simply enumerate remarkable flights. This would be impracticable with the radial as the compilation would fill a volume.

In the foregoing it is not the intention to be critical, but simply to impress upon the aeronautical world that its judgment should not be swayed by present-day high-pressure advertising.

The design and perfection of a really good in-line engine is a real job. Last year the company which made the first really good air-cooled eight-cylinder V-type engine started one, and with 18 years of experience in aero engines of 70 to 850 hp. back of it, the company has not yet marketed its engine.

In America some severe conditions are imposed on engines such as sleet, sandstorms, etc., all of which make at least a partial protection of the valve-operating mechanism desirable. This is comparatively simple in the radial engine but apparently difficult in the in-line type. The only 100-hp. in-line engine to pass the Department of Commerce tests, an American engine, was provided with a Mercedes-type overhead camshaft, and also has a unique gas-distribution control which governs the quality of the mixture by the angle which the manifold branch pipes present to the gas flow, giving a comparatively rich mixture to the cylinders, which normally run hot.

Another point which seems to have received more consideration in radial than in-line engines is lubrication. In this country we must use mineral oils and slow circulation, and wet-sump storage found in most in-line motors is not conducive to low oil temperature and consequent life, while the high-speed circulation and separate tank storage incident to most radial designs is ideal for oil cooling and long life.

As to cost, the radial engine properly designed is no doubt cheaper than the in-line engine of equal quality, and its installation and the structure necessary thereto are undoubtedly cheaper. Airplanes having radial engines will be cheaper than those carrying in-line engines, quality, profit, sales costs, etc. being equal in all cases.

For top overhauls the cost should be about the same in both types, but for complete overhauls the writer thinks the difference in man-hours will be in favor of the radial by at least 50 per cent, provided equal skill is used in the design of both engines.

The question of vibration is most important as an airplane structure is light, and in case of the popular welded steel-tubing fuselages, vibration coming from the motor can be most destructive. The ability to balance the vibration and fairly accurately to place the vibration periods through counterbalancing in a radial is very valuable. In both types more thought should be given to rubber vibration insulators in the mounts.

One thing in favor of the in-line engine, as far as sales resistance goes, is public familiarity with the type. The public, accustomed to seeing vertical steam engines and vertical gasoline engines, both marine and motor-car, understands the type and therefore feels at home with it. On the one hand, it does not understand the radial engine's multiple connecting-rod and valve-operating layout, and not understanding it, has a vague sense of resentment. On the other hand, mechanics who are accustomed to both types prefer to work on radials because of their simplicity.

There are two types of engines which should have a place in our minds. One is the two-row radial which, while it sacrifices some of the simplicity of the single-row and its cheapness of manufacture, has good points in the smallness of its cylinders for the same power, visibility and ease of cowling because of its small diameter, and its even torque due to its 6, 10, or 14 cylinders, and the other is the six-cylinder in-line engine which will undoubtedly come into a certain vogue with the perfection of Prestone cooling and the solution of the temperature difficulties now encountered. In large installations radial types, both air- and water-cooled, are on the gain.

In Europe where the Air Union has always used nine-cylinder water-cooled radials, the British 12-cylinder V- and W-type water-cooled, and the Germans six-cylinder vertical and 12-cylinder V engines, now at Le Bourget one sees nine-cylinder radials on the French and most German planes, and 14-cylinder radials on the British.

Owing to its structural advantages the writer looks forward to the increased use of large multi-row radials, using liquid cooling where 800 or more horsepower is desired. Both the radial and the in-line engines have their advantages and disadvantages, but as skill in designing eliminates some of the non-inherent faults of the present radials, he expects to see them gain ground in future installations, both high- and low-powered, even faster than they have in the past.

E. E. Wilson.[3] As the author points out, an analysis of this problem must necessarily be qualitative because of the present lack of reliable quantitative information. The author analyzes the two types of engines in a way that deserves the careful study of designers.

Our modern radials owe their superiority to fundamental advantages: (*a*) the single-row radial form, and (*b*) the direct or air-cooling principle. Considered from the points of view of light weight, low cost, easy maintenance, dependability, durability, and fuel economy, the advantages of these two features are outstanding. The in-line engines suffer by comparison.

As is pointed out in this paper, the in-line engine's only advantage lies in its improved forward vision. Even this advantage is greatly reduced in low-powered airplanes. The in-line engine's real advantage from this point of view is only attained when the engine is inverted. Designers will have to choose between the inverted in-line and the radial, and will have to weigh the advantages of improved forward vision against the disadvantages of increased weight, increased cost, and increased difficulty of maintenance.

The radials can be improved greatly through reducing their overall diameter and cleaning them up generally. This not only reduces drag but interference with forward vision. Experience to date indicates that the drag incident to cooling an engine is about the same in any good installation. A certain amount of heat must be dissipated in this way, and other things being equal, the cost in drag is about the same. It is clear that the in-line engine offers no advantage from the point of view of drag.

In general the radials have superiority from all points of view. Time will demonstrate to commercial operators what has already been demonstrated in naval aviation, namely, that the single-row radial is fundamentally superior.

Development of the Commercial Airplane

An Outline of Some of the Factors That Have Contributed to Present-Day Success in Aviation With a Discussion of Single- and Multi-Engine Airplanes

BY G. M. BELLANCA,[1] NEW CASTLE, DEL.

AVIATION has recently made great advances in the eyes of the world, but while most of the spectacular accomplishments have come as surprises, they have really represented the culmination of the studies and experiments of the last ten years. Lindbergh, Chamberlin, Byrd, Brock, and many others contributed in the most popular and appealing manner to the development of this new science, but the steady work of constructors and designers must not be forgotten.

Progress in aviation has not always been steady and continuous but has deviated from time to time from a constant course.

The successes of the Wrights inspired the works of Voisin, Curtiss, and Farman; and through their influence the biplane had the official sanction of the aeronautic experts of the world. Subsequently, however, the Blériot monoplane made its entry into the field, followed by the Antoinette, and later by the Nieuport monoplane, and the early prominence of the biplane was threatened. After the crossing of the English Channel by Blériot, public opinion favored the monoplane. From that time on, we see the development of the airplane depending upon accidental or fortuitous successes instead of moving surely and steadily along in accordance with aeronautical laws.

In the books of five years ago, one finds a marked preference for the biplane. Today, in most publications, preference is shown for the monoplane. Typical is the instance of a certain author who, in rewriting and amplifying his book published four years before, changed his views in favor of the popular one.

The same uncertainty characterizes opinions pertaining to airplane power plants. Should they be single or multiple units? Opinion varies widely.

The feeling prevails that the multiple-engine plane offers a greater margin of safety than the single-engine plane. However, it is a fact that in most of the present designs the horsepower required for normal speed and load is about 60 per cent of the maximum available. Therefore, the advertised advantages of the multi-engined plane are limited, especially when we consider the fact that a single-engine plane is more efficient and offers fewer possibilities for engine troubles.

A similar situation prevailed for some time with the cooling system for airplane engines, and when the experts met during the war to give a more reliable engine to the airplanes of the allies, the water cooling system was preferred. This was in spite of the fact that most of the prizes in air contests staged in the first period of aviation were won by airplanes with air-cooled engines. Even now, after the impressive demonstration of reliability and economy given by the small air-cooled engines, the majority of European countries are using the water cooling system in their planes.

To add to this uncertainty and confusion of opinion there was also the practice, in aeronautical contests, of offering awards for superiority in spectacular attainments such as speed, climbing ability, and skill in landing, all of which diverted attention to the size and power of the engine with little or no regard to efficiency. It is worth while to remember that the limitations on the power plant which were laid on Germany by the Allies concentrated researches and experiments on the problems of airfoils and resistance and stimulated noteworthy advances in aviation.

These and other factors have led to uncertainty in the structural work and in aerodynamic design, diverting progress from a standard path, and creating types which are appealing to the eye rather than types which are based on the fundamentals of scientific design.

INFLUENCE OF MILITARY DESIGNS ON COMMERCIAL PLANES

Commercial aviation has been decidedly influenced in the last five years by military aviation. Whatever year book we open, either here or abroad, we see reproduced in commercial designs all the characteristics in structure, proportions, aerodynamic

---

[1] President and Chief Engineer, Bellanca Aircraft Corp.

Presented by the Aeronautic Division at the Annual Meeting, New York, N. Y., Dec. 3 to 7, 1928, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

qualities, and power plant of military planes. England, one of the first countries that undertook commercial aviation, is slowly shaking off this influence. More slowly the other European countries are moving in the new direction. In America, a few years ago, we could not distinguish a commercial plane from a military airplane.

The development of the real commercial cabin airplane finally came as the result of the Philadelphia Air Meet held in 1926 in which a commercial airplane was considered the sensation of the contest. After the Philadelphia event, the commercial airplane began to be considered as a separate and distinctive design with functions no less important than those of the military plane.

The vogue at that time in commercial aviation was the same as that prevalent in military aviation—streamlining, with reduction of the section of the body to the lowest limit. Other conditions such as airfoils, outside bracing, controls, etc., remained unaltered. So also the disposition of the wing truss, the universal use of certain airfoils, the methods of attaching the wings, the type of the landing gear, and the distribution of load were not changed, while every deficiency in performance was remedied by increasing the power of the engine.

At this time the airplane as a new means of rapid transportation was moving along the lines first followed by the automobile in which the "sport" requirements were first considered and only later reliability and comfort. The commercial airplane, however, was designed with the idea of being economical and practical; hence maximum efficiency and comfort were desired.

THE "COLUMBIA" IN THE AIR ON ITS WAY TO GERMANY. ON THIS FLIGHT CHAMBERLIN AND LEVINE BROKE THE WORLD'S DISTANCE RECORD. IN THIS SAME PLANE, A FEW WEEKS BEFORE, CHAMBERLIN AND ACOSTA SET A WORLD'S ENDURANCE RECORD

Previous to the Philadelphia contest the cabin airplane for commercial purposes had made its appearance in 1922 in the Monmouth Air Races; but not withstanding the enthusiasm raised in aeronautical circles and in the press, the design did not have imitators.

The pay load of this airplane was 7.5 lb. per hp. whereas the pay load of the best and most representative foreign machines was at the most about 3½ lb. per hp. Here in America, the Air Mail D.H., rebuilt by the Government, had attained a pay load of only 1½ lb. per hp.

Up to that time the prevailing design had been that of the open cockpit or cabin with the least cross-section. But while the designer was sacrificing every personal comfort in the fuselage many parts were left exposed, reducing the performance considerably.

In commercial aviation, the airplane was designed to incorporate the latest results of researches and experiments. A machine was produced with all the space necessary for the comfort of the passengers; a machine in which practically all the essential elements of comfort were considered as well as lifting power and stability; a machine with a much greater safety factor and with faster flying speed and lower landing speed than machines built along military lines.

A NEW ELEMENT IN CONSTRUCTION

Some time ago, aerodynamic design was considered merely a mathematical exercise. Today, all factors, whether analytical or

based on laboratory expriments, have the main object of putting aviation at the service of the new industries. So rapid has been the study in this direction that we are wondering what new marvelous results are coming in the near future.

Today, in addition to efficiency, comfort is being considered, and with comfort, safety. Safety, to a certain extent, is a psychological phenomenon depending on the pilot's ability in maneuvering. The more at ease the pilot is, the better he controls his plane. Yet the pilot is only one factor, the others lying within the ship. When the ship is unstable and goes into a spin or stalls, the blame falls on the designer, not on the pilot. There is a case of a historical accomplishment attained with an unstable airplane, and there are also cases of good airplanes gone to destruction in the hands of poor pilots.

Single- Vs. Multi-Engine Planes

As previously mentioned, the multi-engine airplane is sometimes preferred, on the grounds of safety, to the single-motor one although the problem does not yet seem to be solved.

The problem of more engines has been considered since the beginning of aviation. Many experiments have been made but as the ships involved required the power of all the engines at the same time, the arrangement resulted in a great disadvantage, because the greater the number of engines, the greater were the possibilities of trouble and consequently forced landings. The multi-engine planes of today are much better, but other improvements in efficiency are necessary before they will be real successes.

To be effective, a multi-engine airplane should be able to fly on 50 per cent of its total power and carry all the load under normal weather conditions. In other words, a ship with two engines should be able to take off and cover its entire range of accomplishment with only one engine. There is, I believe, no airplane at present that meets this requirement.

These considerations bring us to the conclusion that the present uproar in favor of the multi-engine ship does not find justification in the facts. While there are advantages of safety for the multi-engined planes over the single-engined planes, the single-engined plane has its definite advantages in its own field.

Nor did the successful flights accomplished by the *America* and *Southern Cross* change the situation. These accomplishments prove the reliability of the single-engine plane for certain kinds of flights. The fact that three engines did not fail determined without a shade of doubt that the chances of trouble with one engine alone would have been proportionately less.

In one way only could the multi-motored airplane have proved superior and that is by making a long flight in spite of failure of one of the engines. But there is not a single case to support this. The only instance approaching this is that of Mrs. Grayson in the first-attempted flight of the ill-fated *Dawn*. A few hundred miles after the start, trouble developed in a cylinder of one of the twin engines, cutting down the engine speed to about 1500 r.p.m., partially reducing the total power. This was enough to compel the pilot to throw overboard part of the gas, to send out SOS signals, and to hasten back to the base. This isolated case, offered by one of the best multi-engine ships, shows we cannot derive a definite conclusion as to the present multi-engine airplane for oceanic flights.

The single engine has a creditable place in aviation and will keep it. Even after we shall have succeeded in designing a good and modern multi-motor airplane, the single engine will continue to be used in commercial airplanes of medium size.

The Latest Bellanca, the "Roma," a Sesquiplane Powered With a Pratt & Whitney 500-Hp. Hornet Engine. This Plane Took Off With a Gross Weight of 12,500 Lb.

American Supremacy in Commercial Aviation

In commercial aviation, America holds, and for a long time has held, one of the leading positions.

In a report made several years ago by the Joint Committee of the United States Department of Commerce and the American Engineering Council, the following conclusion was reached from a study of the economic characteristics of the commercial plane: namely, that "considering the pay-load capacity and the speed, American designs are ahead of foreign ones."

"As for example, while in America an airplane having a single 200-hp. air-cooled engine attains a maximum speed of 125 miles per hour, a cruising range of 400 miles at 100 miles per hour, and a pay load of 800 lb. or 4 lb. per hp., a German plane with water-cooled engines of the same horsepower and pay load attains a maximum speed of only about 100 miles." It was this economic characteristic that made possible the endurance record of April, 1927, and also the famous Atlantic flights.

Information Available to Designers

After these successes, aviation found itself advancing at a steady pace toward the conquest of the future. Today there is a veritable mine of information available to every designer of

airplanes. There is no problem which has been left untouched.

Even for the beginner, it is no longer a secret that complete success in aviation is a matter of compromise. The designer must balance conflicting factors in order to attain the complete unit that meets certain demands either in speed or in efficiency, maneuverability, or convenience.

The young engineer, depending largely on calculations, makes assumptions of matters of which he lacks exact knowledge. After the first disillusionment which costs him so dearly, he is forced to advance carefully, to be conservative, not to take chances, and not to leave the path marked by hundreds of others.

The Situation Today

Surveying the aeronautical situation today, we find many striking developments in the most important factors with no less important developments expected in the near future.

While the designer is remodeling his airplane in the light of the latest researches and experiments, the laboratory worker goes on incessantly, tackling new problems, pressing eagerly upward and onward, opening new fields of experiments, trying to follow the most intricate pathways, and contributing in every efficient manner to the advancement of science.

In this complicated work we have not lost sight of the main purpose; to develop an airplane which is aerodynamically safe for transportation and navigation; to develop an airplane which can be flown by the average man in almost any kind of weather. In consequence of this impulse, studies have been started all over the world. They cover the most varied fields.

From these studies, great advances have been made in air-cooled engines cutting down the weight, improving performance and reliability, and effecting great reduction in resistance and cost of maintenance.

In America we are following with great interest the experiments of the Wright Company on radial engines and on 12-cylinder air-cooled V-type engine of approximately 600 hp. Other interesting experiments are being made by the Curtiss Company with the "Hex" radial air-cooled engine of 600 hp. having two banks of cylinders; by the Allison Engineering Co. with the inverted air-cooled Liberty engine; and by the Packard Co., with radial and V-type engines as well as its Diesel engine.

The necessity of increased efficiency in flying at all altitudes has concentrated much effort on the supercharger, with the result that it has passed from the experimental stage to practical use.

Research on greater reliability has brought to experimental work the slotted wings of Handley Page and the slotted rear flaps of Göttingen; but while we are taking advantage of this undeniable improvement, we cannot say yet that the solution of the problem lies along these lines. Many structural difficulties are in the way of the arrangement.

Success has been achieved in fuel-injection engines to such an extent that we can already see what a great part it will play in the future airplane for the economical maintenance and in the elimination of inflammable and dangerous materials.

Another promising field of research is that of the variable-pitch air screw, the tests of which in the last two years have given wonderful results. During the tests conducted a few months ago by the Royal Canadian Air Forces, the blades maintained perfect track and no trace of failure or strain was found in the anchorage.

Because of the steady progress of the last two years, we are now engaged in a revision and refinement of theories. Excellent airplanes are in the air already and other better airplanes are coming. The year 1929 will see commercial aviation growing tremendously in every part of the world.

While making this progress, we should be careful not to be side-tracked from the main issue, a good reliable airplane structurally and aerodynamically sound. Every mechanical device should lead to greater efficiency and safety, for it must be remembered that no new ingenious device changes a poor airplane into a good one. It should be borne in mind that commercial aviation is for public service and ought to be safe. Cruising speed and landing speed should be determined by the general purpose of the design and not by the necessity of competition.

There are other questions which need answers; for instance, the magnitude and distribution of the forces acting on the ship; the mutual interference between propellers and the other parts of the ship; the effect of mutual interference between wings, fuselage, and landing gear. The designer, trying and experimenting, attacks these problems. To help him there are studies and experiments pertaining to every field; supercharging, metal construction, welding, strengthening of plates and tubes, fittings, woods and glues, metals and alloys, pressure distribution, wing and tail ribs, covering and dopes, propellers, oil sprays for fuel injection, engines, resistance and cooling power of the radiators, and ground effect.

From these united efforts, there is no doubt that many promising and permanent successes will result. One thing must be remembered; we must continue in the future to apply scientific knowledge and common sense to the problems of aeronautical design.

[The discussion of this paper was conducted jointly with that of the next paper by T. P. Wright and follows it.]

AER-51-33b

Relation Between Commercial Airplane Design and Commercial Uses of Airplanes

By T. P. WRIGHT,[1] GARDEN CITY, L. I., NEW YORK

The paper presents some of the problems of the airplane designers, together with an indication of a trend in airplane design which it is felt possibly may take place. The following topics are discussed: fundamental requirements, design elements, commercial uses of airplanes, and airplane designs.

Under the last item, an attempt is made to analyze the points discussed in the preceding ones, with a view to suggesting certain design arrangements which seem most logically to fulfil the requirements which the airplane so designed must meet.

I—FUNDAMENTAL REQUIREMENTS

A—Singleness of Function in Airplane Design

ONE FUNDAMENTAL consideration with which every airplane designer soon comes in contact is the importance of designing for a single purpose. During the development of a new design one is constantly faced with the necessity for compromise. It sometimes seems that there exists no element of design which does not conflict directly with every other element. Conflicts, requiring compromises, exist between such important elements as weight saving and structural strength; between weight saving and low production cost; high performance and commodious fuselage size; high cruising speed and low landing speed; high power loading and low operating expense; and many others. The difficulties of airplane design are further increased because of the necessity for dealing with many different branches of engineering, including mechanical, structural, aerodynamical, metallurgical, and naval architectural. It is because of these inherent compromises, difficulties, and complications that I feel the designer will do well in order to assure reasonable success in advance of construction to design with singleness of function in view. There must be only one major specific use for the airplane designed.

Up to the present time there have been comparatively few users of airplanes. It has been, therefore, almost a necessity that types produced be capable of performing several functions, in order that the market might be sufficiently broadened to result in enough sales of a given type to allow anything like production. This has not been conducive to rapid advance in the art, and it is felt that the anticipated increase in production possibilities, brought about both thorough introduction of new fields of activity for airplanes as well as demand within each field, will eliminate the necessity for designing multi-purpose planes, thereby permitting the design of single-function planes of far greater efficiency than were possible in the past. As has frequently been stated, it has been extremely difficult to convince the traveling public of the benefits to be derived from air transport, when the airplanes in which demonstrations had to be made were rebuilt, war-surplus, military ships. The same general condition exists in trying to adapt successfully a mail plane to a passenger carrier; a taxi-service ship to a transport; a night-flying transport to a day-flying transport; or even in adapting a ship which operates regularly from low-altitude fields to a ship for identical purpose but which operates from high-altitude fields. It should be noted that in other forms of transportation, wherein the basic problems are less difficult of solution, there is strict adherence to this principle of singleness of function in design. We have freight, coach, Pullman, parlor, dining, and express cars; passenger, freight, switching, and mountain locomotives; pleasure cars, delivery cars, and trucks, and, if you please, race horses, riding horses, truck horses, and plow horses. Now, therefore, that the field of aviation is enlarging and airplane uses are becoming more definite, it is particularly desirable to study carefully the probable trend of development in types of planes.

I believe we may anticipate a greater diversity of types of airplanes than exist in the older fields of transportation, because of the encroachment of aviation into all of these older fields. It is not to be expected that airplanes will supplant steamships, railroads, or automobiles; they will rather supplement and to some extent encroach on the fields of all three. The extent of and varying conditions found within the United States make this country particularly suited to the development of divergent types of airplanes. It is also likely that, once started, the achievement of airmindedness among our people will be rapid. This desired condition will be accelerated by designers if future airplanes are developed with singleness of function as a fundamental requirement.

B—Safety and Reliability in Aviation

The second and perhaps most important fundamental which must obtain in the design of all airplanes is safety and reliability. I feel that safety is in fact all-important. Designs which in any way lack this quality cannot be ultimately successful. It is, to me, the most important design requirement from the standpoint of usefulness in our crusade to make the public airminded. In order that airplanes may obtain a position comparable with that held by other carriers of men and goods, an equal degree of safety and reliability must be present.

As safety, by definition, is freedom from danger, some of the types of danger that at present exist in aviation should be outlined. Causes of accidents which may result either in loss of life or in schedule interruptions may be divided into two classes: (1) accidents brought about by causes not directly attributable to design deficiencies, and (2) accidents brought about by causes directly controllable in design.

(1) Accidents Brought About by Causes Not Directly Attributable to Design Deficiencies

In the first classification of accidents, those not attributable to design deficiencies are those due to errors in judgment of the pilot and those due to weather conditions.

Errors in Judgment of Pilot. Although at present some 50 per cent of accidents are marked against this cause, it is felt that better training schools will be developed rapidly and that in addition airplanes will become easier to fly and more foolproof, so that the percentage will decrease and in relatively short time reach an amount entirely comparable with that which exists in other forms of transportation. With proper training and equipment, there is no reason for expecting the personal equation to become a greater consideration in aviation than elsewhere.

Weather Conditions. Severe storms and fog are admittedly difficult conditions with which to cope. They cannot be con-

---

[1] Chief Engineer, Airplane Division, Curtiss Aeroplane & Motor Co., Inc.

Presented by the Aeronautic Division at the Annual Meeting, New York, N. Y., Dec. 3 to 7, 1928, of The American Society of Mechanical Engineers.

trolled, but to a great extent they can be predicted. Their seriousness can be decreased greatly by the establishment of more and better meteorological stations and by the equipping of all our transport planes with reliable radios. Accompanying ground-control stations must be established. A solution of the problem of ice formation must and undoubtedly will be found. Also there must be further improvements in navigational instruments and equipment in order that the only hazard of fog flying may be one of gas supply. Improvements in airplane control and stability will also lessen the hazards of bad weather. It may be confidently expected that all these improvements will be developed so that here again present dangers which may exist will be to a great extent eliminated. In comparison with other means of transportation, I believe weather conditions will always be somewhat more of a source of danger in aviation, but I also believe that the percentage of accidents brought about by this cause will be small, approaching that which exists in rail travel and equaling that which exists in boat transportation.

(2) Accidents Brought About by Causes Directly Controllable in Design

Accidents brought about by causes directly controllable in design include structural failures, aerodynamic deficiencies, power-plant failures, and miscellaneous causes.

Structural Failures. The small number of accidents credited to this cause furnishes a record of which we may justly feel proud. An analysis of accident reports shows that only 8 per cent of all airplane accidents are caused by structural failure. Present-day stress analyses are accurately prepared, are based on sound assumptions, and make use of refinements unequaled in other fields of engineering. Further improvements may be expected, however, so that the occurrence of structural failures in the future will be so rare as to make them almost negligible.

Aerodynamic Deficiencies. There is a great need for improvement in this field. It is only comparatively recently that there has become general a realization of the importance of designing airplanes which are stable and easily controllable in all respects. Also a knowledge of the means of accomplishing this end has only just been made generally available. I believe the improvements to be expected in this direction are greater than in most others, but that ultimately the piloting of an airplane will be only slightly more difficult than with other means of transportation.

Miscellaneous Causes. There are a number of miscellaneous causes of accidents, such as fires, improper and insufficient airdromes, poor cabin arrangements, poor pilot's cockpit arrangement, and others, which are all appreciated by designers and engineers. The solution of the problems involved are not insurmountable and will, I feel, be overcome rapidly. The landing-field problem particularly is of the utmost importance. Its solution, however, will be almost automatic once the demand for air transportation is built up to such an extent that all communities are forced to provide such facilities if they hope to enjoy the benefits which an airminded people will have learned are attainable. In 1850 and 1860 the town which snubbed the railroad soon found itself overshadowed by its small neighbor who possessed greater vision.

Power-Plant Failure. I believe we can take an optimistic view in connection with the probable solution of all of the causes of accidents previously described, whether due to natural conditions not directly controllable in design, or to design deficiencies which are subject to improvement—at least to the extent of rendering such occurrences sufficiently infrequent as to make them of no greater importance in the public mind than comparable causes in other modes of transportation. There are still some people who do not ride in subways or cross the ocean because of the dangers involved! The effect is negligible, however, and I feel confident that a similar state of affairs will ultimately exist for air transportation. But with power-plant failures a somewhat different condition holds. Although we may expect to witness the development of airplane power plants of equal or even greater reliability than obtain for automobiles, it is nevertheless true that when failure does occur, the results, in the case of single-engine planes, are far more disastrous. It is difficult to convince the ordinary man that he should regularly use airplanes as a means of transporting himself, his family, or his goods, when he has in mind the possibly disastrous results which engine failure may bring about. And remember, he has had first-hand experience in the behavior of engines in his automobiles. The study of this particular problem has convinced me that the only possible solution is the use of multi-engined airplanes, so designed as to be capable of flying horizontally with one or more disabled power-plant units.

I am of the opinion that the fundamental requirement of safety and reliability will make the very general adoption of multi-engined designs in most fields of air transportation imperative. In another part of this paper the limitations involved in the above statement are discussed, and, in more detail, the most likely power-plant arrangements. The present discussion serves to emphasize that safety is a fundamental requirement in the design of every airplane. Every one actively engaged in aviation should constantly bear this in mind, as it is absolutely necessary to demonstrate that air transportation is safe before the country will attain complete airmindedness and regularly use airplanes to the extent which we feel is merited.

C—Economy of Air Transportation

Any commercial enterprise in this country must pay its own way. As applied to aviation, Wm. B. Stout says, "A commercial airplane is one than can support itself financially in the air." The whole political and economic growth of this country is closely related to the development of means of transportation. Air transportation is the latest development, and in order to carry on and parallel the good work of its predecessors, it must be placed on a sound economic basis. Fortunately we do not have the handicap of Government subsidies, either in the construction or operation of airplanes, which are present in most European countries. On this account our advance has been somewhat slower, but will be sounder economically and much more rapid hereafter.

In order that any transportation line may be successful, it must maintain its schedules. This means reliability. However, reliability of schedules alone is not sufficient. Speed also is necessary. It is the objective of air transportation to provide for greater speed with accompanying safety and reliability. The importance of safety and reliability has already been emphasized. It is now necessary to consider the fundamental necessity in air transportation for speed at reasonable cost. The elements, therefore, that must enter into the figure of merit for airplane designs are speed, pay load, and safety as the directly desirable attributes, with power and operational costs as the quantities which must be kept at a minimum. To attain speed the designer must produce a job which is both light and "clean," a term used in aviation to represent aerodynamic refinement. To make possible the transportation of a high pay load, the design must be light and must use efficient airfoil sections. To be safe, the plane must possess adequate load factor, a reasonably low landing speed, adequate navigational equipment, stability and controllability, and, in most cases, multiple power units. In order that such an airplane may be susceptible of economic operation, it must have the least possible power in its engines, must have efficient engines, and a construction which permits low maintenance costs. It is essential that each of these considerations be

analyzed in laying out each new design. Their relative importance will differ for each design depending upon its use or function. In order to arrive at a design which is economically practicable, it is necessary to study carefully the exact nature of its flying duties in conjunction with its design elements.

By paying strict attention to the fundamental requirements above discussed, I feel confident that designs of airplanes will be developed which will be of such excellence as to make certain the rapid adoption of the airplane as a vehicle of transportation equal in importance to the other means now established.

II—DESIGN ELEMENTS

Certain elements of design which the engineer must consider are discussed in the following paragraphs. The relative importance of each element will differ for each airplane used.

A—Load to Be Carried

In addition to its own weight, an airplane must carry the following items of useful load:

(1) *Crew*, consisting always of the pilot, and in addition, in some cases, assistant pilot, radio operator, mechanics, attendants. There is always the possibility of duplicating the duties of the personnel.

(2) *Fuel and Oil.* Considerations of range of operations with cognizance taken as to wind conditions prevalent for the particular route used, govern the decision on fuel supply.

(3) *Equipment.* Under this heading come such items as radio, lavatories, instruments, seats, and cabin appointments and sleeping accommodations.

(4) *Pay Load.* This item includes people, baggage, mail, express, or any other load for which payment is asked for transportation service rendered.

B—Performance Desired

The following are the main characteristics which come under the head of performance:

(1) *Cruising Speed.* This is the most economical speed of an airplane at which the miles traveled per gallon of fuel is greatest. It is the speed at which an airplane engaged in air transportation normally travels. It is usually about eight-tenths of the high speed.

(2) *Landing Speed.* This is the speed at which the plane will land. In order to avoid accidents when landing, it is essential that this characteristic be as low as possible. The landing speed is usually slightly less than the stalling speed or lowest speed at which the airplane can maintain horizontal flight.

(3) *Rate of Climb.* It is essential that a high rate of climb be characteristic of commercial airplanes as it represents a measure of the airplane's ability when taking off to clear obstacles which may bound the airdrome.

(4) *Service Ceiling.* This characteristic must be high in the case of airplanes which regularly operate in mountainous country or from high-altitude fields. It must also be high in the case of planes which are to be used for certain kinds of photographic and spotting work.

(5) *Range.* This characteristic represents the distance that the airplane can fly without replenishing its fuel supply. It is usually given either in hours or in miles at cruising speed.

C—Power Plant Available

The next element which must be completely determined by the designer is the power plant. A great many considerations must be studied in connection with this element, the chief of which are discussed in the following paragraphs.

(1) Power to Be Used

The total power on which the design is to be based must be selected with care. Very frequently designers are too optimistic as to their ability to construct to a low weight figure, and as a result find that when completed the only salvation for their plane is to add power to make up for such deficiency. The result can never be so economical a design as would have resulted had the other characteristics originally laid out materialized as planned. It must be remembered that in deriving the figure of merit the necessity for high power immediately tends to limit the plane as an economical paying transportation unit. The point is emphasized, as it has been so frequently forgotten.

(2) Number of Power Units

Decision as to the number of units into which the total power selected is to be divided is a question receiving much attention at the present time. As previously stated, multi-engine arrangements are essential in many types of airplanes. I believe that eventually the majority of air-transportation functions will be performed by this type of airplane. Assuming that a given type is to have more than one power unit, the next question is, how many? In a succeeding discussion, an answer to this question for each type of use described will be attempted. It is merely proposed here to state some mathematical facts which should aid in making a decision.

Assume that for any one power unit of the general type selected for adoption there is an average chance of completing 97 out of each 100 trips of a given scheduled run without failure. This means the chance of failure is 3 out of 100. (This can be expressed more conveniently as 9700 and 300, respectively, out of 10,000.) In Table 1 the chance of success and failure for airplanes equipped with multiple power units will be found, each unit having the same reliability as assumed above, and on the assumption that the airplane can maintain horizontal flight with one (or in one case, two) disabled power units.

TABLE 1

Number of power units	Least number of units with which horizontal flight can be maintained	Chances in 10,000—of success	of failure
1	1	9700	300
2	1	9991	9
3	2	9974	26
4	3	9948	52
4	2	9999	1

The figures of Table 1 are derived from well-known and reliable mathematical formulas dealing with probability and chance. A study of the failure column reveals at once the vast superiority of the multi-engined plane from the standpoint of reliability. A fact of great interest, perhaps not so well known, is the higher reliability of the two-engined plane that will fly with one engine when compared with the three-engine plane that will fly with two engines. It is important to keep this fact in mind when considering the power-plant arrangement in new designs for which multiple units are to be used. Attention is also drawn to the almost perfect reliability of the four-engined plane capable of flying on any two units.

(3) Type of Engine

Under this heading must be analyzed several considerations of almost as controversial a nature as that last described. These considerations are as follows:

(*a*) Air-Cooled Versus Water-Cooled Engines

The advantages of the air-cooled engine, as I see them, are the following:

Lower weight for a complete power unit

Better accessibility for maintenance, with particular reference to the radial type

Elimination of one potent source of trouble which may cause failure, namely, water system, including radiator and piping

Susceptibility to supercharging by increasing gear ratio of rotary induction system.

On the other hand, there are several important advantages of the water-cooled engine, which may be stated briefly as follows:

Lower head resistance, giving possibility of higher overall speed of the airplane in which it is installed

Greater reliability from the standpoint of the existence of a greater field of past experience and precedent on which to base design

More ready adaptation of mufflers and arrangements for diminishing noise

Possession of basic arrangement which allows for less vibration

Greater susceptibility to use of reduction gears.

In the above comparison, reference in the case of the air-cooled engine is particularly to the radial type. Other arrangements may be developed (and in fact some are now being used experimentally, such as the in-line "V" air-cooled, and the "Hex" type) which may eliminate the superiority of the water-cooled engine with particular respect to head resistance, noise, and vibration. Also as air-cooled engines are further developed and flown, the item "experience," now credited as a water-cooled-engine asset, will diminish in importance. It is also probable that eventually suitable gearing for air-cooled engines will be developed. It is not likely, however, that for some time to come any one air-cooled engine will be constructed which will possess all these possible improvements.

On the other hand, the importance of weight saving can not be overestimated, and in this respect it is believed that the air-cooled engine will always be superior. All things considered, it is my opinion that the air-cooled engine will predominate in aviation, never, however, entirely superceding the water-cooled engine for use in certain types of planes. Basically, the airplane, which requires relatively rapid forward motion for sustentation, is ideally suited for a motor cooled by the medium through which it is traveling. I believe it to be fundamentally sound to expect that eventually the airplane will be powered by air-cooled motors, just as marine craft use gasoline engines which are water cooled. For the present, however, and for some time to come, the designer must give careful consideration to the problem of motor selection from the standpoint of cooling medium, as there are many real advantages for each type, which may definitely indicate the use of one or the other depending on design function.

(*b*) Gearing

There is a very marked increase in overall propulsive efficiency by the use of a large-diameter propeller, as efficiency in general increases with decrease in propeller revolutions. By the use of reduction gears, it is possible to use such a large-diameter propeller, at the same time permitting high motor speed and attendant motor efficiency. The improvement in airplane performance is particularly noticeable in such characteristics as climb and take-off, which are often the most important qualities in a given design. Speed is also improved, as is also the ability of plane to fly on fewer power units than the total number supplied. The disadvantage of gearing is the increased weight, both of gears and propeller, and the imposition of an additional mechanical arrangement susceptible of failure or maintenance trouble. I believe that the use of reduction gears will become more general, particularly in larger types of airplanes.

(*c*) Supercharging

It is quite surprising to me that supercharging has not been more generally used in aviation engines than has been the case. When analysis is made of the marked improvement in all performance characteristics, even at altitudes of from 7000 to 12,000 ft., by the use of superchargers, it is difficult to account for the slow progress of design which has obtained in this line of development. I feel confident that some degree of supercharging will not only be general, but almost universal in the aviation engines of the not distant future.

(4) Type of Propellers

(*a*) Propeller Material

The very general adoption of duralumin for use in propellers, together with the numerous advantages inherent in its use, seem to point to the continued use of this material. The wooden propeller is lighter and cheaper but will not stand up in service so well and is not so easy to repair after minor crashes. Wood is also an ideal medium for satisfactorily absorbing vibration, and great care in the design of duralumin propellers from this standpoint is necessary. Steel has been successfully used for propellers in England, but from the standpoint of weight combined with fabrication difficulties it is not believed to represent the ultimate material for propeller use. Micarta is also successfully used and in large production will probably have an advantage in price over any other type.

(*b*) Propeller Arrangement

There are several designs of duralumin propellers now being successfully used. These include the single-piece type, made either from a rolled slab or forged blank, and the three-piece ground adjustable-pitch type, using a steel hub. The former types have the advantage of cheapness and simplicity, whereas the latter have the advantage of pitch adjustment. This advantage is important in connection with new airplane types in that it permits the ready correction of design errors. It also furnishes a convenient means of altering engine speed in the case of airplanes of a given type for use in varying functions. It is believed, however, that, in general, once a design of airplane is established on a production basis, a fixed-blade one-piece propeller will be found satisfactory, so that price is the determining factor.

I should like to call attention particularly to the controllable-pitch propeller. The advantages of this type are so great that I venture to predict the very general use of the type in the future on all multi-engined airplanes and on many single-engined types. The ultimate type selected may be of the automatically adjustable type, or of the type controllable as to pitch from the cockpit. I rather think the latter will predominate. The improvement in take-off, climb, and ability to fly on power units less than the total number provided is so marked as to render it inconceivable that eventually suitable designs will not be developed and adopted.

(5) Other Power-Plant Items

The designer has before him many installation problems, including gas- and oil-tank location, type of fuel system, installation of starting system, etc. Each must be thought out in regard to the others, and to the use of the airplane.

More and more attention is being paid to the matter of noise elimination. It is undoubtedly true that the noise now present in airplanes is a great handicap in making the public airminded. So much noise is not conducive to comfort when riding, and eventually planes must approach the freedom from noise which now exists in automobiles. The weight and power sacrifice involved in the use of mufflers is warranted in most types of plane. It should also be noted that the propeller noise can be lessened by using the slower turning propellers which accompany the use of engine reduction gears.

D—Arrangement

This design element requires for complete solution a decision on such questions as: biplane vs. monoplane; if the latter is favored, then internally braced vs. externally braced or low wing vs. high wing; disposition of tail surfaces; type of landing gear; open vs. cabin fuselage; satisfaction of requirements of visibility, and disposition of equipment and facilities inside the cabin. Below are given some of the factors which must be taken into account in arriving at decisions on these items of arrangement.

(1) Biplane or Monoplane

In general the biplane, because of better truss arrangement from the structural aspect, can be constructed lighter than the monoplane. It will also usually excel in the matter of airfoil efficiency. It will, however, fall far short of the monoplane both in general aerodynamic efficiency and in overall fineness. I am inclined to believe that, all factors considered, the performance of the monoplane, particularly the internally braced monoplane, will, when developed by equally competent designers, excel that of the biplane for like function and requirements. One of the outstanding advantages of the biplane is the compactness and reduced span made possible. This item will, I feel, become of increasing importance particularly in the large-plane field.

The externally braced monoplane is really a compromise between the biplane and internally braced monoplane wherein advantage is taken of the structural superiority of the former and the aerodynamic gains present in the latter. This development is truly American in both origin and adaptation, and one which has many features to commend it.

The so-called low-wing monoplane possesses advantages in stability and safety and certain performance characteristics, but has not come into general favor in this country, probably because of poor visibility from the passenger cabin. Its successful use in the Junkers series, however, indicates that its advantages may perhaps outweigh its disadvantages.

(2) Disposition of Tail Surfaces

The variations in arrangement include the conventional monoplane tail; the box or biplane tail; or the monoplane tail with duplicate fins and rudders. For single-engined ships the monoplane tail is desirable. However, for multi-engined planes, particularly when using two or four units, an arrangement having two fins and rudders is essential for proper control, particularly for use when flying with the outboard engines only. For very large airplanes the biplane arrangement will often justify itself.

(3) Landing-Gear Arrangement

The chief questions to be settled are tread of wheels and type of shock absorber, together with wheel motion. The tendency is toward large treads, oleo or pneumatic shock absorbers, and forward or combined forward and sideways wheel motion. The general adoption of oleo shock absorbers will undoubtedly greatly lessen the landing accidents which sometimes have resulted.

(4) Fuselage

I am convinced that except for a relatively small class of ships, the cabin plane will almost entirely supercede the open-cockpit type. By exercising proper ingenuity, the problems of vision, weight, and resistance, which are apparently of greater magnitude in the cabin plane, can be eliminated.

(5) Cabin Arrangement

The following are some of the problems which require very careful attention as they relate particularly to passenger comfort which must be present in transport airplanes before extensive patronage can be expected: seating arrangement; ventilation; toilet and lavatory facilities; elimination of gases and odors; heating facilities; elimination of noise and vibration; arrangements both for preventing airsickness and accommodating passengers once afflicted; provision for interesting passengers. As the need and demand for most of these items have only just come before us, their development is somewhat behind that of the airplane proper. They furnish, therefore, a fruitful item for the designer's attention, with particular reference to their provision at low cost in weight.

(6) Airplanes for Water Operations

Although not specifically discussed in this paper, it should be realized that many uses for airplanes call specifically for the selection of the seaplane, flying boat, or amphibian for proper solution. One of the greatest advantages of airplanes capable of operating from the water is the possibility thereby afforded of landing closer to the great centers of population in cities. This is a real problem in air transportation which may eventually find its best solution in this manner. It is also felt that even with multi-engined planes, long flights over water should be carried on only with airplanes capable of landing on the water.

E—Factor of Safety and Degree of Reliability

The selection of safety factor is not now a decision within the power of the designer, at least in so far as minimum factor is concerned, as it is prescribed by the Department of Commerce. Stress-analysis requirements are based upon a required load factor. The load factor represents the accelerations obtainable in a given maneuver when compared with the loads on the wing structure in unaccelerated horizontal flight. The prescribed load factors are sufficiently greater than those obtainable in maneuvers considered as reasonable for a given type, to allow for a real factor of safety of from $1^1/_2$ to $2^1/_2$. The smallness of this factor of safety, which must take care of defects in workmanship or materials, deficiencies of design, depreciation, and unreasonable maneuvering, makes it necessary that stress analyses be accurately prepared; and that the utmost in refinement of design and workmanship be adhered to throughout. And yet, because of the extreme necessity for weight economy, required load factors cannot be much acceded. The British system of permitting one gross weight for normal commercial flying, with another lower weight, and consequently lower useful load, for stunt flying, is believed to be of considerable advantage in permitting a combination of higher real factor of safety and accompanying low weight.

From the standpoint of operating reliability, consideration must be given to the relative degree of safety and schedule maintenance demanded by the particular service for which the particular plane under consideration is being designed. It is no violation of our fundamental requirement of safety to admit of degrees of safety for different types of airplanes. It is this consideration which makes it satisfactory to design single-engined ships for certain types of service.

F—Aerodynamic Considerations

The principal considerations of an aerodynamic nature which must be decided upon for each design are the following:

Fineness Ratio. All performance characteristics of the airplane are improved by "cleaning it up." This consists in eliminating protuberances as much as possible and fairing or streamlining those which must be outside. Expense, weight, and increased maintenance difficulties accompany the incorporation of such refinements. Nevertheless the whole tendency is toward increasing rather than decreasing this method of improving per-

formance, and I am of the opinion that progress will continue more rapidly hereafter to such an extent that in a few years airplanes in everyday use will have a degree of refinement of line and general fineness comparable to our racing ships of today.

Stability. This quality is important from the standpoint of making the airplane easier to fly and more foolproof; it is essential that it be present under many circumstances, such as cloud or fog flying. The ease with which a modern stable airplane can be flown is one of the most certain indications of the continued increase in popularity of flying as a sport. I believe the time is rapidly approaching when no airplane will be considered as at all satisfactory that is not positively stable laterally, directionally, and longitudinally under all flight conditions.

Controllability. It is essential that an airplane be not only stable but controllable. Although on some highly maneuverable military planes there may be some conflict between the two, it nevertheless appears that it is readily possible to have both qualities present to a marked degree in any commercial ship. Vast improvements in the proportioning and balancing of control surfaces have recently taken place, and further improvements of equal magnitude may be confidently expected. In order that the airplane may attain importance as a means of transportation for private individuals, it is necessary that it be capable of being flown by pilots of far less ability than most now operating and with a high degree of safety and dependability. In order that this condition may obtain, the qualities, stability, and controllability must be present in the design to a marked degree.

G—Weight

To a degree unrepresented in other engineering structures, weight is of importance in the airplane. It has been said with absolute truth: "Any airplane can be immediately judged a success or failure, when first it is placed upon the scales." The airplane which when completed is overweight to any appreciable extent had far better be stopped at once in production, rather than linger on to a certain death after money has been wasted in trying to save it. Too often at present such designs are continued with some degree of success by the expedient of adding power to compensate for the extra weight. This is not an economical process, nor will it result in a type which will long remain on the market.

H—Ease of Maintenance

For economy of operations it is essential that attention be paid to ease of maintenance, including inspection, assembly, repairs, and replacements. This is best accomplished by applying sound engineering principles to the design of details, accompanied by the use of materials selected with particular reference to the function in the airplane of the parts into which they are fabricated. I do believe, however, that for some time to come the importance of weight economy is so great that designers must use materials best suited from this standpoint, thus to an extent forcing on service personnel the necessity of finding methods of effecting repairs perhaps more difficult of accomplishment at first than in more commonly known materials.

I—Materials

I feel confident that the use of metal in airplane structures will increase steadily. Metal is better adapted than wood for use in the airplane from the standpoint of greater certainty of strength values and of inspection, smaller depreciation, and cheapness of construction in large production. In order to feel the advantages of this last factor, production must be considerably larger than it is now in any airplane factory. Wood in many parts of the structure can certainly be used conveniently in experimental models, particularly on relatively small planes. However, I believe the future will see most of our planes constructed principally of steel and duralumin.

III—COMMERCIAL USES OF AIRPLANES

In the foregoing discussion have been listed in considerable detail the design elements, each one of which must be considered and judged as to relative importance by the designer. As previously stated, almost every element conflicts in some respect with every other, thus necessitating compromises. It is the exercise of proper discretion and judgment in the case of these compromises which marks the successful engineer. It is only by carefully considering the use to which the finished airplane will be put, in conjunction with the element of design being considered, that one can expect to arrive at such a proper decision. The principal uses of commercial airplanes which are now foreseen will be discussed briefly.

Airplane Designs

There follows in as brief form as possible the design arrangement which to me offers the best solution of the many problems involved in designing an airplane for each of the uses mentioned. I wish to emphasize the fact, previously put forth, that the conflicting elements are so many as to render it really improper to give out any one arrangement as a "best solution." However, from the analysis made so far, many will agree that the arrangement submitted will be suitable for the purpose intended and will perhaps contain less serious compromises than some other.

A—Passenger Transport

Through Lines. The transportation of passengers in large airplanes is of particular importance and interest just now as the establishment of lines having this object in view has only just commenced. A few such lines are now operating on the Pacific Coast, and next summer will see many more in operation, including long transcontinental runs.

I feel that the following elements, in about the order named, are essential to the success of any airplane competing in this field: safety, high cruising speed, comfort, and low maintenance cost.

These requirements are best attained by using a biplane powered with two or four geared engines. At present this would require water-cooled engines. When developed to the same degree of reliability, I shall favor geared air-cooled engines. Also, when available, controllable-pitch propellers will be used.

The biplane arrangement favors safety because of the possibility of obtaining necessary large wing area for low landing speed without using a span which is so large as to make handling and hangar problems disproportionately great. The biplane also offers a more direct solution of the folding-wing problem than does the monoplane.

The analysis made in a previous section indicated the greater reliability of a two- or four-engined airplane than that of a three-engined ship, it being understood that in the case of the two-engined type, horizontal flight on one engine could be maintained, and in each of the other cases on two engines. This arrangement, then, also favors safety. The arrangement having no fuselage engine is believed desirable for other reasons, including increased comfort, performance, cabin capacity, and pilot's vision, with decreased hazard from fire. Comfort is increased by the reduction of noise and vibration and gasoline fumes; performance is increased because of reduced fuselage drag; cabin capacity is increased because with this arrangement the nose of the fuselage can be extended without adversely affecting balance; pilot's vision is improved by placing him ahead of everything in the airplane; and fire hazard is reduced by removing the only im-

portant source of fire, the gasoline tanks and engines, away from the fuselage. In this connection, it should be noted that there are a number of instances on record of safe landings made with raging fires in outer nacelle units, which, if present in the fuselage, would certainly have been disastrous.

In addition to the above considerations, it is essential that the large through-line airplane have a large degree of inherent stability and be readily controllable. In the future it is probable that supercharging will play an important part so that perhaps eventually we shall use planes with oxygen fed, sealed cabins, flying at 30,000 to 40,000 feet altitude at 200 to 300 miles per hour.

Feeder Lines. This type of service closely approximates the one just described, but on a smaller scale. It therefore will require a plane of the same general type. Here, however, as the size is smaller, the aerodynamic advantages of the monoplane can be used to advantage. A monoplane using two air-cooled engines would therefore indicate my solution of this problem.

Private Business Passenger Carrying. There is a good field for a plane capable of carrying five or six passengers, for the use of business firms transporting executives, officials, and associates. As the general requirements are identical for this and the feeder-line plane, it appears that in this case identical equipment can be used for the two functions.

Taxi Planes. A number of uses for this type of plane present themselves and have in fact already been demonstrated, as it is this class of service which is even now being used extensively. Such planes transport newspapermen and cameramen to the scenes of events having news value, such as regions devastated by storm or flood, fires, races, sporting events, and the like. There is also a use in carrying doctors and business men on important rush calls and, in fact, rendering service on all types of unscheduled passenger trips. This general type of plane finds a use in the movies and for advertising.

As the requirements for reliability are not so exacting as on scheduled passenger runs, it is felt that here the single-engined plane finds a field. It should be remembered that here the operator can exercise more discretion in the matter of both route and weather. The plane must be relatively small and easy to handle, and cheap to operate and maintain. The performance, however, must be good, in order to offer an inducement for its use in competition with other methods of transportation.

The single-engined cabin monoplane, either internally or externally braced, and with folding wings, will always find a wide usage in this field. However, as the particular service rendered becomes such as to require fairly long hops, it is conceivable that even in this case the two-engined machine will find a field. In all probability, flying services operating a taxi business will equip themselves with both types, using for any particular job the exact type best suited. I wish to emphasize here again the assumption made in all cases where two-engined planes are mentioned, that horizontal flight on one engine is presupposed. Without such possibility, reliability is far less than with the single-engined plane, although always the length of glide would be markedly increased. For taxi service the advantages of the amphibian plane should not be lost to view. The advantage of landing on water, which is practically always available near large cities, is very real, as it obviates the time loss of the intermediate automobile trip present in the case of most of the present flying fields. I feel certain, therefore, that flying services will equip themselves with some amphibian planes, to realize this advantage.

Sightseeing. In general it is believed that the same requirements here obtain as hold for the feeder-line ship. As safety, reliability, and good vision for pilot and passengers are essential, it appears that the twin-engined monoplane will be best adapted.

Short-Distance Transport to Centers of Population. The amphibian plane has already been mentioned as eminently suited for this kind of service. In addition the helicopter should be mentioned as offering a possible solution to the problem. The vertical ascent and descent features of the helicopter undoubtedly give the best answer, as by this means landing on buildings could be made, thus getting closer to passengers than could possibly be otherwise accomplished.

B—Goods Transportation

In the early part of this paper was indicated my belief that safety is a fundamental consideration in all phases of air transportation. There are, however, degrees of importance, and I feel that in the transportation of goods and mail and express a lesser degree of safety is necessary than in the carrying of passengers. Reliability is of course important, but relatively speaking, economy of operation is more important. Therefore the important design elements are arranged in general as follows: high percentage of pay load, safety, cruising speed, and low maintenance cost.

With these general requirements in view, let us determine the arrangement of plane which appears to be best suited for the types of goods transportation previously listed.

Mail. To date designers have favored the single-engined biplane, with pilot located aft of the mail compartment. I am inclined to believe that the development has been sound and the type will continue. Certainly the biggest percentage of pay load together with high cruising speed is thus obtained. However, I should like to urge the possibility of a future trend to three-engined planes for this service—on account of the added reliability thus attained, and on account of the probable future necessity for larger capacities because of the increased use of air-mail service even now indicated. I do not believe that the twin-engined plane will find a field in mail carrying, as to gain its superior reliability, a decreased percentage of pay load is necessary. It is true that it has a better arrangement for cargo carrying and with equal power will have a higher cruising speed; nevertheless I believe that if multi-engined machines are used, the three-engined type will predominate.

I see no particularly sound reason for the predominance of the biplane over the monoplane in this field. It can be built somewhat lighter, but will be inferior in fineness. It also possesses a disadvantage not yet overcome, namely, an arrangement which makes use of brace wires on which ice collects to such an extent under certain conditions as to force a landing or cause wire failure.

Express and Fast Freight. For this type of service the three-engined plane seems to offer an almost ideal solution. The monoplane arrangement also appears logical, at least until such time as sizes become so large as to make a biplane type imperative. However, in this service higher landing speeds can be allowed, so that the three-engined monoplane will predominate for some time to come.

Plant and Machinery. This heading includes the transportation of heavy equipment, particularly in undeveloped countries where transportation by ground methods is arduous and slow. There are many locations where, for example, oil-well equipment can be transported in a day, which it might well take weeks to transport by any other method. For this type of duty, reliability and capacity lead in importance, with performance a secondary consideration. A multi-engined ship is therefore clearly indicated. In all probability the three-engined plane will predominate because of high pay load carried in combination with excellent reliability and good cubic capacity. The latter consideration, however, would make the two- or four-engined plane superior. The two-engined plane, however, will not carry sufficient load (and still be capable of flying on one engine) so

that it does not appear to be so well adapted. The reliability of the four-engined plane capable of flying on any three engines is very good, and it may be that this will represent a type extensively used in this field.

Film and Newspaper Carrying. The requirements for film and newspaper carrying closely parallel those of the mail plane, when relatively small loads are carried, and of the express plane, when larger loads are present. It may therefore be expected that the lines of development of the carrying equipment will be similar.

C—Training Planes

The training of pilots should be in two stages. First, a primary training course, during which the student learns the fundamentals of flying and aeronautics, including the execution of maneuvers; and an advanced stage, during which training in more difficult maneuvers takes place, and in addition, practice is obtained in the flying of different types of airplanes. For the latter stage, all available commercial planes should be used. This stage is, of course, particularly necessary for the student who intends to take up piloting as a profession. The primary stage, essential for all students, may close the course of the man who contemplates private flying only.

I believe that the type of plane best adapted for primary training is the single-engined open-cockpit biplane, preferably of two bays in the wing cellule. The design must be relatively easy to fly, cheap, and easy to maintain. No great degree of engine reliability is necessary. All of these elements appear to call for a single-engined plane. The two-bay biplane is chosen as being safer in case of a crash and because of possessing the type of controllability which experience has indicated is best suited for the purpose. As performance is of minor importance and as intercommunication between instructor and student is of such great importance, it is surprising that more general use of the side-by-side seating arrangement has not taken place. This may be due to the fact that practically all present pilots were trained in a type descending from the *JN*4 or, in fact, in a *JN*4. On the other hand, it may be that a real advantage in training is gained by having the student alone in his seat. In my own case, I felt that the side-by-side seating arrangement would have facilitated matters, as the head-phone and hand-motion method used was, to me, somewhat confusing and undesirable. I therefore am inclined to believe that eventually, a side-by-side arrangement will be adopted. In such an arrangement the motor must be located sufficiently low to render the vision to both sides adequate.

D—Aerial Survey

As the name implies, the particular types of service rendered by the class of airplane here discussed indicate the use of a plane so arranged as to permit unrestricted view from varying altitudes, in some cases at least 15,000 ft. Reliability is absolutely essential as in general these airplanes are used over a type of country where forced landings would in many cases spell disaster. On the other hand, the load to be carried is relatively small, at least in so far as pay load is concerned. A fairly high fuel load is necessary, however. In many of the divisions of this general classification, the machine should be capable of landing either on the land or water, and it is therefore likely that the amphibian plane, based on a twin-float arrangement of pontoons, may find some usefulness here. The general order of importance of design elements for this class, therefore, seems to be the following, with detail variations as given below: vision, reliability, high ceiling, economy in fuel consumption, and stability.

Photography. Aerial photography has already been extensively used. The preparation of maps for tax appraisals, highway planning, investigation of public utilities such as water power and waterways, telephone and power-line extensions, and real-estate development, are but a few of the uses that one can name. The design elements given above as generally applicable to the whole class all seem to apply to aerial photography in detail. I do not feel that the single-engined airplane offers the proper solution except perhaps for the restricted use which obtains in the case of photographic projects carried on within normal gliding distance of an airdrome. Even here the vision of the pilot placed first in the list of important design elements is wanting. I therefore believe that the twin-engined monoplane offers an unusually good solution of all the problems involved. It furnishes at once an unexcelled view for pilot and observer and a high degree of reliability together with good performance characteristics. A properly designed plane of this type should find a wide usage almost at once, as the functions covered by aerial photography are not duplicated by any other means than the airplane.

Spotting. There are numerous specific uses which can be classified hereunder, such as fish, crop, and timber spotting, forest and border patrol, and coast-guard work. The characteristics required of an airplane for this type of duty seem to be almost identical to those just described for aerial photography. The same airplane, with slightly different equipment, can be used for each.

Exploration. Here again there seems to be no essential difference in airplane requirements when compared with the preceding divisions. Here, however, the field of operation is wider so that in certain cases other arrangements suggest themselves. In general a larger load-carrying capacity is required, and as vision is not perhaps of the same degree of importance, the three-engined monoplane may be best suited for exploration use when the period of absence from civilization is known to be long at the outset of the trip. It therefore seems logical that in this case no general type can be specified in advance as being susceptible of satisfactory use for all exploration projects. Certainly, however, a multi-motored airplane is necessary.

E—Industrial Uses

The possible uses of the airplane in the realm of industry have not been exploited to the extent which obtains elsewhere. We are all familiar with the use of planes for insecticide dusting, tree spraying, and certain forms of advertising. It is believed, however, that a great many other uses will come to light as the use of airplanes for transportation becomes more general. However, for the limited field above indicated it appears that the single-engined ship will be satisfactory, as in general landing fields will be available in the event of forced landing. Here again, however, I am inclined to believe that as the field broadens, and the more general use of airplanes in industry becomes a reality, the multi-engined type will come into its own.

F—Private Uses

The private individual has several uses for an airplane, including sport and touring. The former has become an important field in England where numerous flying clubs are in existence which, I understand, enjoy a large patronage. The country is in many respects better adapted for the use of the light plane than is the United States. Distances are shorter, and landing fields closer together. There are many who, I am sure, will not agree on this matter, but I am inclined to believe that in this country it will be some time before the private use of light planes will be general.

The type of plane which appears to be best adapted for this field is the single-engined biplane with folding wings and air-cooled engine. The British airplanes known as the *Moth* and the *Avion* are well-balanced designs of this type. These are two-place planes, eminently suited for sport use, having a low landing speed

and high degree of maneuverability. For long touring they do not have sufficient space or load-carrying capacity; nor do I feel that the tandem seating arrangement is suitable for this purpose.

Certainly for private use in making long trips, a side-by-side seating arrangement will be required. The American three-to-five-place externally braced cabin monoplane appears to me to be a more logical solution of the problem of design for touring use. In fact this entirely American arrangement, first brought to the front by its use in Colonel Lindbergh's tráns-Atlantic flight, represents a development of which we can be justly proud.

Conclusions

In conclusion I wish to stress the necessity of taking into full consideration, in every design of airplane, the fundamental requirements of safety and reliability, singleness of function, and economy. In order to bring about the general adoption of airplanes for use in the many fields of activity listed, the first and last fundamentals must be present in every design; and in order to accomplish such a high standard at all, the second basic requirement must be followed. Having given proper cognizance to the fundamentals, it then becomes necessary to study carefully the exact nature of the service to be rendered by the airplane which is receiving design consideration, with a view to compromising the conflicting detail elements of design so as to create an airplane which will compete successfully in its field of activity both with other airplanes and with other types of transportation. The problem is difficult, but the future for air transportation and service, which we all see before us, is well worth the effort.

Discussion

Robert J. McKay.[2] From the laymen's standpoint the conclusions as to the relative safety of the two-motored airplane as compared to a single- or three-motored type is particularly notable since, to the casual observer, it seems that there are many more of both single- and three-unit planes in the air today than of the two-unit type. The indicated possibilities for greater safety than is obtained at present would seem to have much public interest.

Another thought which might be useful in this discussion is the fundamental importance of materials in fuselage design. This thought is brought to my mind by the fact that the subject of materials has been relatively little discussed in this most interesting symposium. Again from the observers standpoint, it seems roughly that probably less keen study has been the case than in designing motors. But they are not less important in the case of the fuselage. With the present rapid development in alloys which are corrosion resisting, and those which have special mechanical and physical properties, possibly we may hope for future developments along this line which will make flying more efficient and safer.

Elmer A. Sperry.[3] This is a wonderful Division. Here is a section that is going 100 per cent, absolutely dealing with the most marvelous developments that are going on in this world today. It is fine to have such full attendance, and such upstanding and outstanding personnel as is here present! The Society is to be congratulated most heartily on this Division.

Now, the matter of fact is, the airplane is just about "110 per cent" mechanics. There isn't any chemistry about it, there aren't any miners or mining engineers who are going to have to go very deep to dig up an airplane, you know; the civil engineers give us a little bit better facilities for getting off, but they don't reach up very far in the air, so it is the mechanical engineer who has to do with this problem. It is delightful that such wonderful authorities as Mr. Wright and the others present have come out this morning to help. The best all can do together is none too good.

Points regarding design have been stressed. All engineering is a sort of compromise; the design problem not only has to fit into the picture, but the power plant has to be considered. The paper that was read by Captain Woolson, yesterday, in Chicago, touches on the power plant that is an aim in the right direction. The Diesel power plant has got to come. The marvelous increase in safety is only one incident.

Repeating what the writer said yesterday, downstairs, in the Diesel Division. How safe is Diesel oil? There is an oil that can be obtained on this market for $1.10 a barrel (42 gallons for $1.10, that is pretty cheap stuff), but it has 18,500 B.t.u.'s per pound. It has all the energy gasoline has. It must be used.

Touching on the safety of Diesel oil, Commander Cave-Brown-Cave (it is unnecessary to tell what country he came from) gave an impressive illustration. He took a metallic ladle, put some Diesel oil in it, and tried to touch it off, but it would not flame at all. He put it across the top of a Bunsen Burner, and when it boiled it would light, but when he took it off, it would go out. Then he cooled off the ladle and put a little gasoline in it, touched it off, and he wished he hadn't. It simply goes up and becomes a mass of flame pretty quickly. He cooled off the ladle again, put some more gasoline in, and touched it off again. Then he put some Diesel oil on and it put the flame out. Think of that. The first drop of Diesel oil will go into flame a little quicker than the first drop of gasoline. It has a slightly lower ignition point, but what should any one care about the first drop? It is the gush accompanying a smash-up that is the thing to consider. The following gush of gasoline needs no description as to what happens. The following gush of Diesel oil will not only put out the flame, but it will put out the red-hot steel as well. Why? Because its specific heat is five times that of the steel, and the flow takes care of the gravity difference. This is well worth considering. It is only the red-hot manifold that usually ignites anything, so the Diesel oil provides a perfectly safe fuel.

Now, the engine that Captain Woolson was talking about is just an ordinary, run-a-mile, Diesel radially disposed. He took a gasoline engine designed for the upper limits of preignition, or detonation, which every gasoline engine has to be designed to stand anyway, absolutely about 1100 to 1200 lb. per sq. in., put longer pistons in, put a clever little oil pump on, and started it up. His friends may have backed away, expecting the thing to go through the roof, but they discovered two things: First, it didn't go through the roof; second, its air-cooling was much easier than the air-cooling of the ordinary Otto-cycle engine. Why? Because it doesn't require as much cooling. No Diesel engine requires as much cooling as a gasoline engine.

The reason is so simple that a six-year old can understand it. Less fuel is used, and there is less heat produced and besides, there is more of the heat produced going into the power produced. To date only the surface of the Diesel has been scratched. By continuing the combustion somewhat so as to fatten out the cord, and get larger mean effectives will possibly be found just as applicable to the Diesel as it is to the Otto-cycle.

Then, supercharging. There is some trouble in getting a pump that will run along with 87 and 88 per cent efficiency at a speed of 2000 r.p.m. There is little trouble in the pump in getting rid of the condensed air, because a great deal less air has to be shoved out than is brought in. The great trouble, however, is inhalation. There are ways and means to approach almost perfect inhalation by bringing it in on every side, so the inhalation

[2] Supt. of Technical Service, The International Nickel Company, Inc., New York, N. Y.

[3] President A.S.M.E., Chairman Board of Directors, Sperry Gyroscope Co., Brooklyn, N. Y.

factor can be brought up to about where it belongs by having the mechanics right.

Improvements are going on. The biggest men in all countries are thinking on all these problems, which are all mechanical, as is this whole aviation proposition. It is on its home base here in the Society of Mechanical Engineers. Any demand should be resisted to have it removed and taken over by some other society, possibly, or some other division. It is mechanics from start to finish, and the great challenge should be met by rising to the situation and giving this Division all the support and service that lies within the power of this great Society to give.

Mr. Wright is working on the very latest development of an adjustable-pitch propeller. The propeller, which gives us the best level forward thrust, is not the best for climbing. The best propeller to climb with is not the best for regular projection through the air. Then again, at the high altitudes as suggested by Mr. Wright, the proper propeller is something different, especially for supercharging, but there is no trouble in getting very much better all-round performance through an adjustable-pitch propeller.

If a metal blade running at 2000 r.p.m. be taken, for instance weighing 30 lb., it tends to pull away from the hub. By what amount does it tend to pull away from the hub? Forty tons, that is all. To get a successful adjustable-blade propeller, the adjustment of the pitch of each blade must be within a tenth of a degree of the pitch of the other blades so that one blade doesn't try to do all the work, and that is no small problem. A great many minds have been working on it, but it is not on the shelf for ready purchase today. Mr. Wright is one of the leaders in the development, and when it comes to answering back to the cockpit, Mr. Wright has found how to secure the simplest answer. He says, "Look at the tachometer, simply adjust the loading of the engines entirely by the propeller; if it is right on the tachometer, the right adjustment of the propeller is obtained."

There is a lot ahead. More engineers are needed to study these problems, and give their assistance to these marvelous developments and possibilities.

Author's Closure

T. P. Wright. The reason that the two-motored biplane is favored by the author for passengers is that for so large a ship it is not economical from the standpoint of weight to build it in the form of a monoplane and to maintain a landing speed which is safe. In other words, a biplane can be built in the large size ship, and will be of shorter span, assuming the wing area gives a comparable landing speed. The two-engine ship is distinctly preferable for transporting large numbers of people, say fifteen to twenty passengers, because of the freedom of the fuselage from the engines, which is a consideration not appreciated as much as it should be.

Take the hazard of fire. It is eliminated by having the engines outside of the fuselage. There are on record at least three cases in which military bombers had the power plants catch fire and in which safe landings have been effected. If the power plant had been placed inside the fuselage, the plane probably would have been ruined and the people killed, as in the case of a three-engine ship with one of them in the center. That is why the two-engine ship for passengers, where safety is the all-important thing, is the most desirable, whereas for carrying goods, and where only the pilot has to be considered, the three-engine ship is suitable because the degree of safety is not so exacting, and also with that type of plane, a higher pay load can be carried, and still maintain approximately the same reliability as with a two-engine ship.

Generally the landing speeds are now higher than they should be, but there is probably reason for this, very largely due to the inefficiency of designers in meeting original weight estimates. When the weight goes up the landing speed goes up proportionately.

After a designer first puts the plane out for flight, if it is overweight the landing speed will go up. The designer generally resorts to the expedient, in making the plane successful, of putting in more power, which in turn runs up the landing speed a little bit more on account of the weight, that is one reason, incidentally, in connection with the multi-engine ship as against the single-engine ship, which partly counteracts the question regarding performance. It is legitimate for the multi-engine ship to land at higher speeds than the single-engine plane because it has a greater degree of reliability, and therefore can, presumably, in a great number of cases, reach an airport which is suitable for landing. In other words, if a motor fails on a multi-engine ship, assuming flight with a lessened number of power units, it will be able to make a designated airport, at which a higher landing speed is not particularly detrimental, whereas a single-engine plane must land at whatever point it happens to be passing over, where the higher landing speed is highly detrimental. Landing speeds are too high. For a single-engine ship they ought not to run over 50 m.p.h. and for a multi-engine ship not over 60 m.p.h.

Brakes are applicable to any type or size of ship, equally well. The condition of nosing over must be considered, but brake application is applicable to either type, and it must be considered in the design. At the present time, some wheels are placed slightly forward. The loads in the fuselage under brake-landing conditions are very severe, and run weights up appreciably. There is a torque relation in the fittings to which landing-gear is attached, which is quite a consideration.

The multi-engine ship does not need to be able to take off with the lesser number of power units. In flight when one power unit fails, gasoline should be dropped except perhaps enough for an hour's flight, and the flight can continue on the lessened number of units. There appears to be no condition where it would be necessary to take off (if it is a bi-motored ship) with one engine from an airdrome if the other engine isn't functioning. There is a period of twenty-five seconds just after taking off where, if the power unit fails, there will be danger, even in a multi-engine ship, but the degree of reliability is far superior to the single-engine ship provided it can actually maintain reasonable altitude on the lesser number of power units.

The laws of probability and chance show that the reliability of doubling up the units will decrease provided flying cannot be done on less than the total number of units. Where a two-engine ship can fly only on two engines, if one engine is disabled the ship has to land, and the two-engine ship is then far less reliable than the single-engine plane.

It must be possible to maintain at least three or four thousand feet altitude with the lessened number of power units for the mathematical formulas on the development of probability and chance to show the greater reliabilities. Assuming a 97 per cent efficiency for a single-engine plane, which was given in terms of 10,000 trips, the single-engine job will have 300 forced landings, whereas the two-engined ship which can fly on one engine will have nine forced landings. The three-engined ship which can fly on two engines will have 26 forced landings. The four-engined ship which can fly on three engines will have 52 forced landings, and the four-engined ship which can fly on two engines will have only one forced landing in 10,000 trips. Those are the figures, assuming our original premise is correct that the ship can fly on a lessened number of units. There is no controversy there at all, that is straight mathematics, but one must be able to fly on the lessened number of units. It is a point that is difficult to conceive because to date there have been not over two or three examples of planes built in the world that can fly with pay load

and drop the gas for one engine if they are two-engined ships. This puts it up to the designer to increase the efficiency of the ship. It can be done and it is going to be done, because it is going to promote aviation. It has been done on at least one bombing plane with two engines, which has flown with the other crippled, with all the gas dropped out except a sufficient amount for one hour's supply.

As to the use of materials of high-strength alloy steels, etc., there is no question but what they are going to be used very extensively in the future. The fact that for a time they have been disregarded is because commercial aviation has been developed quite largely by small concerns who are not in a position to put in heat-treating equipment, etc., which is essential for the successful use of the high-alloy steels. With 150,000 to 180,000 lb. per sq. in. of strength high-alloy steels will be used extensively in the airplanes of the future, and of course, duralumin will be used even more extensively.

Some author got up a paper two or three years ago showing that as the span goes up, there is a definite limit at which the weight goes up, disproportionately, so that there is no gain in going above a certain limit. Materials will undoubtedly be improved and therefore move that limit up all the time, but there is a definite limit above which it cannot be hoped to go.

Within the next two years there will be in successful operation, planes carrying twenty passengers and perhaps up to thirty or thirty-five, but it will be quite a while before there are planes carrying fifty passengers, perhaps ten years or so. It is very difficult to look into the future, but there is a definite limit in the size of airplanes. Aviation will not supplant other types of transportation. It merely supplements or aids in those fields to which it is particularly adapted. Higher speeds in aviation than in any other means of transportation will always be possible, but even at the increased cost and when safety is demonstrated, it will not supplant ocean, train or railroad transportation. So it appears that within the next five years, the limit will be about thirty passengers, and perhaps in ten years, fifty passengers. The total life of the plane will be probably in the order of 40,000 or 50,000 lb. gross weight. The four-engined plane will be most common. Undoubtedly, there will be six-engined planes, but four-engined planes is the next step. One manufacturer now is getting out a four-engined plane. The pay load now ranges from about 15 to 20 per cent of the gross weight. A two-engined ship which the writer's company is building has about 22 per cent of gross weight in pay load, and it will still be able to fly on one engine. There are single-engined planes carrying 25 per cent, and one three-engined plane that can carry or fly on about 27 per cent of its gross weight and still maintain altitude on two engines. That means if 30 passengers at 200 lb. apiece are carried, that would be 6000 lb. pay load, and a plane of about 30,000 gross pounds is a pretty good-sized ship. The NC-4 weighed 24,000 lb. when it took off, but it had a lot of power and it was quite efficient. Racing planes, having just sufficient gas for the particular course over which they travel, carry no pay load at all in the same sense that "pay load" is used in the other discussion. They have a pilot, gasoline, and oil, which is entirely part of the airplane, so that the speeds of commercial airplanes, which have economy as one fundamental requirement and safety as another, will be very decidedly less than racing planes probably in the order of half or perhaps less than half.

At the present time, there seems to be a trend away from the use of larger power units than 500 or 600 hp. so it is probable that in the single-engined commercial plane that carries a reasonable pay load, the speed will not go over 175 m.p.h. certainly, for some time to come. The Lockheed-Vega, one of the best in that direction, makes about 160 m.p.h. with a Wasp engine of 450 horsepower, carrying a reasonable pay load. With the Whirlwind engine it makes about 140 m.p.h. With a power plant on the order of 500 hp. the speed will be about 175 m.p.h. and 200 m.p.h. will be quite distant in the future for commercial aviation. That applies, of course, to sea-level speeds. That brings up the supercharging proposition, which is a different thing. As mentioned in the paper, if one supercharges at altitudes of from 7000 to 12,000 ft. the speed goes up tremendously.

The company with which the author is connected built two pursuit ships using the same power plant. The speed of the unsupercharged-engined ship was in a curve dropping off as the altitude went up, whereas the curve for the supercharged ship, starting (probably because of the lack of a controllable-pitch propeller) at a considerably lower speed at sea level, went up in exactly the opposite direction. The curves crossed at 6000 ft. altitude. At 20,000 ft., whereas the unsupercharged-engined ship made about 135 or 140 m.p.h., the supercharged-engined ship made 195 m.p.h., and that was with a very inefficient supercharger. With the present design, the ship can make 225 m.p.h. at 15,000 ft., and it is felt that in 10 or 12 years there will be transport planes flying at 40,000 ft. altitude with hermetically sealed cabins, and perhaps making 300 m.p.h. That is quite a way off, 10 or 15 years, but it is going to come. It is really the economic way to use airplanes, at 40,000 ft. altitude. It will be some time before the hop to Europe will be made with commercial airplanes. Perhaps the time will not come until there are high-flying, supercharged, hermetically-sealed ships. All of the flights which have been made to date have been made with zero pay load, simply with the weight of the pilots and gasoline sufficient to get them there, and when they did get there, they didn't have much gas left.

Commercially practicable flying cannot be expected with less than 10 per cent of pay load in relation to the gross. So it would be five or ten years before flying across the Atlantic, 2500 miles, can be done with sufficient reliability to make it a regular, established traffic. Probably it will be when there are high-flying ships that can gain by their increased speed such a marked amount over present-day airplanes.

But for the present and for the immediate future, there is no question but what hops will be made to Chicago from New York on the order of 1000 miles in one hop. They will not be very common, because they are hardly worth while. If a 500-mile hop can be made with a stop to gas up again, and thereby carry twice the pay load or half-again the pay load, why make a thousand miles? The loss with the stop will be but 20 min. or half an hour. It seems that the objective will be the flying across the Atlantic, and it is likely that will be some time to come with supercharged equipment.

Seaplanes and amphibians have been neglected in this country. The firm I am with is not building a good amphibian right now. I am sorry it has been neglected, because I think there is a wonderful market for it. It has the advantage of getting to centers of population, which is quite difficult with the conventional land plane, although there is the probability that the airport of the future will be the roof of the railroad station or something like that, so that trouble will be minimized.

However, the seaplane, to date, is not as efficient in both weight and resistance, which perhaps answers to a small extent, the reason that the development has been slower. The point is well taken that it is permissible to use higher landing speeds with seaplanes because of the vastness of the airdrome on which to land. One can land practically anywhere on the water, but the seaplane isn't nearly as efficient as the land plane, particularly because of its resistance and weight. The resistance is particularly great in amphibians unless the landing-gear is completely retracted. Mr. Bellanca has worked out such a construction about as well as any one in this country.

The seaplane will not be neglected in the next three or four years, and it will come into its own, although it never will be used probably as extensively as the straight land plane because of the fact that economics enter, and a very high pay load is required to make an airplane commercially pay its way, and as Mr. Stout says, "Support itself financially in the air."

In the small airplanes the problem of making a successful retractable landing-gear without increasing the weight too much is quite difficult. On the larger plane it can be done, although at best it is a difficult problem. As Mr. Sperry says, it is purely a problem of mechanics in working it out at a reasonably low weight, presumably on a low-wing monoplane rather than on a high-wing monoplane, because the thick, low wing would form an excellent place in which to retract the gear.

In connection with the use of the suction medium for changing the flow over a wing to increase lift, it was found that the blower takes quite a bit of power in the first place to form that suction, and the power required is only available in case the motor is running. In case of motor stoppage, the source of power is taken away at the very time when it is needed to lower the landing speed.

As to attaching several engines to a single propeller shaft, there is a real field for development. That proposition hasn't gone ahead since the days the Gallaudet Company was working on it. The problem never will be entirely solved until a controllable-pitch propeller is developed with the development of gears for shifting one or more engines to the same propeller shaft. Obviously, if the power unit is cut, it will be very inefficient for the single power unit. A controllable-pitch propeller is needed, and even there, the efficiency would drop off considerably. Undoubtedly in the future there will be in use several engines geared to the same shaft as it is merely a problem of mechanics.

The general relation of expense of the ground organization as compared to the total expense of air organization of a transport line runs somewhere in the neighborhood of 30 to 40 per cent. That is, for the airplane pilot's pay, depreciation of the plane and motor, together with gasoline and oil.

As to handling on the ground, at the present time, practically all ships are equipped with towing rings of some sort, and an ordinary two-wheeled dolly is used under the tail-skid. At all the larger airports, the hauling is done by tractors for the land planes. All seaplanes have towing rings provided at the nose of the pontoon or hull, which any kind of a tug can attach to. All seaplanes, at least for use on naval aircraft carriers, battleships, and other ships are equipped with hoisting slings so that the craft is hoisted on board much the same as davits are used for lifeboats.

On the larger airplanes there is a ring attached to the tail-skid, and a dolly has been developed which has a jack arrangement, a screw lifting device, which merely slips under the tail, puts a hook in it and hooks it up. That method will be used for some time, although the Transcontinental Air Transport Company now is spending a considerable amount of time in investigating this problem for large planes. It is building hangars especially to handle those particular ships, and so that the greatest efficiency can be secured it is building handling trucks with rails, and trying to arrange the best way of putting the planes into the hangars, either head first or sideways. The author understands that the sidewise method has been adopted, as more planes can be put in that way, although it would be different if the planes had folding wings.

As to the matter of loading, the problem is never going to be anywhere near as great as it is for other means of transportation. The asymptote established a while ago for loading one plane was in the nature of 8000 or 10,000 lb., which is, of course, just nothing to what is handled with other systems. Perhaps the matter of putting small packages into one container is a desirable feature, so as to facilitate checking, by letting all the checking be done indoors before the plane lands, and then putting a few trunks in the ship itself. At the present time, though, the maximum loads are from 2500 to 3500 lb. and the future loads, within the next five or ten years, are anticipated to be only 8000 or 10,000 lb., so the handling of cargo is not a terribly big problem.

The auto-gyro has for its principle, the production of lift through a rotating aerofoil rather than a stationary aerofoil. Its advantages include the attainment of a steeper-climb curve and a steeper-descent curve. It is not possible to land vertically with it, although Captain Richardson of the Navy advises that an auto-gyro appeared to be landing at a 45 deg. angle. That is very desirable from the standpoint of clearing an object, and of getting into a small airdrome.

The auto-gyro, as it is now designed in England by De Cierva, will not land vertically, although it is possible, because any rotating gear has a certain parachute coefficient while descending, that such a long oleo will enable it to land almost vertically, although the author is not competent to say just what angle that would be. Certainly it will land at a great deal steeper angle than is possible with an airplane, which is a great advantage in getting to small fields surrounded by high objects.

One must differentiate between an auto-gyro and a helicopter. The auto-gyro has a motor with a horizontal shaft and propeller, and it obtains its lift as a component of the forward motion, and does not have power go directly into the rotating blades themselves, whereas, a helicopter must have some arrangement of power so that it rotates the blades themselves, thus making possible ascent and descent absolutely vertical. Apparently, the auto-gyro has passed the experimental stage and is successful. It certainly is an interesting experiment in the way of improving landing possibilities.

AER-51-34

Management of an Airport

By MAJOR JOHN BERRY,[1] CLEVELAND, OHIO

The author gives details of the inception and development of this the first municipally owned and operated airport, and enumerates the facilities which it possesses. He further sets forth various precautions which should be observed in the operation of an airport which are based on his experience as manager of the airport since its operating.

EARLY in 1925, without precedent but with vision, W. R. Hopkins, City Manager of Cleveland, procured options on about 600 acres of the 1000-acre tract which the aeronautical authorities of the United States had determined to be the most suitable area from a weather standpoint, as well as the most fitted geographically within a ten-mile radius of the City of Cleveland.

The State Legislature was then requested to pass the necessary law to permit the raising of funds by bond issue. This was done and work was started on the development on June 1. On July 1 this port, the first to be owned and operated by a municipality, was opened, the first pursuit group from Selfridge Field, a bombing and operation group from McCook Field, the Ford freight line, the transcontinental air mail, and overnight New York-Chicago planes all participating.

The opening of the Cleveland Airport completed the transcontinental leg and made possible night service from the Pacific to the Atlantic.

On account of the condition of the field, the landing area on the opening night was extremely limited, yet America saw there the first night-flying "circus" ever organized, and 250,000 people stood spellbound as they gazed upon the greatest group of combat pilots up to that time assembled.

Development of the Airport

From a start of a single runway 400 × 2000 ft. this development has reached 70 per cent completion in four years, with approaches clear on all four sides and a landing area 3800 ft. square, all of which has been drained and made suitable for landings in all directions. On over a thousand acres of ground there was no place where there was a difference of more than 20 ft. in elevation.

In the exact center of the ultimate development there was built a 4-ft. diameter brick sewer 7000 ft. long. From this main artery were built 15-in. laterals every 400 ft., and into these laterals were carried the French drains, which were spaced 20 ft. apart and were adequate for the immediate disposal of water on the landing area. A duplication of this installation has just been completed on the south.

The Cleveland Municipal Airport is bounded by a series lighting system of eighty 600-lumen lights mounted on 24-in. standards, which are fed by a No. 8 steel armored cable buried in the ground. These standards are 200 ft. apart and surrounded the landing area. Green lights mark the approaches from the cardinal points of the compass, and white the remainder of the square. If, due to construction work, it is desired to protect the pilots from any hazard, red globes are substituted for white when needed.

A ceiling light for weather reports and two 24-in. beacons burn from dusk to dawn. A BBT floodlight, which lights the field as bright as day, is available whenever needed, and no pilot, whether or not he may be expected, is obliged to land in the dark. A landing tee equipped with Neon tubes gives the wind direction.

The Department of Commerce maintains the transcontinental lighted airway which east and west leads to the Cleveland Airport. This, together with the Louisville-Cleveland, Albany-Cleveland, Pittsburgh-Cleveland, and Detroit-Cleveland airways, completes the network radiating from the Cleveland Airport.

In addition to maintaining these aids to navigation, the Department of Commerce has installed and operates at its own expense a teletype service between New York and Chicago for the distribution of weather information. The stations for this service are the intermediate fields approximately 20 miles apart on the airway, and to supplement all this a radio station comprising radio beacon, radio telephone, and radio communication operates 24 hours daily.

The Department of Agriculture since 1925 has maintained an upper-air weather bureau where information may be had every hour in the day on the existing weather conditions on any course within a 500-mile radius of Cleveland, and no pilot is ever forced to "shove off" without full knowledge of the weather he is to encounter.

That these service adjuncts have played a vital part in the success of the port is vouched for by the fact that departures and arrivals, entirely exclusive of field "hopping," are about 1800 per month.

For the transient flier, use of the port is free. No charge for landing is made, and service may be had any hour of the day or night.

All operations for profit or hire are controlled by lessees who have built their own hangars on the field and pay a rental for the land only upon which they are built. To them also the use of the field is free. All construction and maintenance are provided for by the City of Cleveland.

The growth of activities on the Cleveland Airport is evidence of the value of this policy, as is borne out by the successful operations of the following leaseholders: National Air Transport, Boeing, operating the Stout Air Services, Universal Air Lines, Continental Air Lines, Colonial Air Lines, United States Air Lines, Thompson Aeronautical Corporation, Dungan Airways, Stewart Aircraft, Skyways, the Cleveland Institute of Aviation, and the 112th Aero Squadron of the Ohio National Guard.

Precautions to Be Observed in Airport Management

The experience acquired during the years the airport has been in operation give rise to the following deductions which the author would submit.

The phenomenal growth of commercial aviation and the diversified types of service, coupled with the countless student-flying activities, present today an operating problem for the airport executive to weigh carefully. Despite the care and thought given to the preparation of laws for navigation and particularly to those that apply to airport flying, by the Aeronautics Division of the Development of Commerce, casualties continue to multiply in an increasing ratio.

The great diversification in types of fields has necessarily led to the formulation of many rules for the governing of local conditions. Flying-traffic regulation is covered in its activity

---

[1] Manager, Cleveland Municipal Airport.

Presented at the Third National Meeting of the A.S.M.E. Aeronautic Division, St. Louis, Mo., May 27 to 30, 1929.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

by the air-commerce regulations, yet lack of standardization in airport construction gives leeway to the individual flier.

At the terminal ports today, with planes landing and taking off every few minutes, it is essential that a control station with unobstructed visibility be the point from which all departures are controlled. The inability of the pilot, in certain types of cabin planes, to see the air from all angles has frequently led him to take off just ahead of another one landing, and thus jeopardized the lives of the passengers in both planes.

The law giving the incoming plane the right of way automatically safeguards the entire traffic if control is exercised from a tower and signals used designating the area that is to take the air. The advancement of the art of navigation, as practiced by the pilots of the New York-Cleveland leg of the N.A.T. service, namely, that of flying "blind" and depending solely upon instruments, makes it extremely necessary that precautions be taken to protect the incoming flier, not only from collision but also from overshooting his landing area.

A four-way field with the perimeter outlined with boundary lights gives a sense of security to a pilot in bad weather if the entire area inside the lights is safe for a landing. This is particularly true in winter, when snow covers runways and the losing of the runway means nosing up, with resultant damage to plane and delay to cargo. Yet the weight increase in present-type transport planes makes hard surfacing seem essential, which surfacing must be over large areas rather than conforming to the runway type.

A far greater source of worry than all the flying activities is the absolute lack of precaution taken by the average spectator at an airport. Whether it is because of his interest in things strange and unfamiliar or whether he is merely exercising his inalienable rights as an American citizen, it seems impossible to impress upon him the thought of caution and the necessity for care.

The whirling propeller seems to be a natural attraction and the average spectator is drawn into danger by a lack of knowledge of this hazard. Naturally it may be asked, why not a fence? Primarily, our first reaction is that a fence high enough for the purpose will automatically become a hazard.

The average port today is municipally owned and for some years to come will be dependent upon the taxpayer for the money with which to operate. Complete exclusion of visitors from the port means lack of public support when funds are needed for further development and added necessities. The enclosed area at Tempelhofer Field seems from the airport managers' point of view an ideal arrangement, yet with eight to ten companies competing for the traffic and the removal of the few from the center of operations we should at once encounter the cry of favoritism and also stubborn resistance from the public.

A sufficient number of mounted police patrolling along a dead line has proved quite satisfactory as far as the sightseer is concerned, but once the latter buys a ticket and becomes a prospective passenger it is impossible to hold him on the line. He is in the hands of the operator, who, with limited personnel and the ever-present necessity of selling another prospect, seems to feel only a negative responsibility.

On single-motored biplanes the wing acts as a guard for the passenger entering and leaving, but the ever-present hazard of the starboard motor on tri-motored monoplanes constitutes what is probably the greatest hazard to the user of air travel. A rope fastened to the fuselage prior to the loading or unloading of passengers would, in a simple, inexpensive manner, reduce this hazard to a minimum.

In the life of every airport certain construction work is necessary. This in itself is a hazard and must be so marked that the pilot unfamilar with the port may know at a glance that the area is closed and unfit for service. The painting of tractors, trenchers, and graders with the standard black and chrome tector striping of the Department of Commerce sets out clearly these obstacles, and the complete surrounding of the area with a series of flags similarly marked and spaced about 20 ft. apart guarantees protection during the daylight hours.

It is exceedingly desirable and should be the practice of airport executives to see that all obstructions are removed before dark; but if the area itself is unsafe, red electric lights, not lanterns, should replace the flags at the same spacing. The insisting of the Aeronautic Division upon fire extinguishers in every ship has been an education for most operators. When a mechanic wheels a ship on the line it should be an inviolable rule that two hand fire extinguishers be mounted in a carrier and accompany him and be available for immediate use in case of backfire.

Every hangar should have spaced about the walls extinguishers that are ready for emergencies. These should be inspected at least once a week, and care should be taken to see that they are immediately refilled after having been used. The hand extinguisher should be supplemented by a forty- or fifty-gallon tank of the foam type, for further protection. The field itself must have an efficient fire department that is motorized and equipped with chemicals, pumps, hose, and first-aid equipment. In addition to this equipment it is the duty of the airport executive to supervise general conditions and, when carelessness and neglect are noticeable, to exercise his authority and eliminate the causes of both.

The duties and responsibilities of the airport manager are so many and of such wide variance that to attempt to cover the entire field would tax a superman. The supervision of flying is a minor incident in the day's work. The fact that the average pilot is a man of sound brain and approximate physical perfection guarantees to the manager strict compliance with the air code. This, of course, applies only to the experienced pilot. Student flying and the period after solo require more attention.

Printed rules mean but little; constant contact by the airport manager with the courses of instruction given by the various schools will educate the student in what is required of him on the particular port, both as to the hours of flying and the priority of flight, and the necessity to conform himself strictly to straight flying.

The care of the layman, is, as has been previously stated, a paramount worry. At Cleveland a week-end average crowd is about 75,000 people. There are from twenty to twenty-four ships in the air from daylight to dark. Each delay in loading and unloading lessens the day's receipts. The reputation of the port rests with the manager, and it is his duty to insure safety to spectator and passenger alike.

Constant supervision of equipment and close contact with the aircraft inspector are necessary in order that no ship not inspected and licensed may leave the ground. The service rendered to transients is bound to react on the reputation of the port. Strange pilots must be accorded every courtesy possible, and the quality of the gas and oil supplied must be unquestionable.

Mechanics who are not licensed are frequently the cause of forced landings, due entirely to their lack of experience, and it should be an inviolable rule that at least one member of each servicing crew be an experienced man and licensed by the Department of Commerce.

The information as to routes, weather, available fields, etc., belongs primarily to the manager's duties. This information or lack of it is a determining factor in the progress of the port.

Where aids to navigation are provided by the government, it little behooves any field manager to remain in ignorance of all conditions that pertain to flying within a 200-mile radius.

Finally, the base of all his work—the bedrock from which he builds—is the prime duty of every airport manager to know every hour in the day the exact condition of the entire flying area. During fair weather and foul the air traffic depends entirely for its very existence upon the airport. If a port is good it must be watched and maintained daily to keep it good. If it is ever to be good, only a thorough knowledge of its faults and a concentration of work on those faults will make it better. No port stays in shape, no matter how well built, unless it receives daily attention.

This close inspection should not be delegated to other than trained men, for upon this, more than upon any factor, does the port prosper or fall into disuse, and from the resultant reputation so fluctuates the efforts of the airport and the airport manager.

AER-51-35

Scientific Studies of Natural Flight

By MAURICE BOEL,[1] CHARLEROI, BELGIUM

In this paper the author gives the results of studies and experiments in bird flight with a view to bringing out features that can be used to advantage in future construction of airplanes. Birds can remain stationary in the air, they can rise and descend almost vertically, and can alight on a particular spot slowly. These are maneuvers not yet possible with airplanes.

The author has also developed a new theory of flapping flight. He renounces the analogy between wings and oars, and shows that flapping flight consists of a succession of short descents in gliding flight. The bird by flapping its wings is lifted a certain amount, and when released moves forward by gliding.

Various classes of flight by birds are discussed under four general headings. They are gliding flight, soaring flight, propulsion flight, and flapping flight. The mechanics, speed, stability, and useful power of the various classes are worked out by typical examples to show how the various types of birds are adapted to particular types of flying. The exterior anatomy of birds, problems of flight, and resistance of air are discussed, and examples are given to show the influence of the lines of the bird on its aerodynamic characteristics.

VALUABLE lessons in flying can still be learned from the birds. Studies of natural flight provide ideas for further progress in aeronautical construction. It can be predicted that some day airplanes will be constructed with retractable landing gear, and will have a speed range of at least ten to one. Birds have some superiorities over the best of present-day airplanes, such as their extreme suppleness, high efficiency, and particularly the very great speed range under their control. These advantages are of first importance, and many technical men are convinced that not only the safety but the future of air transportation is dependent to a large extent upon an increase in the range between flying and landing speeds. Birds capable of attaining speeds of 60 m.p.h. are able to alight on a fixed spot.

Exterior Anatomy of the Bird. From the aerodynamic point of view a bird consists essentially of body and wings, which unlike those of an airplane are inseparable, and ought never to be considered separately.

The Body. With birds best adapted for flight the claws are hidden under the down, and the tail is reduced to a minimum. Ornamentation lessens the ability to fly. Ornamented birds include many of the poultry yard like the cock and the peacock, and among the winged tribes of the tropical forest such as the bird of paradise or the lyre bird. In certain cases ornamentation is accompanied by complete inability to fly.

The exterior perfection of organs and forms is shown by simplicity of lines; a well-shaped body, wings narrow and long, presenting a continuous contour, and a form as nearly elliptical as possible. Each anomaly—each imperfection of line, too long a neck, too large a bill, the existence of which may be justified for other reasons—is a defect from the point of view of flying qualities.

For rapid flight the body must present the least possible resistance to forward movement, and the wings for a given weight of bird must show likewise as little drag as possible. These conditions are generally satisfied, or nearly so, in good fliers such as the swallow, pigeon, eagle, vulture, gull, petrel, seagull, and albatross. All have the body covered more or less thickly with down which fills up the space between head and body, and offers very little resistance to the air. This down is composed of a large number of small feathers which lap over from front to rear, each one consisting of a rib provided on each side with barbs of equal length.

The unit consisting of head and body, covered by the down, forms a sort of spindle, offering a resistance to the air which it is practically impossible to measure with accuracy on living birds, but which must be very small. These organs are constructed better than the fuselage of airplanes, which have sections often rectangular in shape, generally pierced with large holes and furnished with landing gear, the latter indispensable it is true, but whose weight and resistance absorb in flight as much as 25 per cent of the power.

The Wings. The wings, likewise covered with feathers, show the same anatomical features as the lower members of other vertebrates. The greater part of the bones constituting the skeleton of these members is recognized there—the humerus which corresponds to the arm, the radius and cubitus which form the forearm, the wrist, the metacorpus, and the phalanges of the fingers even, but modified by adaptation to their own function. Around these bones are found also, with some differences, the muscles and tendons, some of them, such as the pectoral muscle, considerably developed, and others either reduced in importance or increased in number.

In most birds certain of the important bones are hollow. It would seem that this fact could be interpreted as a lightening of the bird's weight. It is also possible that the cavities thus arranged in some parts of the skeleton have, besides, a physiological meaning. According to certain writers they play a role in respiration, but so far as is known, this function has never been proved with certainty.

In certain creatures, for instance the bat, and certain flying mammals, the wings consist of arm bones and muscles, with folds of skin which extend when the wing is opened. The skin is known as wing membrane, and is similar to that found between the arm and forearm of birds. In these creatures the membranous wings represent a sustaining surface which is totally inadequate. The surface is also increased in extent by the feathers, notably the coverts which form a sort of down, and in particular the wing feathers. Among the latter one distinguishes three kinds, which according to species are distributed in the wings in varying numbers. They are:

(*a*) The primary wing feathers mounted on the hand whose framework in flight is approximately perpendicular to the relative wind.

(*b*) Secondary wing feathers mounted on the forearm.

(*c*) Tertiary wing feathers mounted on the arm, and arranged in flight parallel to the bird's trajectory.

The part of the wing formed principally by the secondary and tertiary wing feathers is called the "fan" in contrast to the "tip" constituted by the extremity of the wing and the primary wing feathers.

The Feathers. All the feathers, whether of down, the coverings, the tail feathers, and the greater part of the wing feathers, are composed of a horny hollow tube prolonged by a shaft of rectangular section whose upper surface is called a scape, and is provided on both sides with two series of barbs of equal length

[1] Professor, Charleroi University.

Presented at a meeting of the Aeronautic Division of the A.S.M.E. at Detroit, Mich., June 28–29, 1928.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

situated in the same plane, and inclined at 45 deg. nearly with respect to the axis of the stem which carries them. Each barb in turn is furnished with barbets which carry hooked rays or barbules which are entangled in the hooks of the neighboring barbs, and give to the whole the consistency of a textile fabric, which for the wing feathers is impenetrable to the air at the relatively low pressures which occur in flight, that is 5 to 20 kilograms per square meter or 0.5 to 2 grams per square centimeter.

The Wing Feathers. The carrying surface of these feathers formed by the barbs and their spread has only a slight thickness. The scape, on the contrary, which is the main member, and which must offer great resistance to bending, reaches habitually a depth in section of three or four times the greatest thickness in the plane of the barbs, and almost always projects beyond and below it. The upper surface of the feather is consequently flatter, and offers a smooth surface to the air, having very little resistance to forward motion. This is just the opposite to the lower surface, which broken up by the shaft is sacrificed to the necessity of resistance to bending.

In certain species of birds, notably the albatross, this defect is avoided as it is in some "soarers" whose first primary wing feathers are smooth on both sides, the shaft not projecting from the barbs of equal thickness.

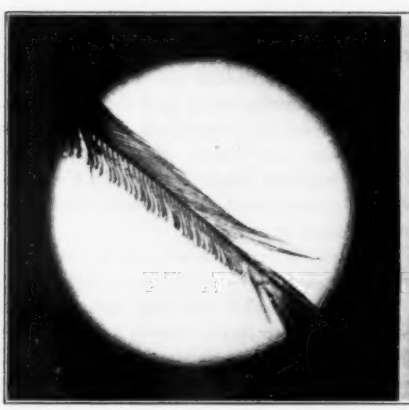

Fig. 1 Barb of a Feather With Its Barbules and Radioles

Fig. 2 Feather Structure With Intertwined Barbules

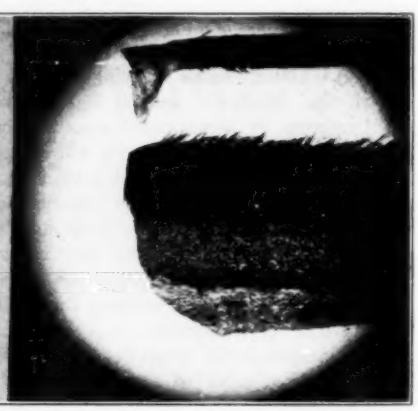

Fig. 3 Above, Barb From the Feather of a Vulture. Below, Barb From the Primary Feather of an Albatross

The primary wing feathers are distinguished from the feathers in general not only by their particular solidity but especially by the relative length of the two series of barbs, short to the front, long to the rear. This peculiarity is quite characteristic of the primary wing feather construction. It is found in the oldest ancestors of the real birds such as the archeopters, and it assures to these feathers the property of taking up, under air forces, an angle of incidence always the same for a given surface, such that the resultant force passes through the shaft of the feather, and which for a given wing feather depends on the center of pressure movement which is peculiar to it.

It is to this property of primary wing feathers that must be attributed the superiority of the birds over fliers without feathers, such as bats and flying fishes for example, as well as in the greater variety of attitudes and speeds that birds can take in flight.

The Tail. The tail of birds, formed by a fan of feathers called tail feathers, serves for their longitudinal and even lateral stabilization. This organ can not only be folded and unfolded, lowered or raised, but even twisted or warped. The shape of the tail is variable in one form or another even among the good fliers, with whom it is generally reduced to the minimum size. In certain cases it ends in two long points, as with the swallow, whose kind of life, especially in the chasing of insects to which it devotes itself morning and evening, imposes on it very rapid evolutions. In a bird which passes its existence in the woods, as the magpie, the tail is very long, giving the bird longitudinal mobility.

Finally, as observed by Leonardo de Vinci in the pigeon, the fan of the tail can be utilized as a lateral stabilizer by torsion in its plane, one point lifting when the other lowers, in a manner to present to the wind a twisted surface on which the air pressure produces a couple similar to that obtained in the airplane by manipulating the ailerons. This effect is evidently favored by the pointed tail already mentioned in the swallow, which owes to this arrangement its great agility and extraordinary maneuverability.

The Problem of Flight

From the mechanical point of view the problem presented by the flight of birds includes: (*a*) A rise from the ground or perch; that is to say, the effects of weight are overcome by having recourse to a counteracting force giving a component opposite to the weight, a force which in this case is the air resistance. (*b*) This result is attained at the expense of a minimum of power. (*c*) In addition to its equilibrium, translational motion must be obtained and the various maneuvers made which are necessary for the animal's subsistence.

With birds these various desiderata are satisfactorily obtained with a simplicity and efficiency of method that are truly remarkable. We admire the ease with which the birds go through the evolutions, the variety of maneuvers which they can perform, the extensive range of speeds at their disposal, the high speeds attained by most of them, and the ability to travel enormous distances out of all proportion to the speed and length of travel permitted to all other animals, land or sea.

It is evident that these results can be reached only by complete adaptation to the conditions which render aerial locomotion possible, and it is presumed that a sufficient knowledge of these conditions could be obtained only by study of the laws of air resistance as well as the construction of the organs of flight and the movements by which they are animated. It will be found useful to recall the essential principles of aerodynamics, limited to those which are indispensable for comprehending the observations and the experiments which follow.

Resistance of the Air

Air resistance is a force made evident when a body moves

through the air. It is manifested most often under the aspect of "resistance to further movement." That is to say, in order to keep a body immovable in moving air, a certain force must be expended, or to keep a body moving in the air, it is necessary to expend power continuously. The quotient of work done divided by distance covered is a force. This force, which can be measured in many cases, constitutes the reaction which is equal and opposed to the air resistance. To measure the force necessary to maintain a body in movement at constant speed relative to the air, means to measure the intensity of the resistance of the air on the body.

All methods of experimentation in this matter are based upon this statement. It is the measure of the intensity of the air resistance plus the determination of its direction, its kind, and its point of application under all possible conditions, which constitutes the object of aerodynamics. At the present time, and especially from the point of view of the present study, aerodynamics is largely an experimental science. Various physicists have been able to conclude from their tests within the limits of

FIG. 4 PRIMARY FEATHER OF A PIGEON SHOWING THE SHAFT AND RELATIVE LENGTH OF THE BARBS, SHORT IN FRONT AND LONG BEHIND

their experiments that, all other conditions being equal, (*a*) the resistance to the air is proportional to the density of the air; (*b*) the resistance to the air for like bodies is sensibly proportional to the surface of their projection on a plane perpendicular to the relative wind, and (*c*) the resistance to the air varies as the square of the velocity of the relative wind.

These laws known, the intensity of air resistance on a surface similar to that used in experiments can be calculated for a speed between the limits of speed obtained during the tests. The unit coefficient of air resistance is known to be different for each form of body. It is represented by the symbol K, which is the value of the air resistance under standard atmospheric conditions on a body of one square meter of frontal surface submitted to a relative wind of one meter per second. From which, taking into account the laws formulated, the intensity of air resistance F is given by the equation $F = K\frac{\delta}{\delta_0} SV^2$ in which δ represents the air density under the conditions of the problem, δ_0 the density of the air at a barometric pressure of 760 mm. of mercury and 15 deg. cent. temperature, S the frontal surface of the body expressed in square meters, and V the speed in meters per second.

Under normal conditions birds fly at low altitudes with the exception of certain birds of prey, so the relation $\frac{\delta}{\delta_0}$ is equal to one and the formula becomes $F = KSV^2$.

In practice it is preferable to introduce a non-dimensional number called the absolute coefficient of air resistance into this equation. This is usually represented by c and is related to K in the expression $K = c\frac{d}{2g}$ or $c = \frac{2kg}{d}$, in which d represents the specific weight of air (weight of a cubic meter, equal normally to 1.225 kg.) and g, the acceleration of gravity, considered constant and always equal to 9.81 m. per sec. per sec.

The formula of air resistance then takes the form $F = c\frac{d}{2g} SV^2 = c\frac{dV^2}{2g} S$ in which $\frac{dV^2}{2g} = g$ is no other than the dynamic air pressure which is registered directly by a pitot tube.

It is clear that c neither depends on air density nor nature of the system of units used. It varies with the form and relative dimensions of the body submitted to the air forces, very often also with the position of the body in the direction of relative wind, and must be determined experimentally in each case, hence the usefulness of aerodynamic laboratories.

Some values of c obtained in a tunnel on some characteristic forms of bodies are given in Table 1. (Values from Eiffel.)

TABLE 1 SIZE OF COEFFICIENT c FOR SOME BODIES

Form of body	Value of c
Hemispherical concave cup	1.400
Disk	1.097
Cylinder with plane bases (axis parallel to the wind)	0.805
Hemispherical convex cup	0.563
Cylinder with hemispherical bases (axis parallel to wind)	0.241
Sphere	0.161
Tapering body	0.145 to 0.113

From an examination of Table 1, all other factors being equal such as speed and frontal surface, the resistance of the air on two different bodies, a hemispherical concave cup and a streamlined body for example, are as 10 to 1.

From this point of view the bird whose body is well streamlined with the longitudinal axis parallel to the direction of the wind, with both frontal surface and coefficient c diminishing and with the claws hidden under the down, would appear to have every natural advantage, and ought to offer very small resistance to the air. It can then, while expending little energy, change its position very quickly. This distinctive characteristic is found to a remarkable degree in the flight of birds.

PROPERTIES OF WINGS

Of all bodies there is but one, the sphere, which always gives, whatever its position, a resultant parallel to the relative wind and in the same direction. All other bodies, even those symmetrical about some plane, such as disks of varying thicknesses, cylinders, spindles, etc., give a resultant sometimes parallel to the wind, at other times inclined to the direction of the wind. Experience shows that the resultant depends on the position of the body in relation to the wind. In most cases, however, the angle included between the resultant and the direction of the relative wind is so small that one neglects it and combines the resultant F with its projection on the line of relative wind.

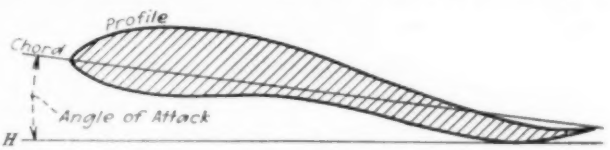

FIG. 5 PROFILE, CHORD, AND ANGLE OF ATTACK OF A WING

On certain bodies, however, when placed in certain positions, the angle included between the resultant and the trajectory can become very large, nearly 90 deg. Thin planes in particular show this property at small incidences as do also a large number of bodies called wings, characterized by their profile, form, and elongation.

PROFILE, CHORD, AND INCIDENCE OF A WING

The profile of a wing is the shape of a section of this wing in a plane parallel to the relative wind, and perpendicular to the line along which the spread of the wing is measured. In this profile, conforming to the definitions generally adopted at the present time, a chord is the straight line included between the front and rear points of the section.

The angle of attack is the angle included between the chord of the wing and the direction of relative wind. This angle

serves to define the position of the wing with respect to the trajectory. It is a conventional term whose value is related to the definition of the chord. It is important not to attribute to it any other significance, and especially, not to think that the lift of a wing is reduced to zero at zero degrees and becomes negative at negative angles. Experience, on the contrary, shows that, for curved profiles analogous to those of a bird's wing, and for a chord defined as above, for incidences of the order of —3 deg. and even —4 deg., positive lift may still result.

Form and Surface of the Wing

The form of the wing is called the projection of its contour when it is spread on a plane perpendicular to the plane of symmetry and passing through the principal chord. The surface limited by this contour is called surface S of the wing. This

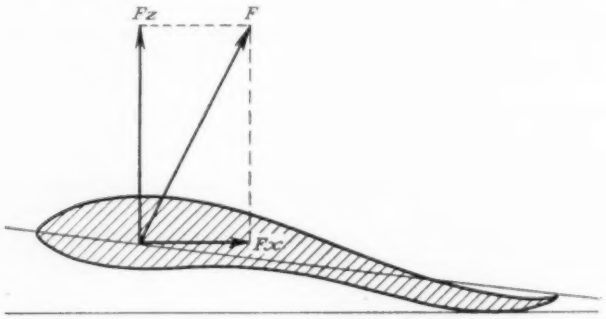

Fig. 6 Components of the Resultant Force on a Wing

definition should be contrasted with that other quite different one, of the surface of bodies other than wings, which should always be called frontal surface or area. In practice the wing is spread out on a plane, the contour of it is drawn, and the area of the figure thus limited is measured.

Spread and Elongation

The maximum transverse dimension with wings spread out is called span b, that is to say, the distance roughly included between the tip of one and the tip of the other.

The aspect ratio is the relative span, that is the relation of the span b to the mean width of the wing or the length of the mean chord l_m. With the usual irregular form of birds' wings, due to the difficulty of measuring the mean chord, and the relative facility of obtaining the wing area by the aid of a planimeter, for example, one finds the aspect ratio by the relation: $R = \frac{b^2}{S}$, since $S = bc$.

The Resultant F and Its Components F_x and F_z

Wings in general, at small incidences, possess the characteristic property of giving a resultant almost perpendicular to the relative wind. It is this property which benefits all flying organisms or mechanisms in dynamic flight, that is to say airplanes as well as birds. At small angles in fact, the resultant F of air resistance projected on two axes, one parallel and the other perpendicular to the trajectory, will give a small component F_x parallel to the relative wind and a component F_z, more important, perpendicular to the wind. (See Fig. 6.)

With birds, in contrast to airplanes, the body and wings being inseparable, one cannot do otherwise than consider them as complete systems in the same capacity as an isolated wing. As a result it is proper to determine not only the absolute coefficients c of air resistance at the various necessary incidences, but also the coefficients of lift c_z and of drag c_x on the organism

Extract from descriptive notes (not published).

of the bird considered as a whole, which are given by the equations:

$$c_z = \frac{F_z}{\frac{dV^2}{2g} S} \qquad c_x = \frac{F_x}{\frac{dV^2}{2g} S}$$

Knowing two of the magnitudes F, F_z and F_x or c, c_z and c_x, one can always find the third as by definition:

$$F = \sqrt{F_z^2 + F_x^2} \quad \text{and} \quad c = \sqrt{c_z^2 + c_x^2}$$

Moreover if the magnitudes could be obtained with accuracy they would allow, as is done in aeronautics, the drawing of a polar diagram or "polar" of the bird, that is to say, a graduated curve of incidences, the projection of each point of which on two axes perpendicular would give: one the component F_x and the other the component F_z of air resistance, the latter always represented on graphical charts, by almost universal consent, in a scale either one-fifth or one-tenth the scale of F_x. From this "polar" on which F_x and F_z are taken proportional to c_z and c_x, can finally be deduced all the facts necessary for calculation of the conditions under which gliding flight and propelled flight are effected.

The study of "flapping" or ornithopter flight, in the light of this discussion, still presents very serious difficulties on account of the continual variations of surface, angle of attack, and speed

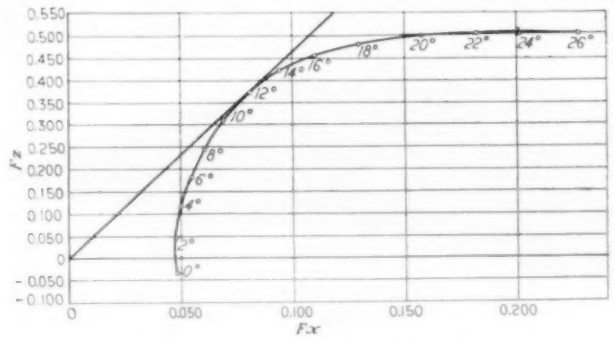

FIG. 7 TEST OF A SWALLOW IN A WIND TUNNEL

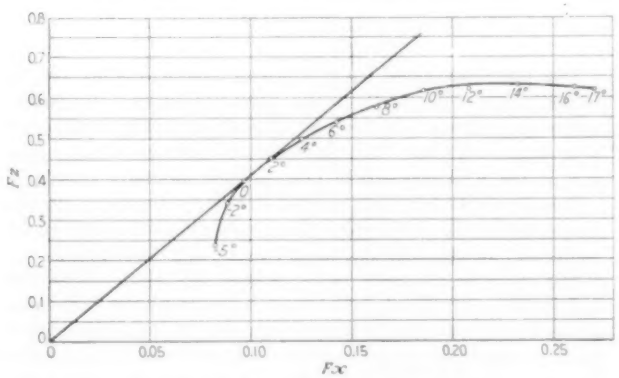

FIG. 8 WIND TUNNEL TEST OF A CHEEL

which for a given weight depend precisely on the surface and the incidence.

POLARS OF BIRDS

Various experimenters have attempted to draw the polar of a bird, notably the late J. L. Nayler and L. F. G. Simmons on the one hand and W. L. LePage (1923) on the other. The results obtained by these experimenters are given in tables and graphs, and are compared with the aerodynamic characteristics of a wing and of an efficient glider.

EFFICIENCY

In every case the importance is seen for the glider, living or mechanical, to provide for a given lift a small resistance to the air or, which means the same, that the ratio lift/drag (expressed L/D) be as large as possible. The value of this relation is independent of the units employed, and within the limits which interest us, of the dimensions of the glider and the relative velocity.

The figures of the fourth column of Tables 2, 3, 4, and 5 can then serve for a comparison of the two birds, the isolated wing and the glider. It is seen that each one of these presents a maximum L/D at a certain incidence, viz.:

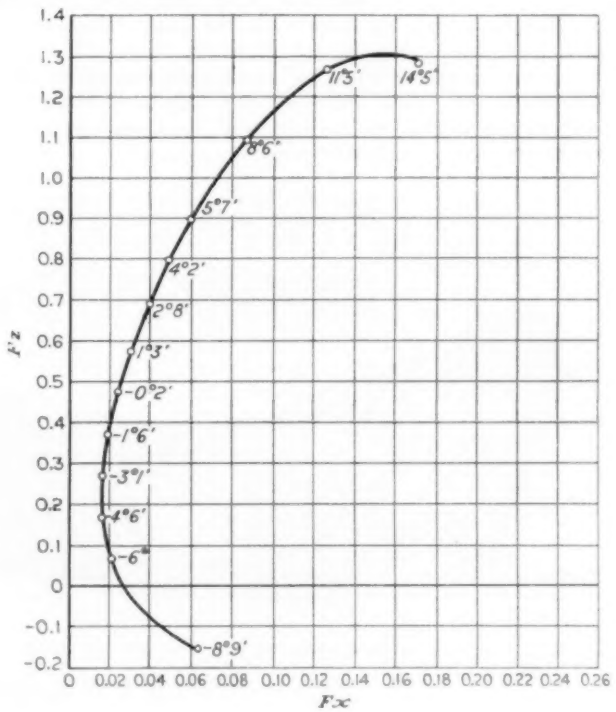

FIG. 9 POLAR DIAGRAM OF THE WING OF GÖTTINGEN NO. 426 SECTION

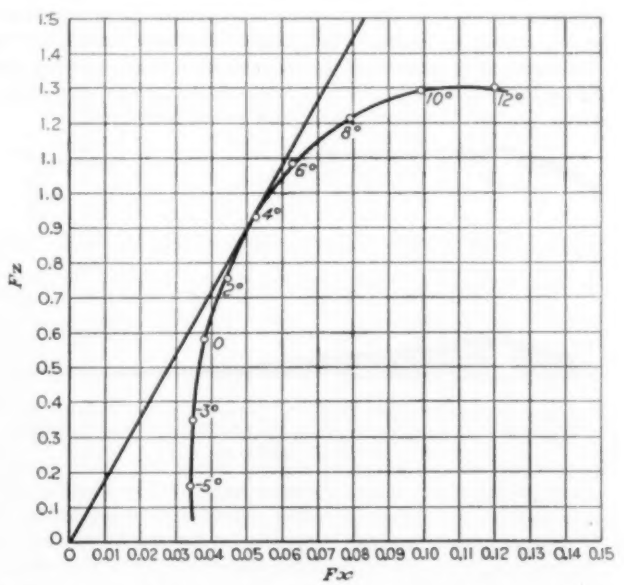

FIG. 10 POLAR DIAGRAM OF THE GLIDER FLORINE FURNISHED WITH A GÖTTINGEN NO. 426 WING SECTION

For the swallow	4.52	at	12 deg.
For the cheel	4.125	at	1 deg.
For the wing 426	17.90	at	—0.2 deg.
For the glider	17.75	at	4 deg.

On the diagrams Figs. 7, 8, 9, and 10, the angle of best L/D is found by drawing a tangent to the polar curve from the origin of the axes. The point of tangency gives the angle of maximum L/D.

The aerodynamic characteristics of the wing and of the glider are then far superior to those of the two birds exposed in the tunnel. Definite conclusions should not be drawn unless there is sufficient guarantee regarding the circumstances under which the graphs are drawn. Probably the tests were made with stuffed birds which do not have much in common with the conditions in which a living bird flies.

ing of the barbs, and in the albatross and petrel the defect does not exist. The primary wing feathers of these birds, the only ones which are exposed to the wind above and below, are smooth on both faces, the barbs near the scope having exactly the same height as the rib (Figs. 3 and 12). This peculiarity reduces air resistance, and consequently a certain improvement in efficiency results. Between a wing feather of common type and the first primary wing feathers of the albatross, there is all the difference which would exist between two airplane wings one with fabric only on the top surface and the other covered on both surfaces.

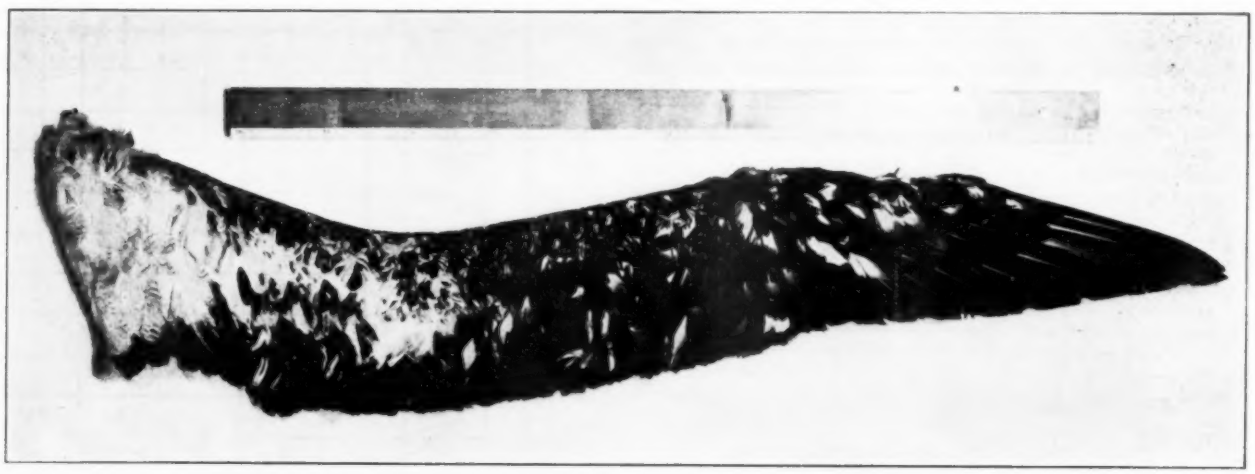

FIG. 11 OUTSPREAD WING OF AN ALBATROSS. THE SCALE IS ONE METER LONG

INFLUENCE OF THE LINES OF THE BIRD ON ITS AERODYNAMIC CHARACTERISTICS

It is on the lines, or expressed in a more general way, on the external aspects that the effect of air resistance on an apparatus or an organism depends. This aspect is characterized (*a*) by the degree of roughness of the surfaces in contact with the air, (*b*) by the shape of the body or fuselage, (*c*) by the form of the wings, (*d*) by their aspect ratio, and (*e*) by their profile.

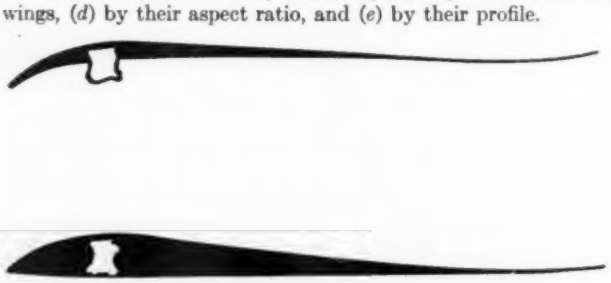

FIG. 12 ABOVE, SECTION OF THE USUAL TYPE OF PRIMARY WING FEATHER. BELOW, SECTION OF THE PRIMARY WING FEATHER OF THE ALBATROSS

The profile of the wings appears in general to be less than the other aerodynamic characteristics of birds. The lower face of the primary wing feathers, especially, is marred by the ribs of the feathers, veritable spars placed perpendicular to the relative wind, which certainly result in a definite increase in the horizontal component of the air resistance on the wings (Fig. 12). This defect is observed in most birds, including the condor and vulture, which, nevertheless, are reputed to be good soarers; also the swallow and the swift, birds that have always been considered as particularly fine examples of efficiency. In the duck, for example, this defect appears to be lessened by a slight thicken-

The more favorable these different characteristics are, the better will be the L/D of the given organism. Birds have bodies covered with feathers of which down is the smallest and most numerous form. The coefficient of resistance in the direction of the relative wind in normal flight is really very small, and varies little from one species of bird to another. For this reason particularly the good fliers can be considered as well equipped and even favored when compared with airplanes.

The shape of the body is an element of greatest importance and varies with the species much more than the consistency of the down. With migrating birds, and marine web-footed birds in particular, the shape is very nicely outlined, larger toward the front, tapered toward the rear, all by smooth, curved lines. The section between the head and the body is filled up by the down. With the sedentary species, on the contrary, these details are more or less neglected or sacrificed for other considerations. Often it appears for esthetic reasons that the birds belonging to this category possess plumages and appendages of an ornamental aspect. These obviously play no role in flight, and can only increase the resistance to forward motion.

The form of the wings in good fliers is, in general, very efficient. Experiments in the tunnel show that it is the elliptical wing which, all test factors being equal, has the best aerodynamic qualities, and that there are no great differences between one wing and the other, if one compares them with forms similar to the ellipse, such, for example, as trapezoidal wings with the smaller base on the outside and rounded corners. The greater number of wings of birds can be likened, when they are spread out, to ellipses, trapezoids, or triangles. These different contours result in an elliptical distribution of lift all along the span which seems to be as favorable for the carrying surfaces of airplanes as for natural wings.

The experimental researches of G. Eiffel, the theoretical works

of Joukovsky, Kutta, Prandtl, etc., show, on the other hand, the influence of aspect ratio. Their researches show that the drag diminishes when the aspect ratio increases, and that this drag must be considered as the sum of two partial resistances called drag of profile, and induced drag, such that the coefficient of total drag c_x must equal the sum of the coefficients of the profile drag c_{xp}, and of the induced drag c_{xi}, that is to say that

$$c_x = c_{xp} + c_{xi}$$

Experience shows that c_{xp} is connected with the form of the profile of the wing, and that for small incidences it remains constant for all aspect ratios. When the profile is very smoothly curved c_{xp} is small. The biconvex sections, for example, give the smallest values of the profile drag.

The induced drag is determined by distribution of the lift which depends on the form of the wing through interference of other parts nearby, and in particular by the aspect ratio. For a given value of c_z it diminishes with increase of R. For a certain aspect ratio the values of c_{xi} are given by the formula:

$$c_{xi} = \frac{1}{\pi} \cdot c_z^2 \frac{S}{b^2}$$

In this equation S/b^2 is the reciprocal of the aspect ratio, and consequently, is equal to I/R which represents the ratio of the span to the mean chord. It shows that if the aspect ratio becomes infinitely large, c_{xi} disappears. At this point there remains the profile drag, which can therefore be defined as the drag of a wing of infinite aspect ratio, or replacing the drags by their absolute coefficients,

if $$c_{xp} + c_{xi} = c_x$$

then $$c_{xi} = 0$$

These deductions compare very favorably with experimental evidence at the angles used by flying organisms, and other things being equal, the total drag of the bird will be inversely proportional to its aspect ratio, i.e., birds with the highest values of aspect ratio will have the highest L/D ratio. One may also conclude that for different values of R with the same weight, form, profile, etc., the angle of attack is also different, the angle being smaller for the higher aspect ratios. It has also been determined experimentally that the angle of best L/D as well as the angle for minimum power is larger for the higher aspect ratios and increases with an increasing difference between these two angles.

Finally, it is seen that an organism should fly at the angle of best L/D in order to offer the least possible air resistance (in aeronautics this angle is called angle of minimum power required), and that birds with very long, narrow wings will support a unit load larger than the others at equal speeds.

These many properties and advantages of high-aspect ratios will be mentioned several times in the course of this study, it being understood that it is due primarily to them that certain birds can claim superiority over others, for example, the swallow over the pigeon and the albatross over the sea gull.

Work and Useful Power

Let us imagine a bird following a horizontal trajectory at a constant speed V. In this case $F_x = W$ and the resistance $F_x = \frac{W}{L/D}$.

We shall see further on that the useful power P_u represented by the motion of the bird ought to be the product of the resistance F_x and the speed, let it be:

$$P_u = F_x V = \frac{W}{L/D} V$$

At a given speed P_u will then vary with F_x. That is to say, the L/D ratio will be better, and the bird will fly at a more favorable angle. One can also consider F_x as the product of the dynamic pressure by the sum of the drags which signifies that, for a given weight, the resistance to the air will be small when its parallel components are small, that is, $qSc_a = D_a$ the parasite drag, $qSc_{xp} = D_{xp}$ the profile drag, and $qSc_{xi} = D_{xi}$ the induced drag. The useful work which the horizontal movement of a bird requires per second can then be expressed by

$$P_u = V(D_a + D_{xp} + D_{xi})$$

It results from this that each fault in the line of the body upon which depends D_a, each factor in the construction of the wing feathers that might affect the profile of the wing on which D_{xp} depends, and insufficient aspect ratio which increases D_{xi} will make the bird more easily fatigued, for fatigue is linked with the useful power and also to the efficiency. This term efficiency, employed in matters relative to animal mechanics, brings us into a field that is still extremely mysterious and raises problems which, from our point of view, must be considered as unsolved at the present time. There will be no longer any question, then, but that of the motive power of living creatures, since they expend their energy in movement, lifting or propelling themselves. The work which one causes them to do many times for the profit of man, for example, and in relation to which their efficiency is calculated, is furnished by the excess of power with which all animals are endowed, and which in a moment of strain can reach a very high value, while it diminishes progressively in proportion to the duration of effort, and to the approach of fatigue. It is well understood that the idea efficiency thus understood has not much in common with the relation P_u/P_m, which would interest us if it were possible to define and determine the motive power P_m.

To relate these ideas to the polar diagram, the useful power which the flight of the swallow represents at different angles of incidence in moving itself at a given speed would be equal if the bird weighed 0.020 kg., probable weight, and possessed a supporting surface of 0.00364 sq. m., to:

$$P_u = F_x V = \frac{W}{L/D} \sqrt{\frac{W}{c_z \frac{d}{2g} S}}$$

which gives, for various incidences, the values shown in Table 6.

TABLE 6 USEFUL POWER REPRESENTED BY THE FLIGHT OF THE SWALLOW AT VARIOUS INCIDENCES, IN KG-M. PER SEC.

Incidence	4°	6°	8°	10°	12°	14°
Kg-m., P_u per S_k	0.2440	0.1375	0.0967	0.0775	0.0685	0.0637
Incidence	16°	18°	20°	22°	24°	26°
Kg-m., P_u per S_k	0.0680	0.0773	0.0897	0.0972	0.1068	0.1220

From these figures one can deduce that under those conditions which appear most favorable, that is to say, at the incidence of 14 deg. which appears to be that of the minimum of power, P_u would be equal to 0.0637 kg-m. per sec., the loading per horsepower being only

$$\frac{0.020 \times 75}{0.0637} = 23.5 \text{ kg.} \qquad (51.7 \text{ lb.}) \text{ per hp.}$$

greater than the extremes of loading used in airplanes, but less than the usual loads of living motors per useful horsepower. In fact it is known that there is not a vertebrate animal capable of developing by continuous effort such power for such a relatively small weight. It would therefore appear that the re-

sistances given by the polar diagram must be considered as excessive. For this incidence of 14 deg. the mean speed of the bird would be of the order of

$$V = \sqrt{\frac{0.020}{0.421 \times 0.062 \times 0.00364}}$$

$$= 14.50 \text{ m. per sec. (32.4 m.p.h.)}$$

which is certainly too low, the speed of the swallow being at least from 22 to 23 m. per sec. (49.3 to 51.5 m.p.h.).

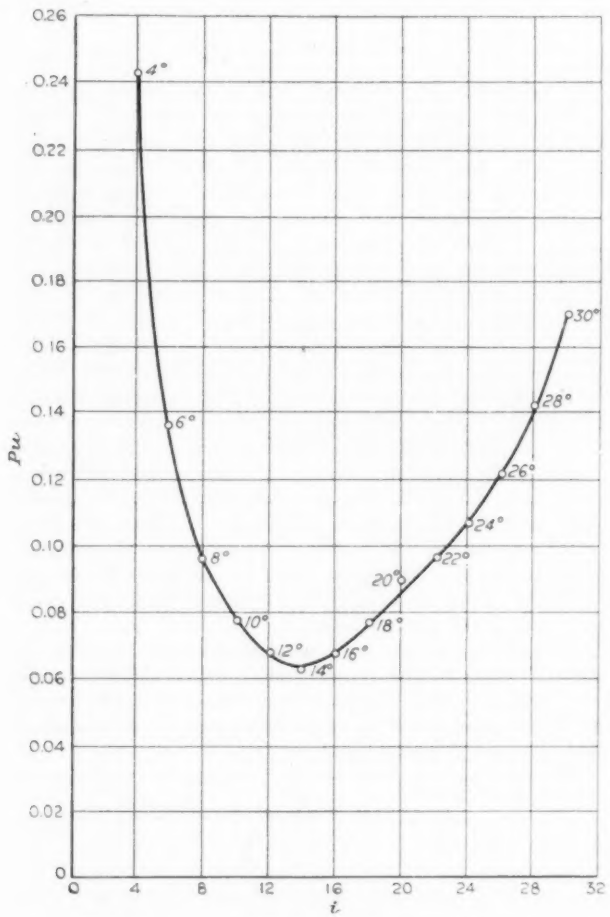

FIG. 13 GRAPH OF POWER EXERTED BY A SWALLOW

It is true that at small angles, eight degrees for example, the power curve admits of greater speeds, of the order of

$$V = \sqrt{\frac{0.020}{0.243 \times 0.062 \times 0.00364}}$$

$$= 36.30 \text{ m. per sec. (81.3 m.p.h.)}$$

which, this time, appears greater than the normal speed of the bird.

Table 6 shows that for this law the useful power is from 0.0967 kg-m. per sec., which represents only 16.6 kg. (36.6 lb.) per hp. of useful power, a value absolutely false, that is to say, much too small for a living motor. A swallow of the same weight and surface as that exposed in the tunnel, but which would present the aerodynamic characteristics of the glider of which Fig. 13 shows the polar diagram, would utilize for P_u the values of power shown in Table 7.

TABLE 7 USEFUL POWER REPRESENTED BY THE HORIZONTAL FLIGHT OF AN IMAGINARY BIRD WHICH WOULD HAVE THE SAME POLAR DIAGRAM AS THE GLIDER FLORINE

i	—5°	—3°	0°	2°	4°	6°	8°	10°	11° 30′
P_u	0.0462	0.0317	0.0162	0.0138	0.0119	0.011	0.0112	0.0136	0.01525

A comparison of these figures with those of Table 6 shows that from the point of view of the necessary power, the superiority of the glider is even greater than was indicated by the values of total resistance at different incidences and that the P_u minima of the glider and the swallow are between them as $\frac{0.011}{0.0637} = \frac{1}{5.79}$, that is to say, that the swallow submitted to the draft by Messrs. Nayler and Simmons would have to exert under the same conditions and under the most favorable circumstances, nearly six times the power of a good glider of the same dimensions. A swallow as well adapted for flight as that one, could, as an extreme case, present a load per useful horsepower of

$$\frac{0.020 \times 75}{0.011} = 136 \text{ kg.} \qquad (300 \text{ lb.}) \text{ per hp.}$$

which appears much more nearly normal. By way of comparison, a man weighing 75 kg. (165 lb.) who could furnish 10 kg-m. per sec. of useful power in a sustained effort and 40 kg-m. per sec. in an exceptional case, would represent a horsepower loading of 562.5 to 140 kg. per hp. (1240 to 308 lb. per hp.).

POSITION OF THE RESULTANT OF AIR RESISTANCE

It is known that the resultant of air resistance on a wing or a system of wings changes its point of application when the angle of attack varies. Occasionally, some rare profiles show, at small incidences, a constant position of the center of pressure. According to G. Eiffel, the center of pressure is a certain point in space through which the resultant passes. In our case, we may designate by center of pressure, the point where the resultant force crosses the mean chord of the wing profile, a point which is necessarily situated in the vertical plane of symmetry of the bird. In considering an isolated feather the same junction chord and resultant force line is taken.

The phenomenon of center of pressure movement is very important for the reason that its behavior determines the stable or unstable equilibrium of the part affected by the air forces. Experiments have shown that while the position of the resultant depends on incidence, the movement of it is related in a wing, to the profile, and in a system of wings, to the profiles, but also especially to the relative incidence of the front and rear wings or as it is sometimes called, the longitudinal dihedral angle.

Given the infinite number of profiles and combinations possible between wings and tails, it is not possible to express the movement of the center of pressure by a law. Each case is a special case. Nevertheless, among the possible movements and within the limits of incidences used in flight, one can distinguish three kinds, viz.:

(*a*) The resultant approaching the leading edge when the angle of attack diminishes and vice versa,

(*b*) The resultant retreating from the leading edge when the angle of attack diminishes and vice versa,

(*c*) The resultant not moving when the angle of attack is varied.

In the first group (*a*) is found: thin plates, the profiles in *S* form or double curvature, the greater number of thick or incurving profiles, but only when utilized at negative incidences in slotted wings and systems having a positive longitudinal dihedral. (Fig. 17.)

In the second group (*b*) are included incurved or thick profiles, but at small incidences only.

In the third group (*c*) are found certain unusual profiles, hardly interesting from point of view of lift and efficiency.

The graphs of Figs. 15, 16, and 17 give some examples of the movement of center of pressure on various profiles and a stable wing system.

Stability or Instability of Static Equilibrium of a Wing or Wing System

In the study of natural flight it is necessary to consider the character of equilibrium in the case of a complete bird in gliding

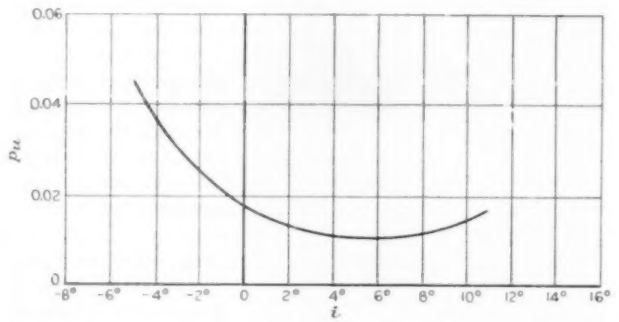

Fig. 14 Graph of Useful Power Exerted by a Hypothetical Bird Having a Polar Similar to That of the Glider Florine

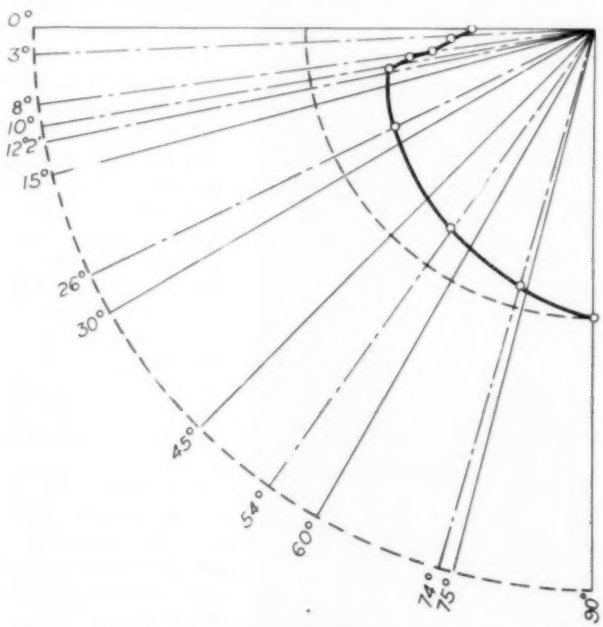

Fig. 15 Center of Pressure Movement on a Plate 85 × 15 Centimeters

flight, and in the case of an isolated feather submitted to air forces.

Let us apply to these two cases the general condition of equilibrium of bodies which is satisfied when the sum of the moments with relation to some axis is zero, where the position of the body or of the feather with relation to the direction of relative wind is constant.

In the case of a bird in gliding flight two forces are to be considered in the same plane, gravity and resultant air force, but gravity acts as though the total weight were concentrated at the center of gravity; therefore, the bird will not be subjected to any couple since the resultant will pass through the center of gravity, and there will be equilibrium only at one definite angle of attack. To put it differently, in the case of a glider or a bird descending in gliding flight, the angle of attack for a given wing position depends upon the position of the center of gravity.

If the resultant does not take up this position of equilibrium with the range of angles used in flight, the glider is unstable and

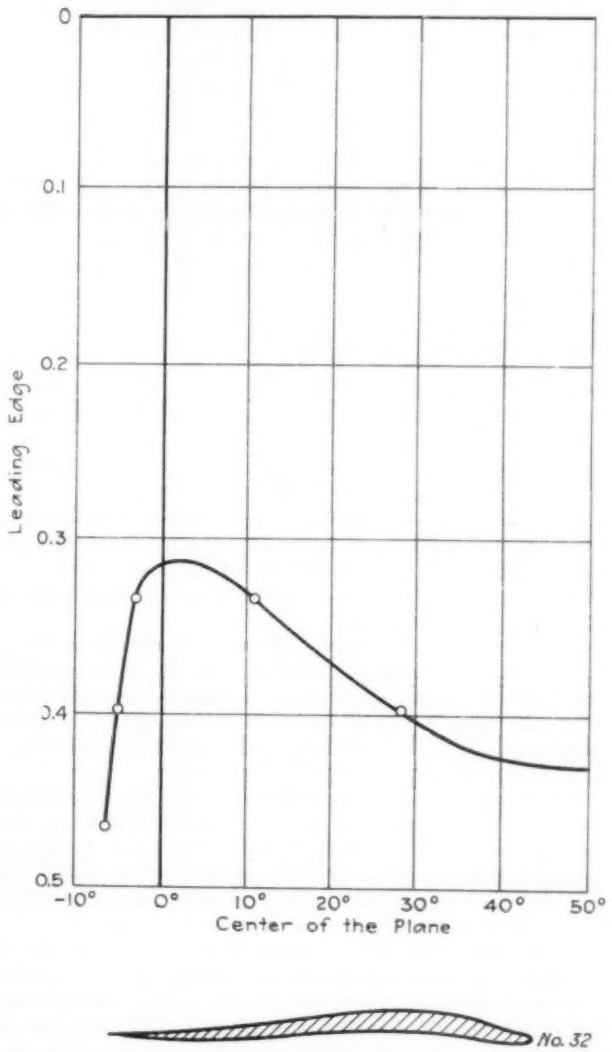

Fig. 16 Graph of Center of Pressure Travel on the Eiffel No. 32 Section

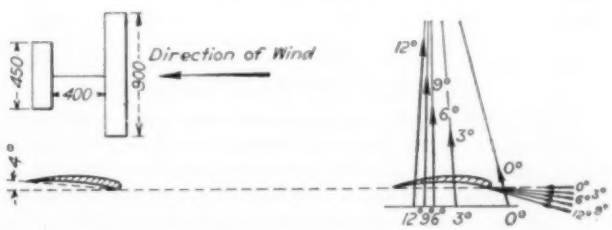

Fig. 17 Portions of Resultant Air Force on a System With Positive Longitudinal Stability

practically useless. In the second case in order that the feather may not have any tendency to turn about its shaft in a relative wind of constant direction, it is necessary that the sum of the moments with relation to the axis of this shaft shall be zero. There can be only the moment of air resistance and the moment

of gravity with relation to this axis. The moment of gravity is zero when the center of gravity is on the axis and is negligible in all other cases on account of the light weight of the feathers. There remains practically then with relation to the shaft only the moment of air resistance which is also zero when the resultant cuts the axis. From this it can be seen that it is the position of the shaft with respect to the leading edge of the feather which determines its angle of attack. There persists still, nevertheless, another moment, with respect to the insertion or fitting of the feather, but this is balanced by the resistance of the tissue itself and of the shaft serving as a strut.

In every case, the angle of equilibrium imposed by the distance between the leading edge of the supporting surfaces and a transverse axis will be stable or unstable according to the behavior of the center of pressure movement on the wings or the feather.

If the resultant advances when the angle diminishes, that state of equilibrium is stable. It is easy to see in fact, that any variation in the angle produces a couple which tends to bring the feather of a bird back into its original position. This is the case for all the profiles and systems of group (*a*). It is also seen that if the resultant recedes when the angle of attack diminishes, the least change in that angle, either increase or decrease, will bring into play a couple tending to turn the wing still further in that direction, rendering the system unstable. The profiles of group (*b*) are included in this category.

When the resultant does not change its position in the range of angles used in flight, the state of equilibrium does not depend upon the condition of coinciding center of pressure and center of gravity, or for the feather, on the center of pressure passing through the axis of the shaft.

For a condition of stable equilibrium, for a glider as well as for a wing alone, when the resultant advances as the incidence diminishes, the angle of attack will be smaller when the center of gravity (case of a bird) and center of the shaft (case of the feather in general and primary wing feathers in particular) is near the leading edge of the supporting surface.

For example, if an airplane can fly at small angles, it is because a vertical line through the center of gravity passes, as a rule, through a point on the wing, between 25 per cent and 33 per cent of the chord length, measured from the leading edge. One presumes that in a normal position of gliding flight, the situation ought to be almost the same with the bird flight.

On the other hand, if at a certain height, a covert, which is a symmetrical feather, is released, it descends along a vertical trajectory, while a primary wing feather whose rear barbs are longer than the front barbs, descends in a spiral, each element of the feather describing a helical trajectory which has the effect of reducing the angle of attack of each of its elements, and allows them to glide at the small angle related to the position of the center of gravity.

Experimental Verification of the Stability of Equilibrium of Birds and Primary Wing Feathers

It is relatively easy to prove and even verify qualitatively, the stability of primary wing feathers taken individually and birds considered as a unit during gliding flight. For this it is sufficient to take in hand a wing feather coming from some large bird and move it to and fro at arm's length, quite rapidly, allowing the extremity of the shaft, called the stem, which is circular in section, to turn freely about its axis. It will be noticed that the feather assumes in each direction an angle of attack which is fixed as soon as the direction of motion has changed, a proof of stability. The angle, which is constant for each face of the feather, appears very small if one is using the first of the primary wing feathers whose front barbs are relatively the shortest with all birds. It is due directly to this property that the primary wing feathers tend, when they are subjected to air forces, to take up an angle of attack which is always the same; at which angle the resultant passes through the shaft of the feather, the actual angle being determined for each feather by the center of pressure movement peculiar to it.

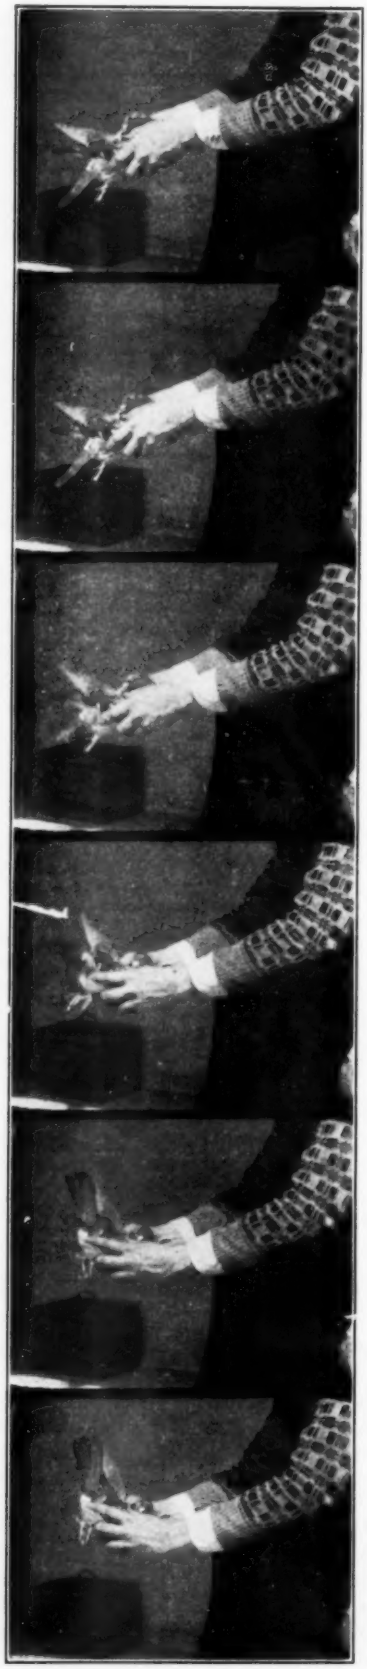

Fig. 18 Section of Film Showing the Reactions of a Pigeon When Suddenly Placed in a Diving Attitude. The Movement of the Tail Should Be Noted. The Center Views Give an Idea of the Quickness of the Reaction

Moreover when a pigeon, for example, descends in gliding flight, it carries the wings forward little by little with the intention not only of spreading them, but especially of increasing their angle of attack. If the birds were unstable they would evidently make the opposite movement. In still more direct fashion, when a pigeon is taken in one's hand and oscillated briskly about a transverse axis, it spreads the tail fairly strongly, and lifts it with a quick movement if it is put at a negative angle or drops it with a movement no less rapid if it is put at a positive angle. These reactions are too quick not to be instinctive. They are representative of the actual movements of the bird in flight and these movements are those of a stable glider. (Fig. 18.) It was evident, besides, that the movements of the resultant air force must have had a stabilizing effect.

Variation of Angle of Attack in Flight

As an example of application of the preceding discussion, imagine a bird in gliding descent.

If the resultant did not pass through the center of gravity a couple would come into play which would have the effect of turning the bird about a horizontal transverse axis. If the incidence of the bird does not vary spontaneously, it means that the sum of moments with relation to this axis can be constantly brought back to a zero value.

Suppose that the bird at a given moment draws back its wings, for example, by turning the hand through several degrees in its own plane, articulated about the wrist bone. In this case, not only is the center of gravity of the whole bird moved back through a very small distance, but also the center of pressure which passes behind the vertical line through the center of gravity is moved back very perceptibly. Under the effect of the couple thus produced, the bird dives, its angle of attack diminishes, the resultant moves forward, and finishes by passing again through the center of gravity. Equilibrium is at once established but at the price of a change in position of the body which is shown by the decreased angle of attack.

Similar reasoning shows that a displacement of wings toward the front would have produced an increase of angle. Following this reasoning it may be said that, with birds, a rearward movement of the leading edge of the wings produces a diminution of the angle of attack, and a forward movement of the wings produces an increase of angle of attack. Moreover, it should be noted that the angle of equilibrium of a feather is small when the zone situated in front of the shaft is narrow with respect to the surface located behind it.

Gliding Flight

There exist many more organisms making use of gliding flight than appear at first sight. In fact, among creatures which use the glide constantly, are found not only birds, but many insects, some mammals such as bats and different kinds of squirrels, even winged seeds and pollen dusts. In principle there are no flying organisms which cannot at least make a gliding flight. It is true that to use the term gliding flight to describe the movements of all these creatures, it is necessary to generalize and to give to this expression a definition broad enough to make it include all possible varieties of descent at constant speed following trajectories more or less inclined to the horizontal.

It is known that in space, bodies fall vertically with an acceleration which is the same for all, about 9.81 m. per sec. per sec. As a result all bodies dropped from a certain height, whatever their specific weight, form, or size, would reach equal speeds at the end of a certain time were it not for the resistance of the air. It is the air resistance that, in our atmosphere, limits the speed of bodies and imposes on them a trajectory which is vertical in only a few cases. In the broadest sense, gliding flight is a descent in which the resistance of the air modifies the circumstances of the fall as well as the speed. As usually referred to, gliding flight is the descent of a body at constant speed following a trajectory somewhat inclined to the horizontal. Gliding flight can further be distinguished from falling by the stability which characterizes gliders and parachutes, and permits them to keep a definite position with relation to their trajectory. It is true that under this definition the descent of a projectile falling from a sufficient height for it to reach a constant speed before grounding is a gliding flight. That, however, is an abuse of the definition. Nevertheless, in the field, of discussion, where we consider only lightly loaded organisms, the term can be used in its broadest sense, and under the term "gliding flight," can be listed the movement of all bodies possessing the facility of descending at constant speed, and following a trajectory of any inclination whatever, even vertical, as for example that of tufted seeds.

There are many bodies in the vegetable world which practice all kinds of gliding from vertical descent, to gliding along a rectilinear trajectory or a spiral. Among birds there are cases of gliding flight, from descent like a parachute to the glide at constant speed following a trajectory more or less inclined to the horizon.

Speed of Birds Descending in Gliding Flight

Imagine a bird in gliding flight with wings extended. For some given position its speed is influenced from the aerodynamic point of view, by its weight, its supporting surface, which is a variable, the position of the center of gravity, a polar diagram, and a curve of movements of the center of pressure, all given. For the speed to be constant, it is necessary that the sum of the forces acting on the bird be zero, that is, it is necessary that the air resistance shall equal the weight $D = W$, and that the forces be opposite. This equilibrium is only reached at a certain speed given by the relation:

$$V = \sqrt{\frac{W}{c\,\frac{d}{2g}\,S}}$$

in which taking c, d, and g to be constants, it is seen that the speed depends on $\sqrt{\frac{W}{S}}$, that is to say on the square root of the specific loading on the wings.

TABLE 8 AERODYNAMIC DIMENSIONS OF SOME BIRDS AND ANIMALS

Name of animal	Weight "W" 16	Surface "S" sq. ft.	Wing spread b ft.	Wing loading $\frac{W}{S}$	Aspect ratio $\frac{b^2}{S}$
Condor	22.04	11.84	9.68	1.86	7.40
Albatross	16.58	5.08	9.88	3.31	19.30
Vulture	11.02	7.21	8.20	1.53	9.32
Percnopter	4.96	5.88	7.05	0.843	8.45
Andes Eagle	4.40	4.94	5.68	0.893	6.50
Raven	1.35	0.33	3.12	1.01	7.40
Wood Pigeon	1.31	0.78	..	1.68	..
Pigeon	0.99	0.625	2.04	1.59	6.60
Grey Petrel	0.95	..	3.64	0.921	12.95
Magpie	0.44	0.55	1.76	0.805	5.60
Jay	0.385	0.505	1.77	0.756	6.20
Flying Fish	0.31	0.131	1.10	2.34	9.20
Dactylopter	0.22	0.086	0.968	2.56	10.90
Swallow	0.066	0.073	..	0.903	..
Sparrow	0.055	0.154	1.115	0.358	8.10
Bat	0.040	0.126	1.15	0.315	10.50
Martin	0.066	0.142	1.315	0.540	12.07

The conclusion is that a given bird can glide with a speed inversely proportional to its specific wing loading, and this speed, for a given angle of attack, will be proportional to the square root of the weight lifted. It is evident, moreover, that a bird can choose its speed between two limits, one a minimum when the wings are spread out to the maximum, the other a maximum when the wings are completely folded to the body.

Table 8 gives aerodynamic dimensions of some flying organisms measured to conform to conventions actually used in aerodynamics.

It is interesting to compare these figures with the following. A school airplane is loaded generally with 20 to 25 kg. per sq. m. (4.5 to 5.1 lb. per sq. ft.); a commercial airplane reaches 50 kg. and more per sq. m. (10 lb. per sq. ft.) and certain record planes exceed 100 kg. (22 lb.).

The albatross has the highest aspect ratio, its value not being approached by any others. A single advantage results from this, it gives a better L/D to the bird. It is reasonable to think the body itself is modeled so as to offer a minimum resistance to the air, under the same influences which causes the increase of relative wing spread, and one is even more strongly convinced of this when sea gulls, petrels, and albatrosses are observed, whose lines are exceptionally good, and whose first primary wing feather,

at least in the case of the albatross, is made with the idea of reducing the drag of the wing. It may therefore be said that birds endowed with the highest aspect ratio are at the same time most efficient and the best soarers. In this class the albatross holds first place.

Equilibrium of the Gliding Bird

Because of the constant position of the bird with relation to its trajectory, one may conclude that the sum of the moments of gravity and air resistance applied to the whole organism is zero. This condition is satisfied only when the resultant of air resistance passes through the center of gravity and this position is only reached at a certain angle of attack. As the position

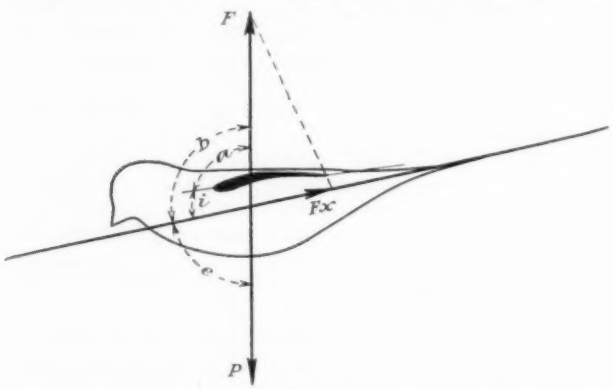

Fig. 19 Diagram of the Forces on a Bird in Gliding Flight

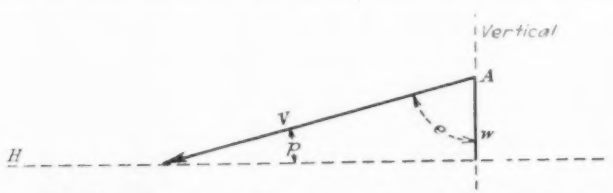

Fig. 20 Trajectory and Speed of a Bird in Gliding Flight

of the center of gravity is practically invariable, the angle of attack depends on the position of the wings, and this angle becomes smaller as the wings are moved back. Given that the size of c varies with the angle, following a law which for small angles can be considered as linear, the speed is also proportional to the square root of the angle but in an inverse ratio.

Slope of Trajectory

The air resistance must counteract the weight, for D is inclined at a certain angle to the chord of the wing. On the other hand the angle i, included between the chord and the line of flight, also has a definite value so that in order for D to be vertical the angle b included between the vertical and the line of flight is equal to the sum of the angles a and i. ($a + i = b$.) In practice the angle of inclination of the line of flight to the horizontal can be denoted by e, supplement of b, such that $e = 180° - b$. (Fig. 19.) This angle is opposite the vertex and is consequently equal to the angle between D and D_z (F and F_z) whose tangent is no other than L/D, that is to say, the efficiency. So that L/D expresses the tangent of the angle e, and the angle of gliding p, complement of e will decrease as e increases. From this it appears that the best gliders will be birds whose relative resistance is the smallest, that is, birds with well-formed bodies, long wings, and with an efficient wing profile.

Vertical Speed w

Examination of Fig. 20 shows that vertical speed in gliding is expressed by $w = V \cos e$. This speed w will vary directly with V and inversely as the angle e whose tangent is no other than L/D, the efficiency at the given angle of attack. Another effect of the high value of L/D is to reduce the height lost per unit time for any given gliding velocity.

Mechanics of Gliding Flight

When a bird descends in gliding flight it takes up a gliding angle which depends on the position of the leading edge of the wings with respect to the center of gravity. It adopts a trajectory inclined at angle e to the vertical, such that its tangent expresses the L/D of the glider at this flight attitude.

On this trajectory it maintains a speed at which its air resistance is equal to its weight. This speed depends on the square root of the wing loading, and does not depend directly either on the will or the vigor of the bird. The speed and gliding angle are therefore determined entirely by two factors, the weight per square meter and the L/D of the bird.

It should be noted, nevertheless, that the bird can modify its supporting surface on which the wing loading depends, by opening or closing the wings, and its angle of attack on which its L/D depends, by displacement of the leading edge of the wings with respect to the center of gravity. To these changes are due the variety of speeds a bird can take in gliding flight, from descents at low speed where the gliding angle is often less than five degrees, to vertical descents at high speed, wings folded (swoops of birds of prey), not to mention the parachute descents of certain vultures observed by Dr. Ahlborn in Bulgaria, during which these birds bring their wings forward so that the center of the horizontal projection of their supporting surfaces and the center of gravity of the bird are brought one above the other. The gliding angle then becomes a right angle, that is to say, the descent is along a vertical path. (Fig. 21.) In other words, a given bird, depending on the wing position and for each particular position, constitutes a glider whose weight alone is constant and whose other characteristics, surface and L/D on which depend its velocity and gliding path, are variables, although of course both of them have a maximum value.

Soaring Flight

A bird or a glider, therefore, in calm air, if it does not want to expend the necessary energy for maintaining altitude can only descend. However perfect its form may be from the aerodynamic point of view, it will inevitably come to the ground at the end of the time t, which may be expressed as the quotient of its altitude at the start h divided by its vertical speed w:

$$t = \frac{h}{w} = \frac{h}{V \cos e}$$

However, observations made by meteorological stations and conclusions formed in recent works on wind phenomena, show that air currents are rarely horizontal or of constant velocity. On the contrary at any one place, the currents change continually in speed and direction. They also increase with altitude but in decreasing fashion. Certain kinds of topography such as long slopes in the right direction, or cliffs of sufficient height, can produce oblique rising currents, which are very steady. A swell which raises the sea with vertical speeds of from 75 centimeters to 1.5 meters per second draws along a thin layer of air above it. Heating by the sun of sandy or rocky spaces devoid of vegetation or humidity can produce local ascending winds.

Now, although the horizontal current at constant speed is useless from the point of view of soaring flight, the rising currents whose velocity changes with altitude, and currents undergoing horizontal variations of speed, can furnish gliders with the

energy necessary for sustentation and enable them momentarily to maintain their height, and even to rise for a few moments without any expenditure of their own energy. The passive character of this form of flight is manifested externally by the absence of flapping which usually accompanies active flight.

Static Soaring Flight

The problem of soaring flight on an ascending current so often observed and described, notably by Mouillard, has been explained quantitively by Colonel Dorand in the Jan., 1922, number of *Aeronautique*. The theoretical principle can be formulated as follows: The speed of a glider with respect to the earth is the resultant of its own speed and the speed of the wind. Therefore in order for a bird to keep its altitude without expenditure of energy, it is necessary that the vertical component of the wind be upward and at least equal to the vertical component of the speed of the bird. The greatest speeds observed of birds being about 25 m. per sec. (case of the albatross) and their L/D being about 20, it is found that the vertical upward component of velocity of the air w_v necessary for keeping such a bird from descending will be

$$w_v = \frac{25}{20} = 1.25 \text{ m. per sec.}$$

It is evident that those birds which have learned to use ordinarily favorable atmospheric conditions, rarely find ascending currents with the exact velocity suited to their characteristics. When w_v is greater than w, there is an excess of up current over that required to sustain the bird, and it can rise with a speed, with respect to the earth, equal to $w_v - w = w_s$. When w_v is smaller than w, the bird must descend with a speed $w - w_v$ or else furnish in the form of useful work the relatively small quantity of energy necessary to lift its own weight to a height equal to w_s.

This process, called static-soaring flight, is used involuntarily and automatically by dust, inert winged organisms, and (consciously, no doubt) by animal fliers, even if flying is not their natural form of locomotion, who find themselves in the air at the time and place where the ascending current exists. Descending air currents exercise the same influence on gliders by reducing the time of falling by adding to the velocity of descent. Birds most likely to profit from this are those that have least speed and best L/D and those that by appropriate maneuvers succeed in keeping up the longest time in a favorable zone.

Vultures in the neighborhood of Dakar do this. In the morning they perch on the enormous baobabs or collect at the tops of the dunes which the wind raises along the shore from Cape Vert to Rufisque. They rise, flapping their wings laboriously, and make for other trees or ridges. This flight shows a peculiar character which distinguishes it from the flapping flight of birds. Toward mid-day when the hot sun has heated the earth they seek convection currents and congregate on this "ascending resting place," as said P. Idrac, where with wings extended they can rise and remain in the air for hours, but always above the same spot. Through the burning sunny days they can be seen thus assembled one above the other, 100, 200, 300 meters high often, turning as in an aerial merry-go-round, in a column of rising air. When the sun is hidden they voluntarily stay perched or fly from one tree to another, flapping and gliding. In the evening if frightened, they rise flapping the wings and go to find a resting place elsewhere. These birds use alternately soaring flight and active flight with flapping wings.

It is the same with the albatross and petrel whose life makes it necessary to stay in the air from morning until evening, and at sea for weeks or months at a time, perhaps. Under such conditions it may be supposed that from necessity they have developed a mode of flying which requires a minimum of power. It is noticed, however, that in the regions where they are found, for example about 42 deg. south latitude and 15 deg. east longitude at 550 kilometers from the nearest land, there are also terns, these swallows of the sea, so graceful and swift in their flight, which is identical with that of our swallows. It is hard to believe that the albatross and petrel are essentially different from any other bird submitted to the same necessities as they are. In reality the flight of the one differs less from the other than it appears, and the little terns do not expend relatively more energy than the large albatross.

With the albatross, it is true, there is more evidence of a certain skill and constant care to profit by the least circumstances favorable to sustentation. It was noticed that they came near a sail boat with 3000 sq. m. of sail rising to a height of 50 m., and here they found ascending currents which generously sustained them. Level with the water and using only the end of their primary wing feathers, they cover hundreds of meters in some seconds, wings extended, rising on the slope of the swell into the region of upward currents caused by the displacement of the wave.

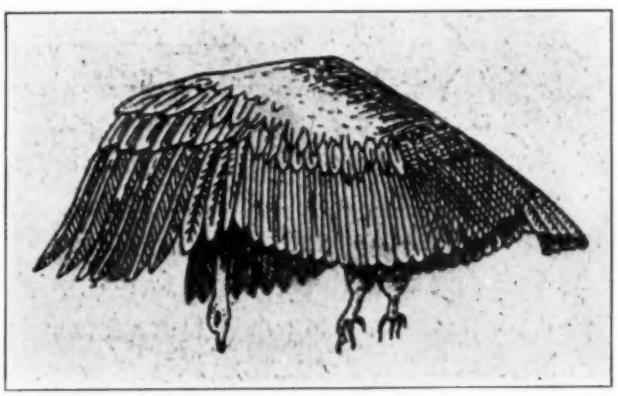

Fig. 21 Vulture Descending as a Parachute

It may be concluded, therefore, that in reality the birds best adapted for flight are those that are able to take advantage of the smallest ascending currents with the expenditure of a minimum of energy, so that they can maintain, gain, or recover altitude as the case may be, with a minimum of fatigue. Just how far they are from flying without expenditure of energy in any form cannot be measured at the present time.

Dynamic Sailing Flight

Observers, however, such as Dr. Hankin (see "Animal Flight" by E. H. Hankin, London, 1913) who studied the flight of vultures in the Indies, and P. Idrac, whose work in the South Seas preceded this study state: first, "that at Calcutta and at Agra flights of considerable duration without loss of height or speed have been observed in the absence of any wind of appreciable velocity;" second, that in the absence of swell, albatrosses maneuver for hours without flapping their wings, in successive ascents and descents from 8 to 15 meters height combined with sharp turns at top and bottom of their trajectories.

Dr. Hankin confessed his inability to penetrate the mystery of the phenomena that he observed. Idrac on the contrary has been able to establish that the albatross utilized the variations of wind velocity by continually changing altitude. "The bird maneuvers in such a manner as to place itself in layers of air having different velocities," he writes. This trick consists in creating its own relative wind in turning face into the wind when

rising (in a rising current) and tail into the wind for descending (in a descending current).

The author then analyzes the phenomenon quantitatively and concludes: The mathematical analysis of the trajectories observed, together with laws of the growth of air currents which have been determined experimentally, permit the prediction of certain phenomena in the maneuvers. Thus they require birds

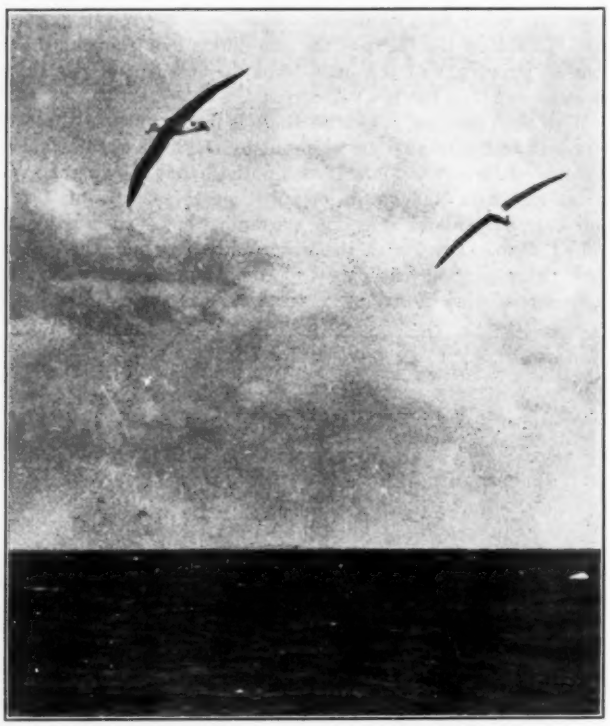

FIG. 22 GLIDING FLIGHT OF ALBATROSSES

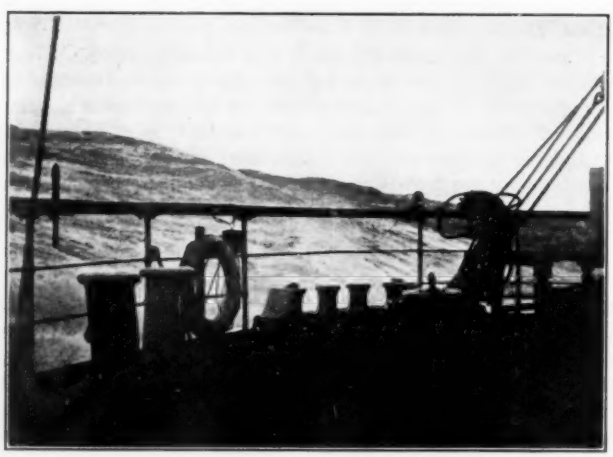

FIG. 23 THE SLOPE OF THE SWELL IN SOUTHERN SEAS PRODUCES UPWARD AIR CURRENTS WHICH ARE TAKEN ADVANTAGE OF BY BIRDS IN GLIDING FLIGHT

capable of high aerodynamic speeds, hence with strong lifting ability. The minimum theoretic wind necessary for soaring flight is of the same order of size as the observed wind. Finally the altitudes reached and the theoretical trajectories for maximum efficiency are precisely those which the birds use. (*La Technique Aeronautique*, Dec., 1924.)

In this study of a certain form of soaring flight different from static soaring flight, there is nothing new to take up. In the course of the maneuvers described, the albatross and petrel search for an altitude where the occasional changes in acceleration of the air currents in a horizontal plane may be utilized. In the latter case their flight was analyzed by Colonel Alayrac in *L'Aeronautique* of March, 1922. The changes in acceleration are taken to mean changes in the relative wind, that is to say, with respect to the bird. That does not mean necessarily an increase of real velocity of the wind. With the wind from behind, for example, a retardation of the air velocity constitutes an acceleration of the bird's aerodynamic speed.

Let A (Fig. 24) be a bird in flight under the acceleration of gravity g and also, for an instant of time, under the influence of a variable wind, from either before or behind, having a relative acceleration $+a$, i.e., in the direction of the line of flight. In this simple case, the direction of the wind being in the vertical plane of flight, the bird is affected by the resultant acceleration:

$$a_r = \sqrt{g^2 + a^2}$$

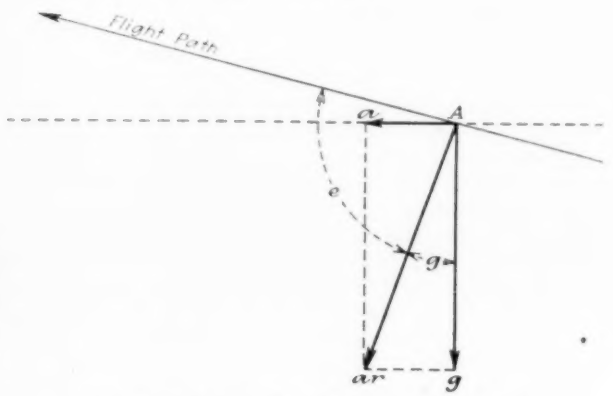

FIG. 24 TRAJECTORY OF A BIRD IN AN AIR GUST

inclined with respect to the vertical at an angle q such that $\tan q = \frac{a}{g}$.

This is just as if the direction of a_r, thus determined, constituted for the bird an apparent trajectory along which it could glide without expending its own energy, at the angle e defined previously. If the sum of the angles $(e + q)$ is smaller than a right angle, the bird descends with an angle equal to 90 deg. — $(e + q)$. If $(e + q) = 90$ deg., the trajectory is horizontal and if $(e + q) > 90$ deg., the trajectory will be inclined upward with respect to the earth and the bird will gain altitude, its line of flight being at an angle $(e + q) - 90$ deg. with the vertical. The conditions necessary in order that the trajectory at a given moment may be inclined upward or horizontal are, then, that the acceleration be positive and that the angle q be equal or larger than the angle p which is the complement to e, i.e.,

$$\tan q \geq \tan p$$

or, again, in replacing $\tan q$ and $\tan p$ by their values, that

$$\frac{a}{g} \geq \frac{1}{L/D}$$

For example, with a possible L/D of 12.5, the horizontal acceleration must be such that

$$\frac{a}{9.81} \geq \frac{1}{12.5}$$

in other words, it is necessary that

$$a \geq \frac{9.81}{12.5}$$

or 0.785 m. per sec. per sec. at least. The principal criterion of a good soarer is therefore a high value of L/D.

The accelerations will not often be positive for a bird unless it maneuvers rapidly with many turns and changes in altitude, and on this account it is necessary for the bird to possess great speed, a conclusion similar to that reached by P. Idrac and a justification of the high wing loading characteristic of the albatross.

In each case the aerodynamic speed at each instant will be

FIG. 25 CAPTIVE ALBATROSS

equal, by substituting for the actual weight its apparent value W_1:

$$W_1 = m\sqrt{g^2 + a^2}$$

$$V = \sqrt{\frac{m\sqrt{g^2 + a^2}}{c\frac{d}{2g}S}} = \sqrt{\frac{ma_r}{c\frac{d}{2g}S}}$$

Observers of these birds in their native seas are surprised to see them already in the air at break of day and to notice them in the evening during the very long twilight which, in summer, ends the day, in 42 deg. latitude. It is imposible to suppose that they could regain the land during the night, for it is often 2000 kilometers distant. One must conclude that they sleep on the water rocked by the swells as in a cradle.

In the air all day in the course of their monotonous existence, they are forced to expend the least amount of energy possible, and they adapt their flight to momentary conditions, seeking the ascending winds wherever they can be found. In between times, perhaps once a minute, especially in light winds, and always while soaring, they work hard for a few moments. When circumstances are not so favorable, they increase their speed to the necessary value by a slight effort, the flapping being so slight that it can be detected only at the wing tips, where there is sufficient movement to cause a disinterested observer to attribute to the wing tip an essential role in the normal flight of these birds.

Often during their descent, they perform this maneuver, thus acquiring a greater speed which enables them to climb vertically higher if they wish it than the point from which they started.

Thus the vultures and their cousins, the condors, as well as the albatross and petrel, divide their time between a kind of active flying and soaring which is a gliding flight practiced under favorable circumstances. Obviously it is necessary for them to expend at irregular intervals a certain amount of energy to make up for unfavorable atmospheric conditions. None of them would succeed in keeping in the air if they did not have recourse from time to time, oftener than it appears, either to propelled flight or to flapping flight, these being the active process of flight.

FLAPPING FLIGHT

This method of flying appears to be most ingenious, and perhaps the most efficient process of aerial locomotion known. It is moreover the only one, which so far man has not succeeded in imitating or interpreting, not because it has not been attempted, but because the mechanics of it are not understood.

Flapping birds do not use a propeller, and researches to discover a similar organ in the gull, for example, have been futile. The author renounced the analogy which has been established between wings and oars, and has developed a theory perhaps a little paradoxical in certain respects but which is quite rational and promises to give excellent results.

From a study of documents collected by E. J. Marey, and additional observations of birds in flight through use of slow motion pictures made at the laboratory of Rhode St. Genese and at the Institute of the Mechanics of Animals at Boulogne on the Seine, the latter by Mr. P. Nogues, it appears that there are only two essentials; (*a*) that which gives a sinuous motion to the center of gravity of the bird, and (*b*) that movement which, with reference to some fixed point, is characterized by a trajectory in the form of a closed curve at the end of the wing. (Fig. 27.)

FIG. 26 FLAPPING FLIGHT OF A GULL

Other phenomena which accompany the flapping flight such

as the marked bending of the wing, just as it begins to rise from its lowest position, are minor matters, easily explained, and not necessary for the existence of flapping flight. The essentials (*a*) and (*b*) are linked up with this kind of flight so that they constitute, in one way, a definition of it which should be called an ornithopter. This name should not apply to any system of flapping wings, but to all apparati without a propeller whose trajectory in a vertical plane is sinuous and whose angle of attack is always positive and alternate rhythmically between two angles not very different in value, the definition applying even when these results are obtained without flapping the wings.

It is easily established that, in the movements described by

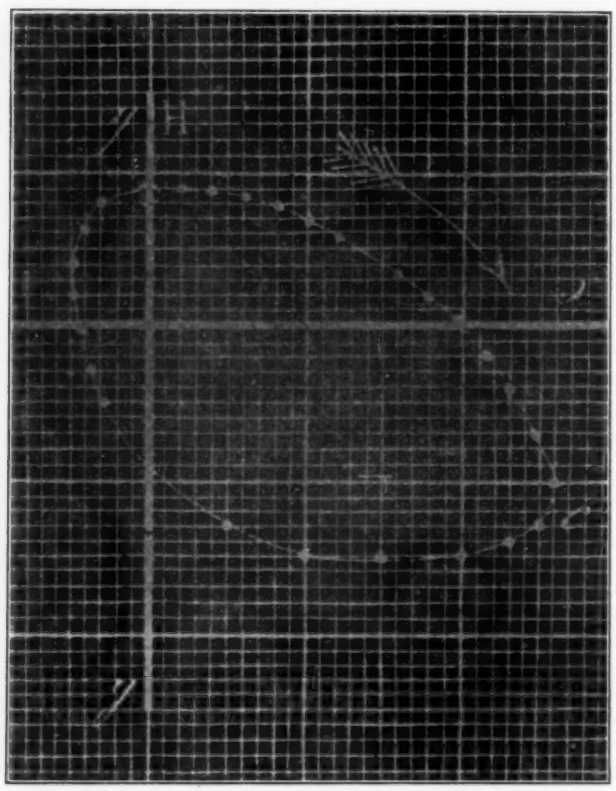

FIG. 27 PATH OF A POINT ON THE WING TIP ABOUT A FIXED POINT. THE POINTS ON THE CURVE ARE SEPARATED BY EQUAL PERIODS OF TIME

Marey, there is a clear relation of cause and effect. The trajectory of the end of the wing in the form of a closed curve is a result of the combination of two different movements which the bird gives to its wings. They are flapping in a plane nearly perpendicular to its longitudinal axis and moving the wings alternately from front to rear in their own plane. The first is very apparent and the second appears clearly on the end of a film taken of some pigeons passing overhead. Although the motion of the wings changes continually the position of the center of gravity of the bird, the variation is slight and almost negligible. The weight of the wings represents on the average only a seventh or an eighth of the total weight of the bird.

It follows that the double movement of a point in front of the wing for example, can be treated with respect to the center of gravity, considered as a fixed reference point, and the effects of the longitudinal displacement of the wings during flight are easily visualized. In fact, this particular motion of the wings from front to rear in their own plane can have only one important effect, that of varying the angle of attack. At least, that would be the effect on a glider, if one were able to move the main planes longitudinally. Upon moving the wings farther back the angle of attack would decrease, and vice versa, within certain limits. In the case of the bird, however, whose wings may be spread out or folded like a fan, there is not only a variation in the angle of attack, but also a variation of the supporting surface. That is to say, the angle of attack increases as the wing is opened and decreases as it is folded. Since the air resistance is expressed by the equation:

$$F = c\frac{d}{2g}SV^2$$

in which, taking V, d, and g as constant, R varies directly with c and S, and it is seen that for a given speed, F is dependent upon the changes of size, surface, and angle of attack which largely determine the value of the coefficient c.

It is therefore concluded, that the resistance of the outspread wings carried forward is greater than that of folded wings carried backward. Now, on looking over Marey's curve and the various films it is seen that the different phases of the flapping are distributed in such a manner that the descent of the wing, which takes place while it is in the forward position, and consequently at a high angle of attack, coincides with the rising of the body, and that the wing which is lifted, being in the rearmost position, at a smaller angle of attack, accompanies the curve in the trajectory of the center of gravity. To state that the bird mounts or descends periodically with respect to a mean horizontal trajectory, establishes the fact that the resistance to the air, in flight, increases and decreases in the same period, and its variations follow very closely the changes in angle of attack and supporting surface, being directly proportional to them. Under these conditions flapping flight can be represented as a succession of short descents in gliding flight, the bird sacrificing, upon raising its wings, all or part of the height gained in the active period preceding. In the first case the mean trajectory is horizontal; in the second case it is inclined upward.

In other words, the bird progresses like a glider that is lifted up to a certain height, released for a certain period, lifted up anew and so on, and which will succeed in covering considerable distances in this manner without being drawn or pushed. It follows that in flapping flight, the movements of the wings and their functions are not comparable to the movement and role of the oars on a boat. The former accomplish only a sustentation, the latter only a propulsion. Therefore in order to practice flapping flight it is necessary for the flying organism to be furnished with supporting surfaces capable of performing the double movement of flapping and oscillating observed by Marey. The nature of the structure of these supporting surfaces matters little; they may be either continuous membrane or independent feathers. It suffices if they are light and strong. This is why flapping flight can be practiced by animals other than birds, bats and flying fish for example, which are nevertheless unable to make a getaway. In January, 1925, the author made a voyage to the tropics during which he was able to observe some flying fish and some dactylopters. When they are taken in hand, living, they wriggle and struggle vigorously as in the water, without ever using their wings. These wings are made of a very fragile membrane, not at all rigid but crossed by narrow radial cartilaginous ribs.

Moreover, the sailors have found that the flying fish, when it has fallen on the deck, does not succeed in getting away, in spite of the bewildered flapping of its fins, which perform the function of wings. The bats, for their part, have anterior members, a posterior member, and the tail joined by a continuous wing-like membrane. They are incapable of taking flight from the ground. These two types of fliers have to be given a start, in order to

fly. The fish obtains its high initial velocity in the water by violent movements of its caudal fin, and the bats by simply letting themselves fall from the beams where they hang for the day's rest. Their usual active flight is flapping flight, identical with that used by birds. The latter at the getaway use another process, which enables them to make a point take off.

The Ornithopter-Glider

It ought to be possible to verify directly by experiment the mechanism of flapping flight. Let us imagine an ornithopter consisting essentially of a wing capable of performing the double movement as described, that is, rotation about an axis parallel to the body and of oscillation along this axis. Provided that certain other conditions were satisfied such as maximum admissible weight, sufficient power, and a good value of L/D, the apparatus could reproduce mechanically the flapping flight of the bird, without, however, being able to make a take off. It would have to be launched like a glider. In the same way one can conceive of a second apparatus, somewhat similar to the first with wings capable of a double movement with respect to the fusilage alternating from high to low and from front to rear, not by oscillation around a point but remaining constantly parallel to each other. Their longitudinal displacement could even be replaced by motions of their elevators, this being also capable of providing the necessary variations in angle of attack.

Thus the beating of wings, a relatively complex motion, could be reduced to some movements of the elevators and to the alternate displacements of the wings, with relation to the fuselage, in a plane perpendicular to its longitudinal axis, or to a similar displacement of the fuselage with relation to the wings which would give the same results. This movement, whose effect is due entirely to the consequent vertical displacement of the center of gravity relative to the plane of the wings, could finally be substituted, in an ordinary glider, with fixed wings. A periodic displacement of weights in the interior of the fuselage, following a suitable rhythm, would necessarily cause changes of position of the center of gravity. So it might happen, in perfectly calm air favorable for gliding, that forward motion might be effected, or even an upward motion, in a very light, efficient glider. The pilot would have to furnish a certain amount of muscular work by rhythmic bending of his legs, a further condition being that the movements of the pilot and the oscillation of the elevator should be coordinated so that the apparatus would glide at a certain angle when the pilot is seated and at a greater angle if he stood up.

As an initial experiment this result could be obtained by the use of a model, consisting of a glider and a clock-work mechanism as a motor. This last would be arranged so as to make itself turn about its own axis situated at the distance $D/2$ from its own center of gravity, and on a vertical through the center of gravity of the complete machine. The motor would be at its lowest position in the position of horizontal flight with an angle of attack included for example between the angles of $(L/D)_{max}$ and of P_{min}.

Let the expression

$$\frac{\text{weight of glider + weight of motor}}{\text{weight of motor}} = \rho$$

and let it be assumed that the object to be attained (work to be furnished) is to lift, with each revolution, the center of gravity of the whole machine to a height at least equal to W (vertical component of the speed of the apparatus at incidences included between the incidences of $(L/D)_m$ and of P_{min}), and greater if possible; it is necessary that the diameter D of the circle described by the center of gravity of the clock-work mechanism shall be equal to or greater than

$$\rho = \frac{w}{n}, \quad \text{that is} \quad D \geq \rho \frac{w}{n}, \quad \text{or} \quad \frac{D}{\rho} \geq \frac{w}{n}$$

n being the number of wing flappings per second, for the bird, and the revolutions of the motor in the case of the ornithopter-glider.

With this condition satisfied, the mechanism, passing from the lowest to the highest point of its trajectory, will lift at each revolution the center of gravity of the machine to a height

$$h = \frac{D}{\rho}$$

Looking more closely at the problem, the moving motor should be raised from the rear of the axis and lowered from the front. In this manner it will also displace the center of gravity of the machine longitudinally displacing it alternately in front (descending at a small angle of attack) and toward the rear (rising at a large angle of attack) from its neutral position. In the case of the glider, it is also necessary to take account of the relation which must exist between its own period of oscillation around a transverse axis xx passing through the center of gravity and the duration of one revolution of the motor.

The oscillations of the apparatus being efficiently damped by the resistance of the air on the fins and on the wings themselves, it will be perfectly safe to reduce to a minimum the moment of inertia of the apparatus around this axis xx, so as to render the period of oscillation much smaller than the duration of one revolution of the motor, to which would correspond the period of a forced oscillation. The fuselage and the fins must therefore be very light; in this manner it will be possible for the apparatus to follow with a minimum of lag, the variation of angles which the longitudinal displacement of its center of gravity will impose upon it, and there will be no need of fearing an amplification of the oscillations by resonance. In certain cases, nevertheless if one cannot succeed in constructing a glider presenting a sufficiently small period of oscillation around the axis xx, one could always increase the duration of one motor revolution without changing the power output, by increasing the torque.

Again, due to the lack of exact information as to the conditions under which birds fly and ornithopters function, it is impossible at present to ascertain or guess the precise limiting angles between which it is advantageous for such an apparatus to fly. These angles, moreover, depend upon the type of performance desired. By taking a range of angles low in value greater speeds would result, and taking a range of large angles, would give smaller speeds, but in each case at the expense of a greater expenditure of power. Now, as in the apparatus proposed it is necessary to be economical with the available power, which in any case is on the small side, even for horizontal flight. One can take as limiting angles $(L/D)_{max}$ which corresponds to the smallest gliding angle and a relatively high speed and the angle of P_{min}, which causes the least loss of height per unit of time in gliding flight.

The range between these two angles varies directly with the aspect ratio, and the angles are always in the same relative position, the angle of $(L/D)_{max}$ smaller than the angle of P_{min} which is favorable to the objective. It is necessary, in fact, that the machine should not lose too much speed at small angles or too much height at large angles. In certain cases the range between these angles may not be great enough. One must then choose some limiting angles from the curves of P, either side of the incidence of P_{min}, so long as one does not go beyond the angle of maximum vertical speed. With these conditions in mind, let us imagine a glider weighing about one kilogram, half of which, namely 500 grams, being the motor weight, whose speed should not, if possible, exceed 10 m. per sec. at

angles in the neighborhood of 338, the apparatus being balanced in such a way that it takes up the minimum angle of attack called for when the motor is in its forward position. With a sufficiently high aspect ratio one obtains at this angle coefficients c ranging from 0.75 to 1.15. For a mean value, $c = 0.95$, one can deduce an approximate value for the necessary supporting surface:

$$S = \frac{W}{c\frac{d}{2g}V^2} = \frac{1}{0.95 \times 0.062 \times 10^2} = 0.17 \text{ sq. m.}$$

Assume the following dimensions:

$$L = 1.80 \text{ m.} \quad l = 0.10 \text{ m.} \quad S = 0.18 \text{ sq. m. and}$$

$$R = \frac{1.8}{0.1} = 18$$

with a wing load of $1/0.18 = 5.5$ kg. per sq. m.

One could then anticipate, in the range of flying angles, an L/D which could not be better than 0.06, and a speed W that would not exceed a maximum calculable value. In fact, L/D

FIG. 28 FLYING FISH

$= tg\ p$ and, since at small enough angles, the sign and the tangent are approximately equal, if $V = \sqrt{\frac{1}{1.95 \times 0.062 \times 0.17}}$ = 10 m. per sec.

$$w = 0.06 \times 10 = 0.600 \text{ m. per sec.}$$

These figures represent a useful power

$$P_u = 1 \times 0.6 = 0.600 \text{ kg. m. per sec.}$$

to be furnished by the motor whose weight was estimated at 500 g., that is to say, it must be able to lift its own weight at 0.600/0.500 = 1.2 m. per sec., or per revolution

$$d = \frac{1.2}{n}$$

The general formula is

$$d = \frac{\rho w}{n}$$

from which

$$n = \frac{\rho w}{d}$$

If ρ is equal to 2, w to 0.600 m. per sec. and in taking d = 0.10 m., one finds

$$n = \frac{2 \times 0.600}{0.10} = 12 \text{ per sec.}$$

This result is not suprising since the frequency of the wing flappings of the pigeon is about 10 to 15 per second. This frequency could be reduced by a reduction of ρ.

If this term has a value 1.5

$$n = \frac{1.5 \times 0.6}{0.1} = 9 \text{ per sec.}$$

It is understood that it would be difficult to construct a clockwork motor capable of furnishing one-half kg-m. per sec. of

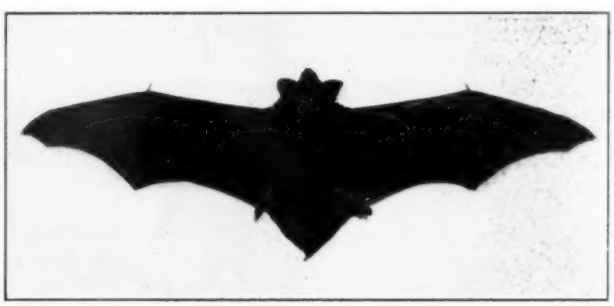

FIG. 29 BAT

power, even for 60 or even 30 sec., and in spite of the fact that 500 g. for 0.600 kg. represents about 62.5 kg. steam horsepower.

Horizontal flight is therefore not likely to be attained by the ornithopter glider described above, but whatever may be the available useful power, the maximum duration in gliding flight will be different from the maximum duration of ornithopter flight, and it is these durations that it would be useful to measure and interesting to interpret. No doubt it would be better to be able to measure flight distances with relation to the ground, these values being more easily used, but experience of model glider contests shows that it is very difficult to keep the machines flying in a straight line. It therefore becomes practically impossible to measure the distances covered, and it is worth while to take account, as proposed, of the comparison of durations of flight. From the practical point of view, the only advantage of the new process is its high efficiency, and it would be accompanied by various inconveniences, among which the most obvious are the sinuous trajectory of the apparatus and the impossibility of ever making a take-off.

SPEED OF FLAPPING BIRDS

The mechanism of power flight as described shows the similarity of the bird to a glider, and to a certain extent to an airplane. One might suppose that flapping wings fill a role comparable to that of the sustaining screws of the helicopter, and indeed, this is often the case. It is sometimes the one, and sometimes the other, but in flapping flight it is indisputably a glider. It is known that in the case of a helicopter, the speed of the center of gravity of the apparatus is independent of the relation of supporting surface to weight lifted, otherwise called the wing loading. The latter has no influence except on the speed of

rotation of the screws, to which, in the bird, would correspond the frequency of wing flapping.

In the glider, on the contrary, this speed is determined only by the angle of attack and the supporting surface and at a given angle by the square root of the wing loading only. From this fact it is possible to deduce a new experimental verification of the theory of flapping flight. One would simply take some birds having known speeds, modify their wing loading and register the influence of this modification on the speed of flight. If this variation of speed is zero or negligible in value, there would be good reason to doubt the foregoing conception of flapping flight. On the other hand, if the surface reduction was accompanied by a measurable increase in speed, the theory would be better established.

In order to perform such experiments there is in Belgium a large number of carrier pigeons, probably several millions, and one can benefit also by the accuracy of the data accumulated by the fanciers themselves on the occasion of the numerous races which they organize every year, in calculating the distances covered, the elapsed time and the average speeds.

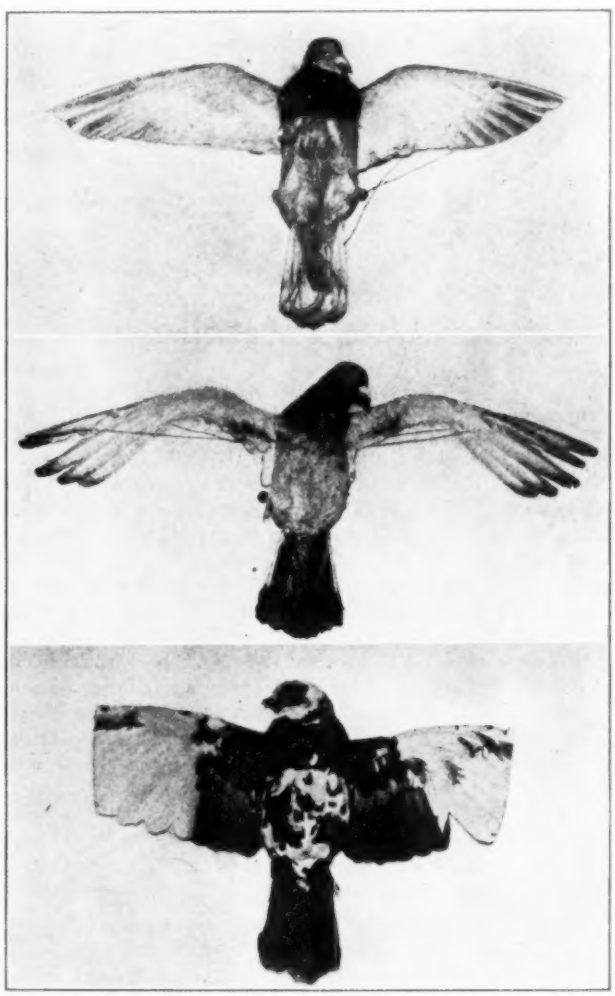
It has been determined as the result of a very great number of experiments made in all sorts of weather that the speed of a carrier pigeon in calm air is about 66 km. per hr. (41 m.p.h.), and that a maximum rate is attained on shorter trips diminishing in proportion as the length of the journey increases. It remains to determine the effect on the speed of a modification of area of the supporting surface. There appeared in 1905 in the "Travaux de l'Institut Marey" a very accurate account of the experiments made by Messrs. Ch. Richet and P. Noguès, respectively director and chief of the Institute Laboratory, a summary of which follows:

The authors admit, with Harting (1862), that there is a constant relation, or nearly so, between the square root of the supporting surface and the cube root of the weight of birds capable of flight, such that the value of the relation $\frac{\sqrt{S}}{\sqrt[3]{P}} = R$ varies very little. The extreme values found after a large number of measurements varied from 2.5 to 6, the average value for pigeons being 3.5. By modifying the wing surface of some pigeons in various ways, the experimenters arrived at the following results. Reduction of S according to Fig. 30 (parallel clipping)

For R = 3.1 the pigeon flies admirably
3.0 the pigeon flies quite well
2.95 the pigeon flies well
2.90 the pigeon flies a little
2.85 } the pigeon still flies a little
2.80 } (limiting value)
2.75 } the pigeon does not fly

Reduction of S according to Fig. 31 (clipping of the tertiary and secondary wing feathers)

For R = 2.85 the pigeon flies admirably
2.75 the pigeon flies well
2.60 the pigeon can still fly a little



Reduction of S according to Fig. 32

For R = 3.20 the pigeon flies
3.15 the pigeon flies a little
3.10 the pigeon flies a little (limiting value)
3.05 the pigeon does not fly

The authors add another method of determining the limits of the ratio R to increasing the animal's weight in place of reducing its wing surface, but owing to the difficulty of dividing up the weight in the right way, this system would be difficult to carry out. Brazilian vultures have a high value of R, about 5, as do all birds capable of soaring in light winds. By putting lead in plates around the body, the ratio was lowered to 4.5 and that was sufficient to prevent the vulture from making a prolonged flight.

From these tests it is concluded that pigeons are least affected by reductions in the supporting surface, when the reduction is in width, i.e., the length of the tertiary and secondary wing feathers (Fig. 31); for that operation increases the aspect ratio, with the beneficial results already discussed.

Other conditions being equal, V varies as $\sqrt{\frac{W}{S}}$, that is to say that at least in gliding flight, by reducing the supporting surface

MODIFICATIONS OF THE WINGS OF PIGEONS: FIG. 30 AT TOP, PARALLEL CLIPPING. FIG. 31 IN CENTER, TERTIARY AND SECONDARY WING FEATHERS CLIPPED. FIG. 32 AT BOTTOM, ENDS OF WINGS CUT

of the pigeon V is increased, W being considered constant. In reality the formula of speed is $V = \sqrt{\frac{W}{c_z \frac{d}{2g} S}}$ in which the factor c_z may also be varied at the will of the bird, by modification of the angle of attack. It is therefore almost certain that in the pigeon it is not possible to keep all the conditions constant, and it may be said that the variation of speed of flight will not

follow strictly the variations of $\sqrt{\frac{W}{S}}$. In flapping flight moreover, the problem is complicated by the fact that useful power grows with the speed, that an increase of speed lessens the excess of power, and that in any case an increase in speed gained by reduction of S may take place only up to a certain limit, probably a little less than the total excess of power available at first.

For the purpose of verifying these deductions, in 1924 the author made a large number of measurements of pigeons, in order to obtain the mean of the weight P, the carrying surface S, and the wing spread L. The weight W was obtained by weighing the pigeon in a paper bag, when possible in the morning before feeding, the weight of the bag being balanced by a similar bag placed in the other pan of the scale.

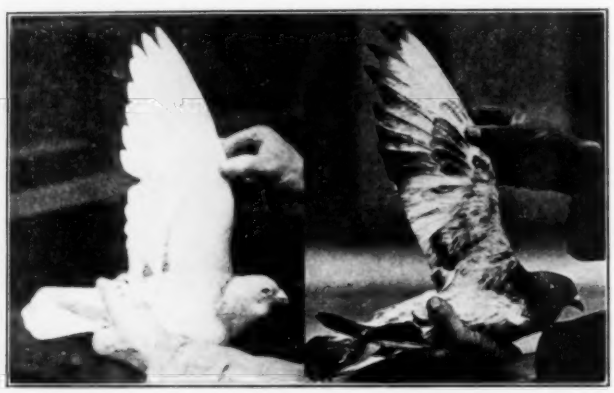


FIG. 33 · WING OF A PIGEON IN ITS NATURAL FORM

FIG. 34 WING OF A PIGEON WITH REDUCED SURFACE

To obtain S it is necessary to put the pigeon on the table, claws upward, and one of the wings spread out as far as the separation at the end of the primary wing feathers. The outline of the wing is then drawn on a piece of paper. The extremities of the curve thus obtained are joined by a straight line and the surface of the figure taken by a planimeter, which gives S with even more accuracy than is strictly necessary.

The wing spread is taken from the pigeon held in the hands, the two wings spread out as in drawing the outline of one of them. From these values the aspect ratio (R) and wing loading ϕ may be found. As a result of a large number of measurements it is found that in the carrier pigeon the extreme values of the wing loading vary from 5.8 kg. to 10 kg. per sq. m. (1.2 to 4.0 lb. per sq. ft.) and the aspect ratio from 6.7 to 9. Table 9 gives some dimensions taken from carrier pigeons of good stock, among which the numbers 8, 9, and 15 belong to the same breeder, the birds having won the second, first, and sixth places, respectively, in a competition at Dax.

TABLE 9 DIMENSIONS OF CARRIER PIGEONS

No.	W lb.	S sq. ft.	$\frac{W}{S}$ lb. per sq. ft.	b ft.	$\frac{b^2}{S} = R$

14	8.27	0.538	1.843	2.23	7.75
15	9.92	0.631	1.843	1.97	6.75

Similar observations which were confirmed several times quite naturally led to the theory that if pigeons capable of remarkable performances are loaded normally from 8.3 to 9 kg. per sq. m. then those loadings suit the birds better than extreme loadings of 6 and 10.

Systematic experiments were undertaken. Various pigeon fanciers loaned pigeons for single tests. One of these pigeons in particular, a bird 3 years old which had never taken a prize, but had a habit of returning regularly, which is a sign of a well-developed sense of direction, was weighed and measured. Values found were $W = 0.460$ kg. and $S = 0.0696$ sq. m. The surface was then reduced to 0.0600 sq. m., an increase from 6.60 to 7.75 kg. per sq. m. The bird, sent to Vendome and released June 1, 1924, was placed twenty-first out of 3176 competitors.

Several tests of the same kind gave similar results on each occasion. In order to proceed in a methodical way the cooperation of the military dove cotes was obtained. A movable pigeon cote (wagon No. 14) of 120 pigeons was placed at the disposal of the aerotechnical laboratory about May 15, 1925, and maintained at Rhode St. Genese up to the beginning of July. To accustom the pigeons to the country each day they were moved from their home and several baskets at a time were released. The distance from the base was raised progressively to 15 kilometers and was maintained at this distance. Releases were finally made basket by basket and later single birds were released at 2- or 3-minute intervals according to atmospheric conditions. In the course of these numerous tests those pigeons having the least regularity or apparently endowed with the least sense of direction were removed from the experiments and this process of selection finally reduced the number to 24 pigeons. From these the six swiftest were chosen as examples and the six slowest for those intended to be modified.

TABLE 10 DIMENSIONS OF PIGEONS TESTED

No. of pigeon	W lb.	S sq. ft.	$\frac{W}{S}$ = wing load	b ft.	$\frac{b^2}{S} = R$	After modification		
						S_1	Wing load	R_1

1040	0.867	0.605	1.41	2.13	7.50			

In the tests the times of pigeons taking more than one hour to return to their cote were neglected, these birds being considered as having wandered en route. Table 10 gives the dimensions of 12 pigeons retained for speed measurements.

In the course of seven tests on the same route performances given in Table 11 were obtained, the speed being those relative to the ground.

TABLE 11 PERFORMANCE OF PIGEONS IN TEST

No. of pigeon	Speed in meters per second							Mean speed of pigeon m. per sec.	Mean speed ft. per sec.	Class
	1st test	2d	3d	4th	5th	6th	7th

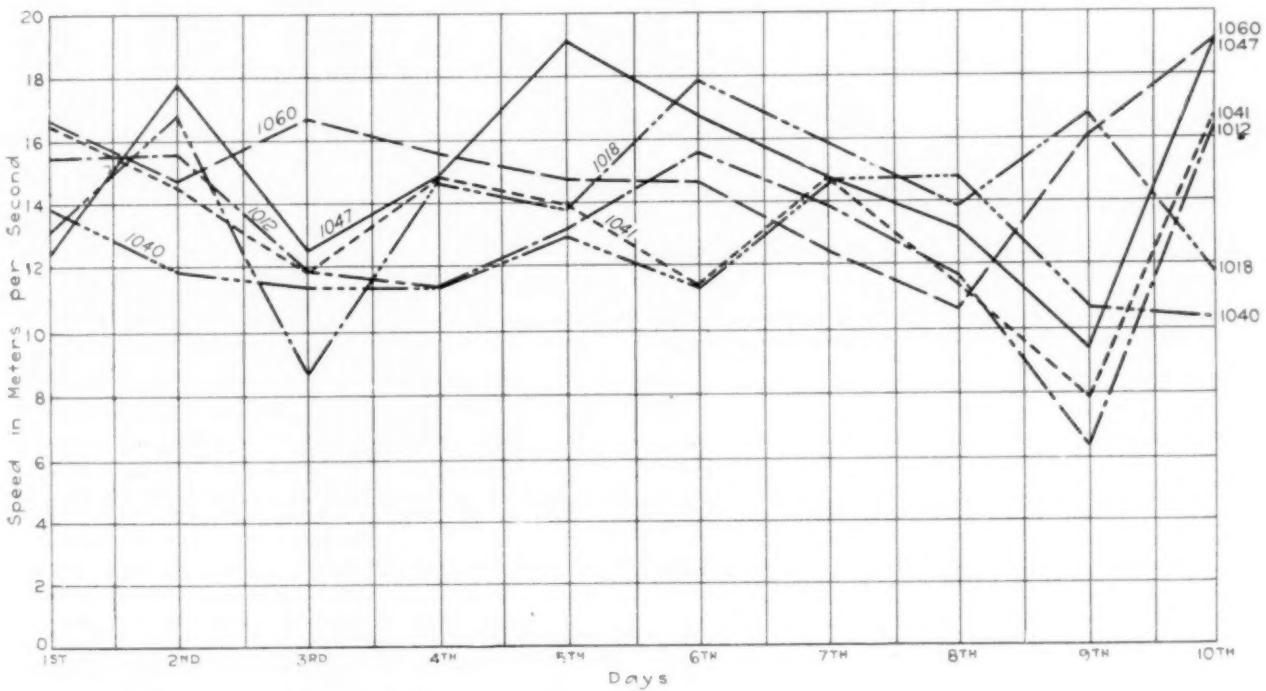

FIG. 35 SPEED ATTAINED BY STANDARD PIGEONS IN TEN-DAY TEST

by the 12 pigeons of which numbers 1048, 1026, 1029, 1050, 1037 and 1002 had their carrying surface modified as shown in Table 10 after the seventh trial.

These figures have been expressed in curves in the accompanying diagrams. Fig. 35 gives the speed realized each day by each one of the six standard pigeons; Fig. 36 the daily speed of each one of the pigeons treated before and after changing the wings and Fig. 37 the daily mean of the speeds realized by the six standard pigeons and the mean of the speeds of the treated pigeons before and after modification. The effect of increasing W/S is shown in a most striking manner. For example, in the course of trials 5, 6, and 7 (before modification), the mean speed of the six treated pigeons is 10.40 m. per sec. and in trials 8, 9, and 10 (immediately after modification), 16.95 m. per sec. The standard pigeons in the same trials gave means of 14.10 m. per sec. and 12.40 m. per sec.

The benefit derived from the operation is indisputable and the performances of the modified pigeons showed marked superiority over the performances of the standard pigeons. It is certain that further increases in wing loading would have resulted in still higher speeds. The figures in Table 9 especially show that pigeons normally loaded with 8.3 to 9 kg. per sq. m. could be classified first, second, and sixth on the Dax–Brussels distance, and that among a distinguished group of contestants.

INFLUENCE OF SPEED ON THE FATIGUE OF THE BIRD

Although increased wing loading is unfavorable to speed the power necessary for the pigeon increases at least proportionally to the speed, whatever method of flight is used, providing the weight and L/D remain the same. Birds do not possess motors whose power remains virtually constant, at least up to the wearing or breaking of parts, but they have a motive system whose power at the end of several hours of effort, falls according to the laws formulated by Prof. Mosso (see "La Fatigue Intellectuelle et Physique" by A. Mosso, Professor at Turin University).

As an example take pigeon number 2 of Table 9, which weighs 350 grams and has a surface of 0.0506 sq. m. Its unit load is $\frac{0.375}{0.0506} = 7.4$ kg. per sq. m. The mean speed of this pigeon on short distances must be nearly 16.60 m. per sec. (54.5 ft. per sec.). This value is low which is only natural in such a lightly loaded bird. On the contrary, the largest wing load shown by a pigeon in its natural state is 10. The useful limit appears to be 9.

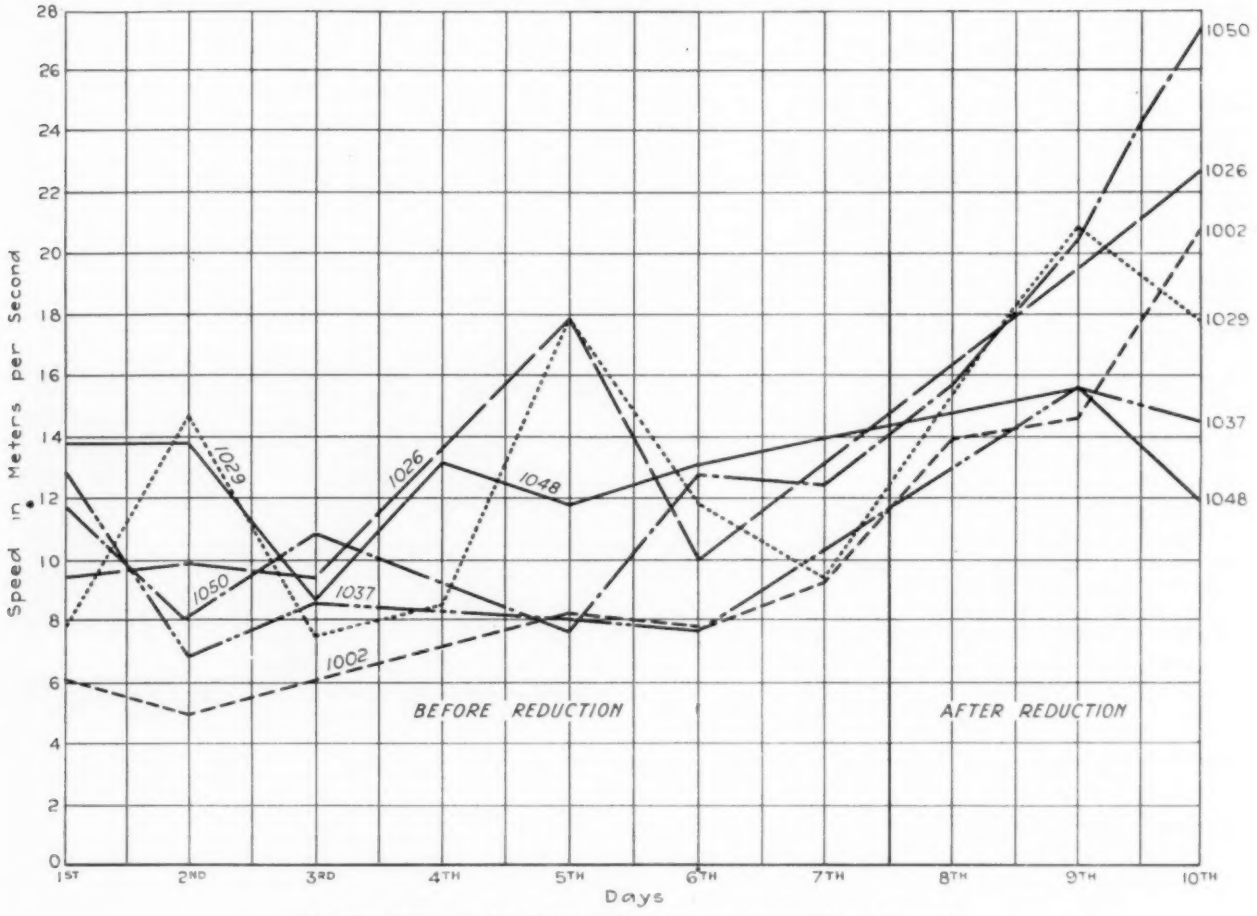

FIG. 36 SPEED OF SIX PIGEONS BEFORE AND AFTER WING CHANGES

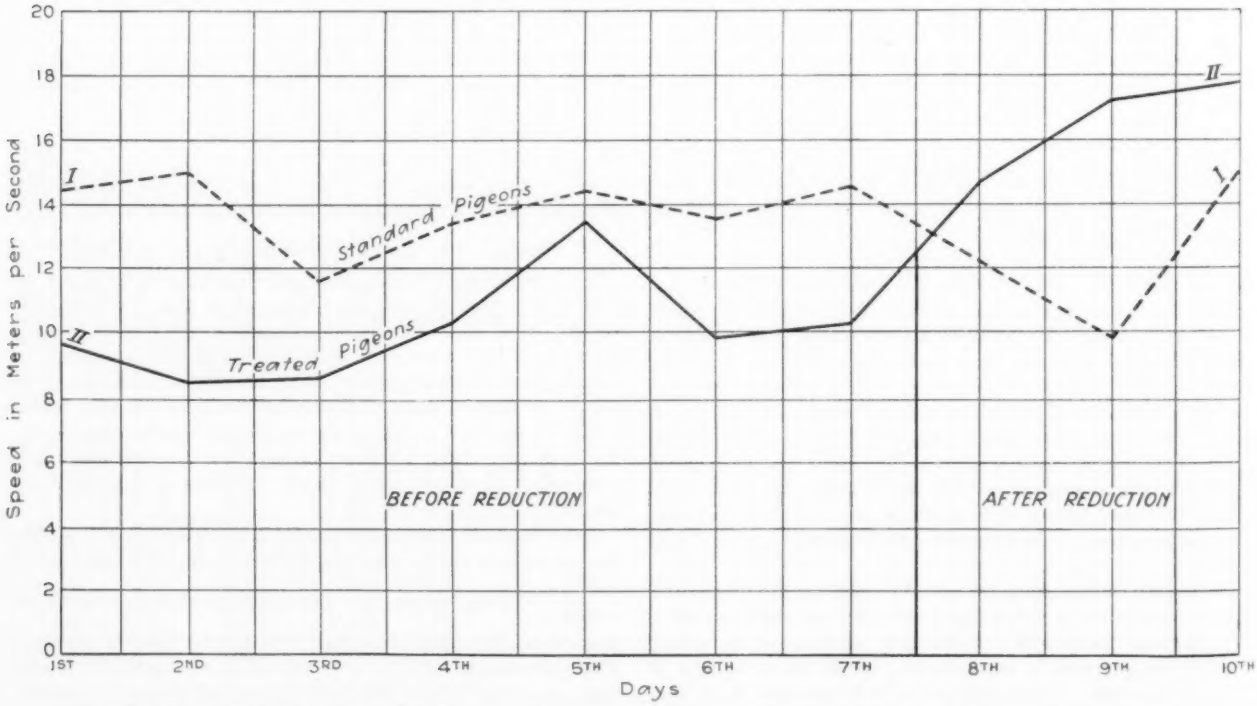

FIG. 37 DAILY MEAN SPEED OF SIX STANDARD PIGEONS AND TREATED PIGEONS BEFORE AND AFTER MODIFICATION

By reducing the wing surface the maximum load of this pigeon is calculated. Conforming to the data given this becomes $\frac{16.60 \times \sqrt{10}}{\sqrt{7}} = 19.85$ m. per sec. (65.2 ft. per sec.), a speed superior to the best observed average. The necessary power, which is proportional to the speed, will then change from 1 to $\frac{19.85}{16.60} = 1.2$. This is a high value, considering that it must be maintained for some hours.

In reality things would not happen in quite this way. When the bird perceives that the effort required is too great it probably modifies its mean angle of attack by longitudinal displacement of the wing, thus compensating in a certain measure, by increasing c, for an excessive reduction of S. Although still obliged to fly rapidly it no longer has to fly at the calculated speed. The result is that the effort and fatigue are lessened even if the L/D was decreased with the angle of attack.

Useful Power of the Flapping Bird

The work expended in the course of flapping flight, which is the product of the motive power times the time, cannot be measured or calculated exactly. The useful power, on the contrary, should be capable of expression. If it is considered that the efforts of the flapping bird have the effect of lifting it by a certain amount at each flapping

$$P_u = Whn = \frac{Wh}{t}$$

in which W equals the weight, n the number of wing strokes in a unit of time, and h the height that the bird will lose in descending by gliding, with the angles of attack and surfaces successively adopted during the full period of a wing flapping.

The height h lost depends on the speed and the L/D. At each instant it is equal to $h = V \sin p$. It will therefore vary directly as the speed and inversely as the L/D at each angle of attack.

Finally, it is seen that P_u will then become smaller as W and h or W and V are smaller, and L/D larger, or S and b^2/S larger and W smaller. The conclusion is that in all cases a bird should have as high an L/D as possible, and one will recall that this quality is closely related to the aspect ratio, the profile of the wings and the form of body not varying to any great extent.

The Speed Range of Birds

It is important to remember that flapping or ornithopter flight cannot supply a start, and that those animals which use flapping only, such as flying fish and bats, must find some special way to gain an initial speed, since they are incapable of taking off from the ground. Without their primary wing feathers, birds would be in the same situation, but the feathers which can be moved to and fro in any direction give an important component of resistance to the air perpendicular to the plane of flapping or oscillation.

The result is that when a bird starting from rest wishes to rise vertically, or when at the end of its flight wishes to alight, it is not obliged either to run or to swim in order to gain horizontal speed or to land by gliding at a speed proportional to the square root of the wing loading. In order to gain the desired result which is summed up in being able to remain stationary in the air over one spot, and descend or rise slowly almost vertically, maneuvers not possible to airplanes, the bird simply flaps the wings in a horizontal plane, spreading them to induce the separation of the primary wing feathers. The alternating movement obtained under these conditions produces on each primary wing feather, which is now an independent unit, a force F having a vertical component F_z. The sum of these F_z components, acting on the primary wing feathers, if equal to the bird's weight, will sustain it, and if greater, it will raise it with an acceleration equal to $a = \frac{\Sigma F_z - W}{m}$, and if less, it will allow a descent with an acceleration of similar order, $a_1 = \frac{W - \Sigma F_z}{m}$ always, evidently a small value, which will quickly become zero in every case, as soon as the air resistance reduced by the ascent or increased by the drop becomes equal to the weight.

These considerations are verified in a photograph of a vulture taken in the Antwerp Zoological Garden at the instant when it launched itself from the rock which served as its perch. The small size of its cage did not allow it to reach the ground by gliding so it had to come down vertically by flapping its wings to reduce its speed. An examination of the photograph taken shows that the axis of the body is evidently vertical, that the plane of flapping of the primary wing feathers is horizontal, that the wing feathers are separated one from another, and that the amplitude of movement of the tips is greater than the dihedral angle described by the main portion of the wing. This phenomenon had also been explained by E. J. Marey, who recorded it on his chronophotographs of birds in flight, and stated in particular that ducks flapped their wings much faster when taking off than in horizontal flight and that at the take-off there were large spaces between the primary wing feathers. These birds, which are very heavy and have a small supporting surface, perform this maneuver so vigorously that their feathers have become adapted to this special condition, and in order to reduce their resistance, the barbs are thickened near the rib, not as carefully as in the albatross, but in a characteristic manner nevertheless.

The mechanics of helicopter flight appears also very well on slow motion pictures showing vertical take-offs of pigeons and alightings of the same birds. At the take-off the wings always flap faster and in a horizontal plane. In certain cases the separation of the wing feathers can be seen. On alighting the birds arrive in flapping flight, with the axis of the body nearly tangent to the trajectory. As they approach the landing shelf, the body straightens up, the flapping becomes more rapid, passing from 10 to 15 per second in a plane more and more approaching the horizontal, while the amplitude of flapping increases up to 180 deg. It sometimes happens that pigeons having commenced this maneuver change their mind, and still flapping their wings stop an instant above the perch without alighting, then bringing back the axis of the body toward the horizontal, lessening the rapidity of the flappings and decreasing their amplitude, they set off again in flapping flight.

The same theory must apply to the little birds which rise vertically, like the lark, or begin their flight from one spot, as the swallow at the entrance to its nest or the humming bird before the corolla of a flower. The phenomenon has been accurately observed by the Duke of Argyll and reported as follows in "The Flight of Birds" by Marey:

"The humming bird, when it hovers over one spot, holds the tail open, fan-wise, and the body almost vertical. The wings are seen only as a dim shape, very vague because of the rapidity of their movement." It is this which gives birds the valuable range of speeds with which they are endowed, allowing them to land vertically with a horizontal speed either zero or negligible, and makes it unnecessary for them to seek open areas for landings and take-offs, such as the plane requires. The faculty of being able to hover over one spot constitutes, then, in a way, the limit of speed variation, the goal toward which airplane constructors should strive, and which would be attained by a successful helicopter.

Propulsive Flight

Because of the faculty which all birds possess of utilizing their primary wing feathers to sustain them by oscillating movements, there are some species which use this process for horizontal translational motion, either by that remarkable vibration that may be readily observed in the sparrow hawk doing the "saint esprit," or else by flapping the whole wing, though with an amplitude which increases considerably toward the tips like the rotation of the hand about the wrist. This method of flying requires that the primary wing feathers be independent, so as to be able to oscillate freely about the axis of their shafts. Now it happens that the wings of birds using this special form of flight

Fig. 38 Primary Wing Feather of a Bird Fitted Especially for Propelled Flight

Fig. 39 A Gathering of Percnopters Near Cape Verde, Senegal

give the appearance of having been cut off at the ends, the wing feathers being separated one from another by spaces which sometimes are of several feather widths. Taken individually these feathers show a marked narrowing some distance from the point of insertion. (Fig. 38.) Also, the ribs which have a rectangular section for a large part of their length, and in a tube of circular section which is evidently designed to facilitate changes in the angle of attack.

These peculiarities, which are complementary, can have no other effect but to adapt the primary wing feathers to their function of propellers. Again, there are some birds that actually move the tips of their wings in one or another of these ways, and this movement is indispensable for their sustentation and translational motion. At first sight this seems easy to demonstrate. It should be sufficient, in fact, to remove from one of these birds the front edge of its primary wing feathers, an operation which would result in taking away the precious property which they possess of balancing themselves at small angles of attack, and would deprive the bird of the use of its propellers, like screws whose blades had been straightened, and the pitch reduced to zero. It would be necessary to apply such a test to a bird having wings specially equipped for propelled flight, and incapable of flying otherwise or of adapting itself to the situation as the sparrow hawk for example, which is a strong flapper.

Experimental Verification of the Mechanism of Propelled Flight

In this class are found only certain birds of prey such as the condor, the vulture, and the eagle, perhaps also some other birds of great weight and stature, as the pelican and the stork. A living vulture was captured having the following dimensions: weight 2.25 kg. (4.95 lb.), carrying surface 0.546 sq. m. (5.87 sq. ft.), wing spread 2.15 m. (7.05 ft.), $\frac{W}{S} = 4.120$ kg. per sq. m. (0.845 lb. per sq. ft.), aspect ratio 8.45.

The bird was in perfect flying condition before modification of its primary wing feathers. (Figs. 40 and 41.) When taken to the coast where it had been captured and given its liberty, it faced the wind and began to run, flapping its wings in its normal manner. At a distance of 150 ft. perhaps, the bird tried vainly to rise and finally disappeared behind a ridge of

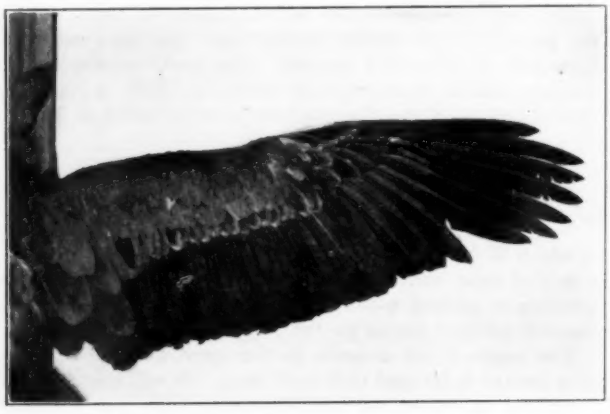

Fig. 40 Wing of a Vulture in Its Natural State

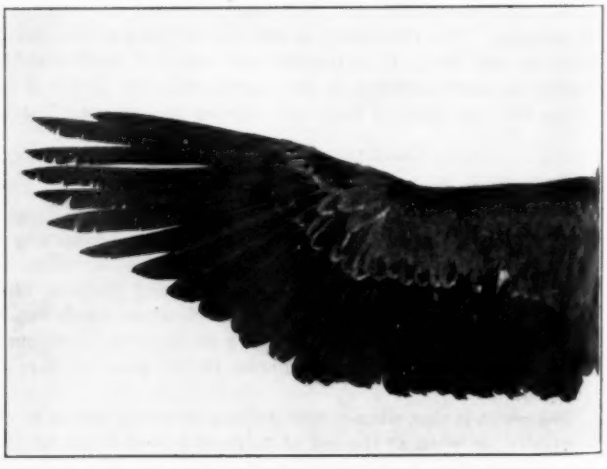

Fig. 41 Wing of a Vulture With Modified Primary Wing Feathers. Note the Front Edge of the Tip Feathers

rocks. It was found on the sand below with wings folded. When thrown into space toward the sea, free again in the air, and having some initial speed, the vulture flapped its wings in vain, without succeeding in maintaining its height. Seemingly discouraged, it soon ceased its fruitless efforts and resigned itself to descending in a glide.

A pigeon, under the same treatment, does not show any immediate effects. It takes flight without appearing to notice any difference. This is because it is accustomed to flapping flight and can take-off even in gliding flight, the change from gliding to flapping taking place without difficulty after the bird attains a sufficient speed of translation.

Messrs. Demonty and Poncelet, director and shop superintendent at the S.A.B.C.A., the most important of our airplane manufacturing plants, have produced a kind of scull or oar with constant angle of attack based on the principle of wings in equilibrium at an angle determined by the position of an axis. On a tube of duralumin 25 mm. inside diameter and 1 mm. thick they slipped 20 profiled elements, biconvex of 170 mm. depth, 20 mm. width (dimension along the wing spread), and 32 mm. thick. The blade thus constructed presents a surface of $0.170 \times 0.40 = 0.0680$ sq. m. (0.731 sq. ft.). Maneuvered alternately from left to right, this oar is deformed as a helicoid and adopts, both in going and coming, an incidence which remains constant, whatever may be the variations in the rapidity of oscillation and speed of translation of the vehicle being propelled. When tried out with a canoe, this apparatus worked better than an oar used as a scull, not only in point of speed attained but also in respect to the effort exerted by the oarsman.

FIGS. 42, 43, AND 44 ALBATROSS IN GLIDING FLIGHT. AT LEFT WINGS SPREAD OUT. AT RIGHT WINGS BENT SLIGHTLY

This particular oar plays the same part relative to the boat, that is, an oscillating, propelling movement, as do the primary wing feathers in birds such as the vulture, and the mechanics of it is identical.

EXTENT OF THE THRUST IN PROPELLED FLIGHT

Certain examples of flight where the primary wing feathers, acting as sustaining surfaces or as propellers, are of first importance, can be readily observed by aid of moving pictures. The use of the process by the vulture, even when it seems to be flapping, cannot be doubted after the experiment just related. Moreover, the birds of prey, from sparrow hawk to condor, appear to have recourse to it each time when, from the heights, they spy their prey or when, conditions not being favorable for gliding flight, they have to supply a certain effort. It is only rarely that they employ pure flapping flight, that is, the flight of marine soarers, and the greater number of birds best described as ornithopter flight.

This mode of support can be compared to the flight of helicopters or of airplanes, according as the plane of flapping or oscillation of the wing feathers approaches a vertical or a horizontal plane. In the first case the component of resistance perpendicular to the plane of flapping must be opposite, that is to say vertical and equal or superior to the weight of the bird.

This fact does not affect the possibility of the phenomenon. There is even less reason to doubt it in the case of horizontal flight, which is that of the hawk, the eagle, the vulture, and the condor, and which requires in comparison, only a very small lift of the order of $^1/_{15}$ or of $^1/_{20}$ the weight of the bird, since in propelled flight, the thrust T necessary for horizontal flight, equal to the resistance of the air, is expressed by $T = F_x = \frac{W}{L/D}$, where L/D represents as before, the efficiency of the bird at that angle of flight. It is seen from this that in the condor, which is the heaviest bird practicing this form of flight (an example of great size captured in 1925 at Uspallata in the Cordillera Andes weighed 10 kg. or 22 lb.), has approximately: $F_x = \frac{W}{20} = \frac{10}{20} = 0.500$ kg. (1.102 lb.), or, since there are 14 primary wing feathers for the two wings, $\frac{0.500}{14} = 0.036$ kg. (0.0793 lb.) per wing feather.

To be perfectly accurate, having given that this force of 36 grams is the value of only one of the components of the air resistance on the feather, it is possible, using an L/D of 20, to find the size of the average force applied on each wing feather, that is,

$$F_{x1} = \sqrt{\overline{0.036^2} + \sqrt{\frac{0.036^2}{20}}} = 0.0365 \text{ kg. } (0.0804 \text{ lb.})$$

The difference is negligible and the figures obtained are quite within the realm of possibility.

USEFUL POWER IN BIRDS PRACTICING PROPULSIVE FLIGHT

As in the case of flapping flight, this well-defined conception of propulsive flight permits one to deduce a clear expression of the useful power represented in horizontal flight. Knowing the resistance to the air, the useful power consumed, as in an airplane whose flight is strictly comparable to the above, is simply the product of F_x by the speed, as

$$P_u = F_x V = \frac{W}{L/D} V$$

In the condor, whose mean speed is about 15 meters per second (50 ft. per sec.) $P_u = 0.5 \times 15 = 75$ kg-m. per sec., that is to say, that this bird seems to weigh $\frac{15 \times 75}{75} = 150$ kg. (330 lb.) per useful hp., a normal enough value compared to that of other living creatures.

This phenomenon whose existence is indicated by the present knowledge of aerodynamics, which instantaneous photography and slow motion pictures reveal to perfection, which is proved by experiments as simple as that at Dakar, and which mathematics has shown to be practicable, may be observed in many different places, even in the flight of insects, for which it constitutes the essential mechanism, and in widely different species of birds. Some, specifically those which have the primary wing feathers separated, appear better adapted for it than those

provided with wings of continuous contour or not serrated. The latter, that is to say the majority of the flapping birds, from pigeon and the marine web-footed birds to the albatross, often have recourse to it on special occasions such as in take-off and particularly in landing, in order to increase their range of speeds.

The existence of propelled flight can no longer be doubted, and one can conclude that it exists in the nature of parachutes, gliders, and also naturally ornithopters but equally helicopters and airplanes.

Conclusions

The theory of natural flight as discussed under the several headings of gliding flight, flapping flight, and propelled flight, does not explain all the attitudes that birds adopt in the air. It describes the mechanics of flight and enumerates the essential phenomena, some of which are used to the exclusion of others by certain birds but which are all used by many birds, the processes succeeding each other according to the circumstances or necessities of the moment.

It appears certain that an exclusively gliding bird or soarer does not exist. There is none using only propelled flight or flapping flight. There are some birds better adapted than others to one or the other of these processes but that is all.

It is evident that all birds can glide, but the majority do not use this method except at rare intervals or in descending, because they are not particularly suited for gliding, lack sufficient L/D, or have too little supporting surface. Often they do not acquire the habit, because they do not live where atmospheric conditions are generally favorable to gliding. Species that live in favorable regions and have learned to lose but little height in a unit of time, use it as often as they are able, and the fact that they fly almost always with the wings extended, has earned them the name of soarers.

Birds with separated wing feathers generally show marked preference for propelled flight, while flapping flight is practiced in particular by birds with continuous contour to the wings. Small birds such as the swallow use the two methods alternately flapping to effect horizontal forward motion, and using helicopter flight to remain stationary, to alight or to rise vertically.

Birds of medium size, such as the pigeon and the sparrow hawk, might use either form, but the anatomy of their wings and feathers shows the effect of a preference in the pigeon toward flapping flight, and in the sparrow hawk toward propelled flight. The former in fact has no recourse to the properties of primary wing feathers except when taking off and alighting. In case of necessity usually a pigeon prefers to take off with a glide. The hawk, on the contrary, often uses propelled flight even when it is flying horizontally.

Finally, it should be noticed that flapping flight is that used by migratory birds that cover long distance, while the sedentary birds such as birds of prey, which never leave a certain region, prefer propelled flight. Birds of very large size having wing spreads of two or even three meters such as the eagle and condor, are so sensitive to the removal of the forward barbs of the primary wing feathers, that they cannot fly after an operation which has left intact the precious faculties of the flapping birds.

Only fliers not furnished with wing feathers use flapping flight as their sole mode of locomotion in the air. The albatross flies with the whole wing but by alternations, irregularly, with all movements voluntarily reduced to a minimum and on account of the increase of tangential speed along the wing span, apparent only toward the tips of the wings.

AER-51-36

The Metalclad Airship[1]

By CARL B. FRITSCHE,[2] DETROIT, MICH.

This paper sets forth the advantages to be obtained from the employment of all-metal construction in dirigibles, and discusses at length costs and other economic questions involved. Extended particulars are then given regarding the design, all-metal construction, erection, and assembly of the U. S. Navy Dirigible ZMC-2, together with data on dimensions, weight arrangement, shape and stress analysis, and performance, as well as conclusions on the test flights.

IT IS ALMOST impossible to present a description of the metalclad airship without comparing it with the well-developed Zeppelin art in rigid-airship construction. However, it should be clearly understood that where such comparison does occur in this presentation, it is resorted to in order to clarify the description and to stimulate engineering inquiry into the art as a whole. Therefore it is hoped that no one will misinterpret any technical comparison as indicating an attempt on the author's part to speak in disparaging fashion of the wonderful contribution the entire personnel of the Zeppelin organization has made to lighter-than-air development.

Rising again and again above disappointment and failure, which would have crushed the ordinary man, Count Ferdinand Zeppelin gave to the world the rigid airship. He and his associates have personified the indomitable spirit of progress. Obstacle with him spelled opportunity. His fine courage has been a constant inspiration to airship engineers and constructors in all countries. His spirit was truly that of the philosopher who is sure of his ground, unconquered and unconquerable. Disaster with him meant only temporary delay in progress. It did not stop progress.

Many of Count Zeppelin's associates and his co-adventurers in other countries have been the victims of tragedy, which always takes its toll along new frontiers of science. On each occasion the world at large has said that men have gone too far in daring exploration. But invention has always to convince skeptics. This was well illustrated in May (1929) when the *Graf Zeppelin* turned back to Toulon on its attempted second flight from Germany to America. Public comment generally was unfavorable. The fact that no lives were lost was attributed to luck. The airship was denounced most bitterly in some papers, while the airplane was pointed to with pride.

Unfair Criticism

Now newspaper editors, as a general rule, are men of scholarly attainment and possessed of exceptional power of analysis. Yet only a few on this occasion differentiated between the failure of four engines and the extraordinary performance of the *Graf Zeppelin* in landing safely without a scratch under the power of its one remaining engine. And still fewer newspapers commented on the tragedy that would inevitably have happened to an airplane if four out of five engines had failed in a storm over the Mediterranean.[3]

This illustrates how deceptive and inaccurate is the public's understanding of the safety of airships and their ability to fly independently of engine power in emergency. The burden of the proof, therefore, still rests with the designers, builders, and operators of airships.

Orderly Development

Progress is made in any line of endeavor, first, by retaining the best of the past; second, by developing the good of the present; third, by encouraging the development of that which may be better in the future. The metalclad airship belongs to the last category. In the middle classification belong the big fabric-covered airships such as the U. S. S. *Los Angeles*, the *Graf Zeppelin*, the British *R-100* and *R-101*, and the two large airships (*ZR-4* and *ZR-5*) now under construction for the Navy by the Goodyear-Zeppelin organization.

To put it another way, there are four major stages in any new scientific development: (1) Invention, (2) Engineering, (3) Production, and (4) Distribution. The metalclad airship is classified under the second stage, namely, engineering. The "Zeppelin" fabric-covered airship, on which, of course, engineering improvement is possible, has very nearly reached the third stage.

Airship Lines to Encircle Globe

Those who have had the good fortune to study the craft must be impressed with the immensely useful field in aerial transportation open to the dirigible airship. With its large weight-carrying capacity; its safety; its increasing speed; its long range; its improvement in efficiency with size; its comparative economy in operation and the fact that the air is "open" in all directions; it is no idle prophecy to visualize a network of airship lines encircling the globe, supplementing our present land and water transport facilities and penetrating remote regions of the world now little known to civilized man.

The sheer economy of this service will dictate its accomplishment. Think of a fuel cost per passenger for crossing the Atlantic in a super airship of only $20 and of a fuel cost per passenger for flying from New York to Chicago of only $5, or little more than that required for touring in a $4000 automobile.

Airships More Economical Than Airplanes

The commercial airplane and the flying boat have demonstrated their useful field of activity, but until much greater progress is made in their design and motive power, their useful radius of economic operation is limited to about 500 miles and 800 miles, respectively. On the other hand, the modern airship possesses

---

[1] Author's Note. Building an airship is not a one-man job. Any comprehensive description of a new type, particularly, requires the cooperation of the key men responsible for its development. In the preparation of this paper the author desires to acknowledge his indebtedness to the following members of the Aircraft Development organization for their technical aid and for their personal contribution to this unique project: namely, Edward J. Hill, William E. Kepner, W. A. Klikoff, V. Pavlecka, S. A. U. Rasmussen, Arthur G. Schlosser, and Ralph H. Upson.

[2] Vice-President of the Detroit Aircraft Corporation, and President of its subsidiary, the Aircraft Development Corporation. Mem. A.S.M.E.

Presented at the Third National Meeting of the A.S.M.E. Aeronautic Division, St. Louis, Mo., May 27 to 29, 1929. Revised and brought up to date of September 20, 1929, after the *ZMC-2* had completed its test flights, and been delivered to Lakehurst, N. J.

[3] The most extraordinary achievement of Dr. Hugo Eckener and his associates, starting at Lakehurst, August 8, 1929, and encircling the globe in the *Graf Zeppelin* in 21 days, revives the old adage, "Seeing is believing." Editorial writers in all lands vied with each other, and rightfully so, in singing his praises. It should be recalled that out of nine attempts to fly the Atlantic in both British and German rigid airships, all but one have been successful, and on this one occasion, May, 1929, the *Graf Zeppelin* returned safely to its base in spite of serious engine trouble. Likewise, the one attempt to conquer the Pacific, by the *Graf Zeppelin* in August, 1929, was successful.

a radius of economic operation which exceeds the width of the Atlantic or the Pacific in distance. For example, let us compare the performance of a 57-ton flying boat with that of a 75-ton airship on a mail route between a California port and Hawaii, a distance of 2540 statute miles. In the light of present development, the flying boat would be able to transport about 1000 lb. of mail while the airship could transport 14,000 lb. The power requirement for the flying boat would be 6000 hp. and for the airship, 4000 hp. Flying non-stop in still air, the fuel cost per pound of mail transported in the flying boat would be about $1.85, while in the airship it would be only 10 cents for the entire distance. Amazing? Not at all when further examination reveals that the pay load in the flying boat is only $2^2/_3$ oz. for each horsepower as compared to $3^1/_2$ lb. in the airship.

Then why this enormous advantage in favor of the airship? Because searching investigation by leading scientists and qualified engineers proves conclusively that there are inherent limitations in the performance of heavier-than-air craft. It is a matter of common knowledge in engineering circles that the efficiency of an airship increases very rapidly with increase in volume, while in heavier-than-air craft there is little increase in efficiency with size, and in extremely larger sizes there may be an actual decrease.

Airship's Fuel Cost Low

It is realized that the cost of fuel represents in itself only a small portion of the cost of operation. However, for the purpose of simple comparison, fuel cost is a vital consideration for the reason that it is a direct index of the cost of power-plant operation, maintenance, replacement, and depreciation, which collectively, in long-range transport, represent at least 50 per cent of all operating charges.

Attention is invited to the fact that the 75-ton airship used in the above comparison has a displacement of only 2,500,000 cu. ft., which is small as airships go. On the other hand, the 57-ton flying boat, according to some authorities, seems to approach the economic limit in size, with little hope for improvement in performance except by resorting to the very questionable expedient of increasing the wing loading per unit of area, which in turn increases the landing speed and thereby reduces the operating safety factor. Of course, any improvement in the use of fuel or in the thermal efficiency of engines will be of value, but this same improvement will aid the rigid airship also.

Consider also that the field of safe activity of the airplane is limited to land and of the flying boat to water. The airship, however, can combine both land and sea in a voyage, and any large industrial center, no matter how far inland it may be located, may become a seaport, so to speak, and be connected directly with some other large industrial center that is inland in some other country.

Schwartz's Airship

These are some of the considerations which explain why a group of Detroit men, identified principally with the automotive industry, turned their attention as early as 1921 toward the possibility of constructing airships built entirely of metal, hoping thereby to develop a distinctly American type of dirigible applicable to both commercial and military uses. Roger Bacon had dreamed of this achievement in the thirteenth century, but it was not until the latter part of the nineteenth century that an Austrian named Schwartz actually built in Berlin a rigid airship covered with thin aluminum. This ship was 155 ft. long, had a maximum diameter of 44 ft. and a displacement of about 130,000 cu. ft. In its first flight (1897) the driving belts slipped off their pulleys on the crude engine, and the powerless craft, with one man on board, was carried by the wind to a forced landing in a forest. The ship was badly damaged and it was soon dismantled by curio seekers and the task passed on to succeeding generations having available better engines, stronger aluminum alloys, and a higher degree of technical skill.

Metalclad Construction the Obvious Step

Encouraged by the availability of dependable engines, of light, thin alloys, and of more seasoned engineering talent, the Aircraft Development Corporation was organized in 1922 to modernize the rigid airship, already a metal-framed structure since 1900, and make it all-metal like the hull of a seagoing vessel, which seemed an obviously desirable step.

For five years engineering research and study was carried on at a total expense exceeding $300,000. Trial-and-error methods disclosed that while the Zeppelin development was extremely valuable from the standpoint of the definition of technical problems, still the methods of solution were in most cases different. This is due to the fact that the entire theory of the accommodation of shear stresses in the metalclad ship is different from Zeppelin practice. In the metalclad the shear stresses, and to a large extent the tensile stresses, are carried in the metal hull covering, the plating of which also very definitely reinforces the internal frame members, thus reducing their design weight requirements. In the Zeppelin the shear stresses are carried through a complex system of diagonal wiring in the planes of the ship's surface. The fabric covering serves mainly to fair the surface and to resist the outer air pressure in flight. It may, under favorable conditions, carry minor shear stresses, but designers do not include it in their calculations.

In the course of the development work, hypothetical metal ships of different sizes were designed in considerable detail and a thorough stress analysis, involving even the integration of all forces as applied to each square foot of the hull surface, was worked out carefully. A large metal water model built to a 1:30 scale was tested at different angles of pitch to verify the theory of the design; of the main bending and shearing actions; and of the stress safety factors involved. So gradually, through years of painstaking and systematic effort, the general theory of the metalclad airship was mathematically and experimentally proved by an excellent and patient engineering staff.

Metalclad No Heavier than Fabric Construction

It was discovered that not only can an airship be built, possessing all of the obvious advantages of all-metal construction, but contrary to common belief, metalclad construction in the larger sizes does not add any considerable weight in excess over fabric construction. This surprising development is due largely to the fact that, as previously described, the shell or hull plating of the metal airship itself carries the tensile and shear stresses, and also reduces the internal framing necessary. To illustrate more fully, let us examine the actual physical structure of the two different types.

The surface of the fabric-covered ship consists of five layers, (exclusive of framing) from outside to inside: namely,

Outer fabric cover with doped coating
Shear wiring
Gas pressure wiring
Cord netting (eliminated in the *ZR-4* and *ZR-5*)
Gas-cell fabric lined with goldbeaters' skin.

These five layers in the fabric-covered rigid airship collectively perform the functions of:

Fairing the surface
Protection against atmosphere
Transmission of shear stresses

Accommodation of pressures
Retention of buoyant gas.

The single metal surface in the metalclad ship performs all these functions and performs each of them with less construction cost.

In the fabric ship the rigid frame members receive little substantial support from the fabric, due to its varying tension with change in weather conditions.

Metal Plating Carries Direct Stresses

The metalclad ship is a single structural unit in which the surface plating carries a considerable portion of the direct stresses. The metal plating, which is the outer cover, is the principal strength member and is also the gas container.

All-metal construction seems, therefore, to assure fulfilment of the world-wide demand for a commercial airship which is:

Fireproof
Weatherproof
Durable and permanent in structure
Navigable in practically all kinds of weather
Economical in the use of buoyant gas and ballast
Capable of high speed—up to at least 100 miles per hour, and
Limited in cruising range only by the expanse of the broadest ocean.

The *ZMC-2* Too Small for Commercial Use

No doubt all will understand that these ideal specifications do not apply to the first experimental unit, the *ZMC-2*, which is entirely too small to comply in detail with such high standards. In load capacity it is similar to the non-rigid fabric blimp, but in performance characteristics it is superior. In the magnitude of its importance as an engineering achievement, it is believed it equals that of any rigid airship ever built.

Its size of 200,000 cu. ft. was determined upon as sufficient to fulfil Government experimental requirements. Prior, however, to submitting a definite proposal to the Government, various systematic experiments were conducted.

Tests made in three different wind tunnels indicated that the new hull form and fin arrangement constitute an improvement in aerodynamic qualities.

The results of the large-size metal water-model test checked with our stress formulas and gave practical proof of the remarkable gain in strength obtained with the metalclad design.

Fins, girders, and other full-size parts were similarly built and tested. Tests made at the Bureau of Standards and in the corporation's own laboratory showed satisfactory resistance of the thin sheet and seams to vibration and diffusion.

The Automatic Seam-Riveting Machine

Paralleling the scientific work was the mechanical development and finally the completion and demonstration of a successful automatic riveting machine, a remarkable achievement and an economic necessity in the production of large-size metalclad airships.

This machine (Fig. 1) has successfully driven about 3,500,000 rivets of 0.035 in. diameter in the *ZMC-2*, with only one-third of one per cent of defective rivets. In its operation three strands of wire are fed like thread into the machine and three rows of rivets are "sewed" simultaneously. The machine shears off the wire in rivet lengths; these tiny wire lengths are punched through the two sheets of metal and revolving cams head them up into rivets.

The spacing of these rivets is also automatic. With this machine two men are able to accomplish as much work in a given time as 128 men working by hand. It inserts and completes 140 rivets per minute or about 40,000 rivets in an eight-hour shift. The cost per lineal foot of seam is about the same as the cost of sewing, cementing, and taping one foot of fabric seam. Thus we were prepared to answer the all-important question, "How are you going to join these thin sheets of plating together?"

Fig. 1 Metalclad Dirigible "ZMC-2" Taking Off on Her First Flight
(Grosse Isle Airport, August 19, 1929. Flight lasted 46 min.)

Congressional Appropriation for Building Experimental Unit

On the basis of the foregoing experimental work, in 1926 Congress was asked for an appropriation of $300,000 to be added to the Navy Bill for the construction of the first experimental unit. It was explained that this amount would be less than one-half the cost of the ship, which was estimated to be—including preliminary development—about $700,000. Actual experience to date indicates a total cost in excess of $750,000.

After many committee hearings, during which various objections were answered, Congress appropriated the money and the United States Navy awarded the corporation the contract to build the *ZMC-2*. It is true that this first unit, with a displacement of only 200,000 cu. ft., is too small in size to have any extended military or commercial value. It is not designed to accommodate passengers; it was not intended for that purpose. This small size was selected in order to prove the theory of all-metal construction with the least expenditure of capital, labor material, and time. On the experience thus gained it will be entirely feasible to base the design and undertake the construction of the larger and more useful sizes.

The *ZMC-2*, as the Navy has designated this first unit, made

its first trial flight August 19, 1929. It was delivered to Lakehurst on September 12, and on September 16 it completed successfully its final test, exceeding all contract specifications. It is of exceptional interest to relate that the actual finished construction weight permits a useful load of 127 lb. in excess of contract requirements. The original weight estimates were calculated in 1925. We believe this compares favorably with any experience in forecasting weight estimates of large airplanes. The general characteristics and performance data are given in Tables 1 and 2.

TABLE 1 GENERAL CHARACTERISTICS OF THE "ZMC-2" AIRSHIP

Length of hull	149 ft. 5 in.
Diameter of hull (max.)	52 ft. 8 in.
Fineness ratio	2.83
Displacement of hull	202,200 cu. ft.
Total ballonet displacement	50,600 cu. ft.
Front ballonet displacement	22,600 cu. ft.
Rear ballonet displacement	28,000 cu. ft.
Ratio of ballonet volume to hull volume	25 per cent
Thickness of skin	0.0095 in.
Length of car	24 ft.
Width of car	6 ft. 6 in.
Number of air valves	3
Number of gas valves	2
Number of fins	8
Total fin area	440 sq. ft.
Total elevator area	190 sq. ft.
Total rudder area	95 sq. ft.
Total automatic rudder area	95 sq. ft.
Engines (Wright Whirlwind J-5)	2
Power at 1800 r.p.m.	440 hp
Propeller diameter (all metal)	9 ft. 2 in.
Lineal feet of seam	17,600 ft.
Surface area	19,436 sq. ft.

TABLE 2 PERFORMANCE DATA OF THE "ZMC-2" AIRSHIP

Gross lift (100 per cent inflation with 92 per cent pure helium at 60 deg. fahr. and 29.92 in. Hg)		12,242 lb.
Weight empty		9,115 lb.
Useful load		3,127 lb.
Crew (three)	600 lb.	
Fuel (200 gal.)	1,200 lb.	
Oil (25 gal.)	200 lb.	
Ballast (50 gal.)	420 lb.	
Passengers and cargo	707 lb.	
Range with 250 gal. (cruising speed)		680 miles
Maximum possible range (still air)		1,000 miles
Maximum speed at 440 hp		62 ±2 m.p.h.
Cruising speed at 220 hp		50 ±2 m.p.h.
Static ceiling		9,000 ft.

A more detailed description of the *ZMC-2* structure is contained in Appendixes Nos. 1–5. Consideration is also given in these to tests performed on the structure; principles of the basic shape and of stress analysis; shop facilities and methods used; construction problems overcome; and method of inflation.

Assuming, from the experience thus gained from this initial unit, that we can proceed confidently to build the larger and more useful sizes, what use will they be commercially? How will they compare in economic performance with the large airplane or the super flying boat? This is an important question and deserving of consideration in this discussion.

With the experience in design, construction, and operation of the *ZMC-2* available, we have concluded that we can safely proceed with the design and construction of a metalclad airship of approximately 2,500,000 cu. ft. displacement (plus or minus) as the next succeeding unit in size. A ship of this size inflated with helium will have a gross lift of about 75 tons. Its general characteristics and performance are given in Table 3. It is designated *MC-25*.

Proposed 75-Ton Airship for the California-Hawaii Route

This ship would not be large enough for commercial operation across the Atlantic to Europe, but it would be practicable for operation on the shorter route from California to Hawaii, a distance of 2540 statute miles. This latter route is very desirable for any pioneering effort in commercial-airship transport for several reasons. First, it would save between four and five days of the time now required by Pacific steamships. Thus the first-class mail to Hawaii, which averages about 5000 lb. per week each way, would be greatly expedited. Furthermore meteorological conditions on the Pacific are much more favorable to the operation of smaller airships than they are on the Atlantic, for the simple reason that head winds are considerably less violent. Monthly pilot charts compiled from maritime records during the past 21 years indicate head winds with a force of 8 (Beaufort's scale, 39–46 m.p.h.) on an average of only twice per month between California and Hawaii. From the experience thus gained in operation and in the training of personnel, the development of larger and more useful airships applicable for continuous flight across both the Atlantic and the entire Pacific could follow in the natural course of events.

TABLE 3 GENERAL CHARACTERISTICS AND PERFORMANCE OF THE PROPOSED 75-TON METALCLAD AIRSHIP "MC-25" ON THE CALIFORNIA-HAWAII ROUTE

Displacement (actual gas-cell volume)	2,540,000 cu. ft.
Gas, helium 95 per cent pure, 60 deg. fahr., 29.92 in. Hg	62.5 lb. per 1000 cu. ft.
Lift, 95 per cent full	150,800 lb.
Weight empty	89,300 lb.
Speed, maximum	100 m.p.h.
Speed, cruising	70 m.p.h.
Horsepower, maximum	4,000 hp.
Horsepower, cruising	1,360 hp.
Range	2,540 statute miles = 2,200 nautical miles
Time required at cruising speed	36 hours
Fuel and oil consumption per hour (cruising)	750 lb.
Fuel required for range	27,000 lb.
50 per cent fuel margin	13,500 lb.
Total fuel	40,500 lb.
Mail and express	10,000 lb.
Passengers (10)	4,000 lb.
Crew (28)	7,000 lb.
Useful load, 40.7 per cent	61,500 lb.
Skin thickness	0.016 in.
Surface area	120,000 sq. ft.
Fineness ratio	4.5
Length	472 ft.
Diameter	105 ft.

In the construction of this larger ship, the same principle of utilizing the metal skin as outside cover, as the principal strength member, and as the gas container will be retained. The girders will be located so as to carry the loads in most advantageous manner. The interior structure will consist of deep transverse frames rigid enough to maintain the circular shape without any wire bracing. In addition, longitudinal members will be provided for supporting the skin and carrying the stresses, which the skin is not designed to transmit. The thickness of the skin will be determined as a function of dynamic and operating pressures and of the ship's dimensions. The frame dimensions will be determined by the external loads that they are required to carry.

A spacious corridor at the bottom of the hull will be provided the whole length of the ship. The passengers will be housed directly above the control and lounge cabin. The frames will be large enough so that all crews' quarters, fuel, cargo, and probably the engines, can be located inside. The outside appendages such as fins, control cars, and handling lines will be attached to the main frames.

Gas Compartments. The gas space will be subdivided by transverse fabric partitions into separate cells. The fabric partitions at the bottom of the cells will divide the hull into gas and air compartments. These partitions will be so arranged that the whole hull may be filled with either air or gas. This feature of cell arrangement will simplify the inflation and will take care of any possible deflation of a cell or a partial loss of gas in flight. It will also compensate for the expansion and contraction of the buoyant helium.

The hull will be maintained during flight under pressure by utilizing scoops providing the necessary internal pressure to counterbalance the dynamic pressure and by auxiliary blowers located in the ship and driven by separate engines. The hull will be designed to maintain its shape at slow speeds without internal pressure, so that it can be safely maneuvered in the air in case of temporary lack of pressure.

The water-recovery system developed by the U. S. Navy which condenses water vapor from exhaust engine gases can be very easily adapted to this metalclad ship. The metal plating will provide a perfect radiating surface so that for each pound of fuel consumed, one pound of water ballast will be recovered. This will effect a large saving in helium gas, which otherwise would have to be valved to compensate for the loss of fuel weight.

This ship will be constructed on the same principle as *ZMC-2*, by building it vertically in several sections and joining them together in horizontal position.

Cost. The estimated capital investment required for the building of two metalclad airships for the California-Hawaii route is set forth in Table 4. It is suggested that each airship would make one round trip per week. With a pay load of 14,000 lb. these two ships would transport 1456 tons or 2,912,000 lb. of pay cargo per annum.

Inasmuch as these ships would be inflated with helium, it is interesting and important to investigate the annual operating cost of helium for two ships flying on a schedule of one round trip per week each. Table 5 contains a study of these helium costs, based on the best available experience to date. The annual operating charge for helium on two ships, based on a cost of $40 per 1000 cu. ft., is $328,000. Surprising as it may seem, this is only about $50,000 more than the annual cost for fuel.

TABLE 4 CAPITAL INVESTMENT FOR AIRSHIP EQUIPMENT—CALIFORNIA-HAWAII ROUTE

2 metalclad airships (75 tons gross lift each) at $2,500,000	$5,000,000
Spare parts, reserve engines, gas cells, helium, etc.	500,000
1 hangar	1,750,000
2 mooring towers, fuel tanks, and utilities	400,000
Helium purification plant and gasometers	400,000
Repair shops	150,000
Crews' quarters and miscellaneous buildings	200,000
2 terminal buildings and office equipment	250,000
Land	250,000
Electrical equipment, radio stations, etc.	200,000
Unforeseen items	900,000
Working capital	1,000,000
Total capital investment required	$11,000,000

TABLE 5 HELIUM NECESSARY FOR ONE YEAR'S OPERATION OF TWO CALIFORNIA-HAWAII AIRSHIPS

(Based on experience with fabric-covered airships of 2,500,000 cu. ft. capacity)

Initial inflation of one 2,540,000-cu. ft. airship to 95 per cent of its displacement with 98 per cent pure helium (2,413,000 cu. ft.)	
The purity will drop to 94 per cent the first month with a loss of	96,520 cu. ft.
The loss will continue at the rate of 2½ per cent per month, or 60,325 cu. ft. per month, which for 11 months shows a loss of	663,575 cu. ft.
Repurification of the entire contents of each gas cell once per annum will result in a loss of about 9 per cent gross volume, or	217,170 cu. ft.
Total loss for one airship for one year's operation	977,265 cu. ft.
This constitutes a loss of 40½ per cent of the gross volume per annum.	
Under the proposed Pacific schedule each ship will make 104 trips per annum. Let us assume for the purposes of conservative estimate that 1 per cent of the volume of helium gas will be valved on each trip. This is contrary to experience, but this expense is included in order to provide against any emergency that might arise.	
104 per cent of the gross volume of helium (2,413,000 cu. ft.) would show a loss from this source per annum of	2,509,520 cu. ft.
Total helium required per annum per ship	3,486,785 cu.ft.
This constitutes 144½ per cent of the gross volume. At a cost of $40 per 1000 cu. ft., this shows an annual operating charge per ship for helium, of $139,471.	
For two ships operating on the Pacific schedule, the helium cost per annum would be	$280,000
To this must be added the cost of repurification of 2,413,000 cu. ft. for each ship. This is estimated at $10 per 1000 cu. ft. or $24,130 for one ship, and for two ships let us say	48,000
Total operating charge for helium per annum	$328,000

Economy of Operation as Compared With a 57-Ton Flying Boat

The economy in airship operation can be emphasized in no better way than through comparing the operating cost of this size of ship with the largest flying boat in the world. It was built in Germany.

This super flying boat has a gross lift of about 57 tons. It is equipped with engines developing 6000 hp., and its cruising speed is announced to be 115 m.p.h. Its useful load minus crew, according to its designer, is 56,815 lb. Assuming that the entire useful load capacity would be available for fuel and pay cargo, let us endeavor to ascertain how much pay load it would be able to transport on a route from California to Hawaii, a distance of 2540 miles.

At a speed of 115 m.p.h. it will require twenty-two hours for this boat to negotiate the voyage in still air. 2100 lb. of fuel will be required per hour at crusing speed. Twenty-two hours' flying will require 46,200 lb. Allowing for 20-mile head wind, which is the minimum allowance that would be safe to consider, would require additional fuel of 9615 lb. The total fuel required would then be 55,815 lb. Subtracting this figure from a useful load of 56,815 lb. would leave only 1000 lb. carrying capacity for pay load.

Assuming that each boat would make a round trip every four days, this would allow approximately 24 hours at the end of each voyage for adjustment and repairs. It would require 17 of these boats to transport the same weight of pay cargo per annum that two 75-ton rigid airships, previously described, could transport.

Power Ratio. The amount of power required to transport this pay cargo by flying boat is so extraordinarily large that it is ridiculous. Each boat is capable of carrying 1000 lb. of pay load. Each boat has engines developing 6000 hp. One horsepower is equivalent to 33,000 ft-lb. of energy per min. Applying this formula to the flying boat and utilizing 70 per cent of its gross power at cruising speed, this means that for each minute approximately 138,000,000 ft-lb. are developed. Inasmuch as the boat carries only 1000 lb. pay load, it is a matter of simple arithmetic to determine that for each pound of pay load transported, 138,000 ft-lb. of energy are required each minute.

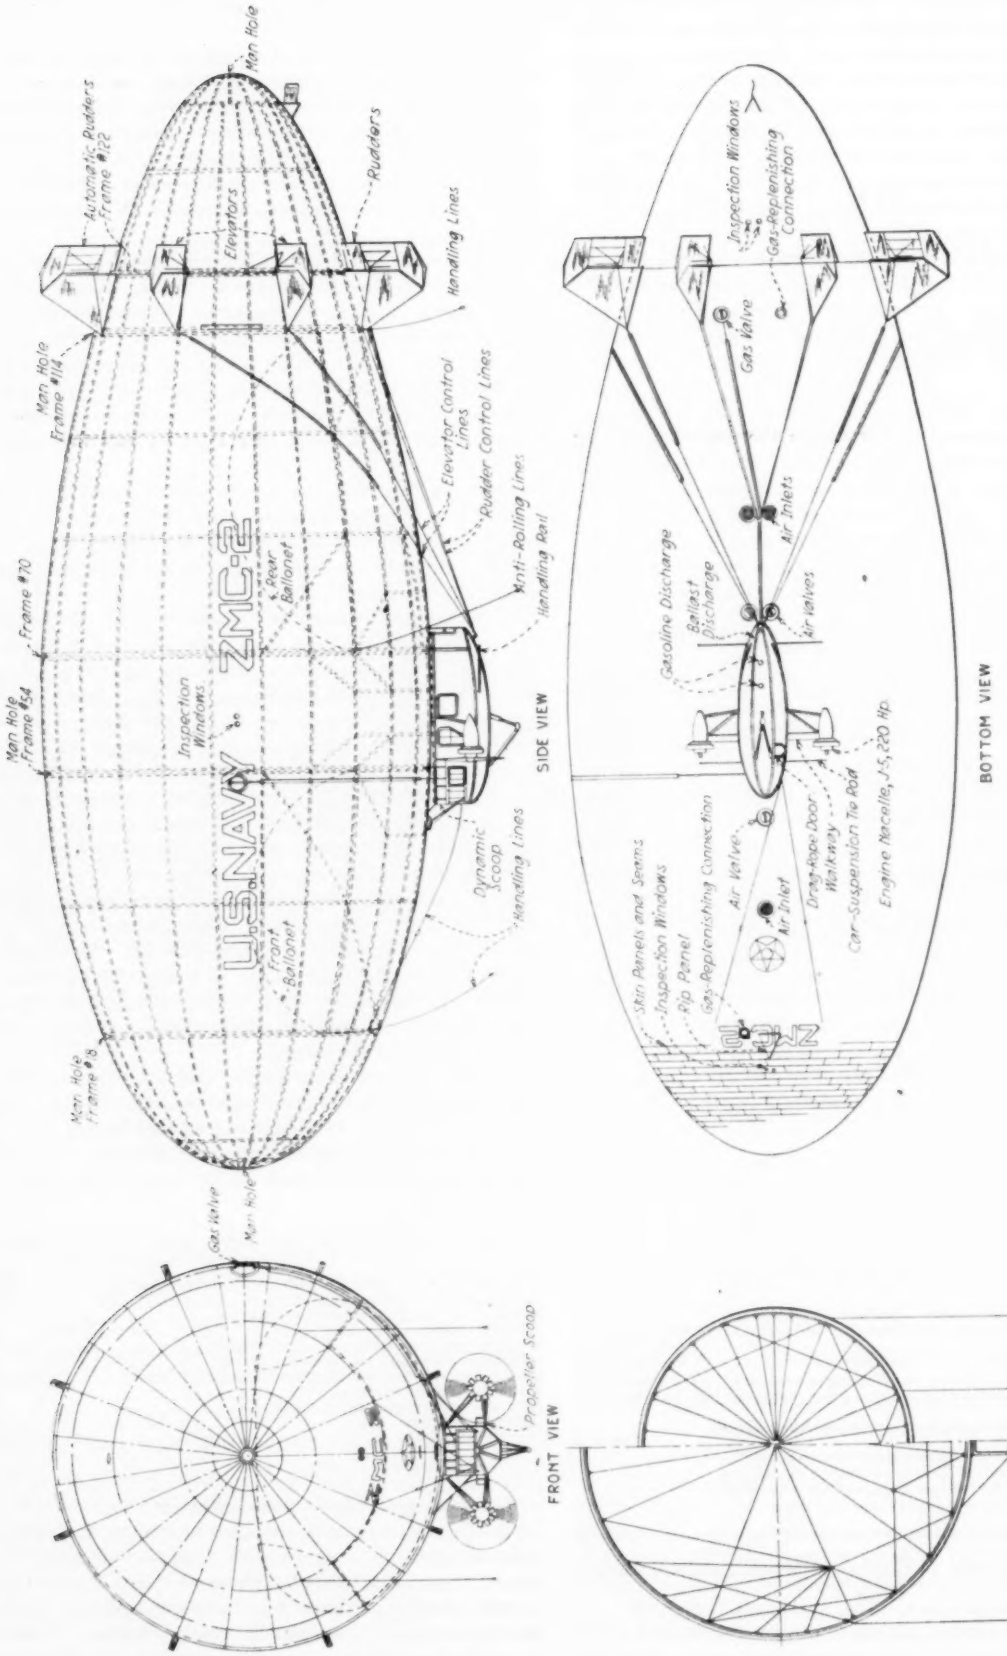
Contrast this with the small amount of energy required for the operation of the rigid airship. Each airship carries 14,000 lb. pay cargo. Its engines generate 4000 hp. At crusing speed approximately 67,000,000 ft-lb. of energy are developed each minute. Therefore, for each pound of pay load transported, only 4800 ft-lb. of energy are required, or a power ratio of almost 29 to 1 in favor of the airship.

In order to carry an actual pay load equivalent to that of the two 75-ton metalclad airships, these seventeen 57-ton flying boats would have to make 2912 trips one way per annum, as compared with only 204 trips negotiated by the airships. The estimated capital investment for these flying boats, equipment, etc., is given in Table 6.

TABLE 6 CAPITAL INVESTMENT FOR FLYING-BOAT EQUIPMENT, CALIFORNIA-HAWAII ROUTE

17 flying boats (57 tons gross lift each) at $425,000	$7,225,000
Spare parts, reserve engines, etc.	1,500,000
Hangars, dry docks, and marine railways	600,000
2 repair shops	225,000
Docking facilities, fuel tanks, and utilities	500,000
2 terminal buildings and office equipment	250,000
Crews' quarters and miscellaneous buildings	200,000
Land and harbor frontage	250,000
Electrical equipment, radio stations, etc.	200,000
Unforeseen items	1,050,000
Working capital	1,000,000
Total investment required	$13,000,000

With the capital-investment estimates before us for the two types of craft performing the same volume of work per annum, it is important to compare their respective operating costs per pound of pay cargo carried. These estimated costs are not guaranteed as perfect. There is no authentic experience at this time on which to base a reasonably exact estimate. However, the author has had access to the related experience found in the actual



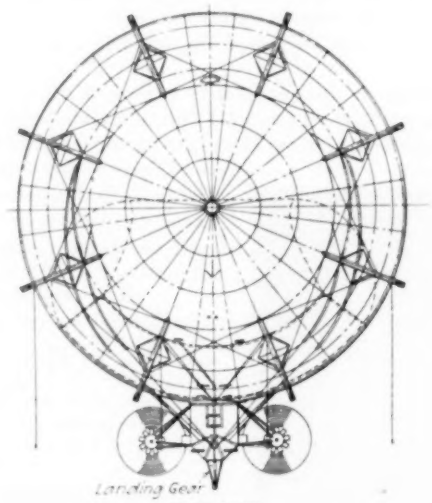


FIG. 2 SIDE, BOTTOM, AND FRONT VIEWS OF THE METALCLAD DIRIGIBLE "ZMC-2"
(For rear view, see Fig. 2a. For dimensions, other characteristics, and performance data, see Tables 1 and 2.)

operation of the larger and more important air-mail transport lines in the United States. Therefore no important or essential items have been overlooked and, while future experience may disclose that the individual figures are somewhat in error, still the totals are reasonably certain for purposes of comparison.

REAR VIEW

FIG. 2a REAR VIEW OF "ZMC-2"

Table 7 shows that the total estimated cost for carrying one pound of pay cargo in the flying boat from California to Hawaii is \$8.34, while in the airship it is only \$2.63.

TABLE 7 COMPARISON OF OPERATING COSTS ON THE CALIFORNIA-HAWAII ROUTE—17 FIFTY-SEVEN-TON FLYING BOATS VS. 2 SEVENTY-FIVE-TON METALCLAD AIRSHIPS

(All figures based on cost per pound, assuming that 100 per cent of pay cargo capacity is utilized. Total volume, 2,912,000 lb. pay cargo, per annum for both types of craft. Fuel consumption based on operation in still air.)

	Item	Cost per lb. Flying boat	Cost per lb. Airship
1	Executive expense	\$0.03	\$0.03
2	Administration: general overhead	0.07	0.07
3	Traffic: expense of sale of service and handling of passengers	0.05	0.05
4	Transportation, including crews' pay, gasoline, oil (and helium for airship)	2.62	0.43
5	Operation of terminals, including taxes, labor, salaries, etc.	0.10	0.10
6	Maintenance of equipment, including aircraft, engines, motor cars, tools, etc.	1.03	0.26
7	Communication, including teletype, radio, etc.	0.14	0.07
8	Insurance, including flying personnel, passengers, and equipment	0.26	0.17
9	Depreciation of flying equipment (aircraft 20 per cent per annum and engines on basis of 1000 hr.)	3.00	0.50
10	Depreciation of buildings and terminals	0.03	0.07
11	Unforeseen items	0.12	0.12
12	Profit, assumed, because of pioneering hazard, at 20 per cent on total capital investment	0.89	0.76
	Total cost per lb.	\$8.34	\$2.63

In analyzing Table 7 it is apparent that cost items of lesser importance for the two types of craft are reasonably close together. However, in the major items there is a wide difference as is illustrated in the cost of transportation, which includes crews' pay, fuel, and, for the airship, the additional cost of helium. In order to carry the assumed pay cargo, the flying boats would consume \$5,380,000 in fuel per annum. The airships would consume only \$275,000 in fuel plus the additional cost for helium amounting to \$328,000. In other words, by spending \$328,000 for helium, the airships save \$5,105,000 in fuel. Subtracting the helium cost from this latter figure we have an indicated net saving of \$4,777,000 in fuel. Consequently each dollar spent on helium saves about \$14.50 in operating charges for fuel.

Tariff Charge per Pound. It is recognized, of course, that no vehicle engaged in commercial transport consistently carries a 100 per cent load. Therefore, for the purpose of estimating a fair and minimum price per pound to charge for such service, it is assumed that the average cargo for each type of craft will approximate 75 per cent of its pay-load capacity. On this basis the rate per pound for the flying boat would be \$11.12, and for the airship it would be \$3.50. The ratio is 3.2:1 in favor of the airship.

It is important to emphasize that this differential in cost between the two types of craft does not begin to disclose the economic advantage of the airship over the flying boat, for the simple reason that the flying boat herein described, according to the conclusion of eminent authorities, seems to approach its economic limit in size. On the other hand, the 75-ton airship is relatively small as airships go, and if a super airship of 300 tons gross lift were employed, the cost per pound of cargo would be reduced to approximately \$1.25. Therefore, in comparing the super flying boat with the super airship, the differential in tariff in favor of the airship has a ratio of 9 to 1. It is believed also that approximately the same ratio in favor of the airship will prevail in the operation of any modern dirigible of equal size.

The Airship's Fuel Reserve Greater. Furthermore it should be emphasized that the airship carries a 50 per cent fuel reserve

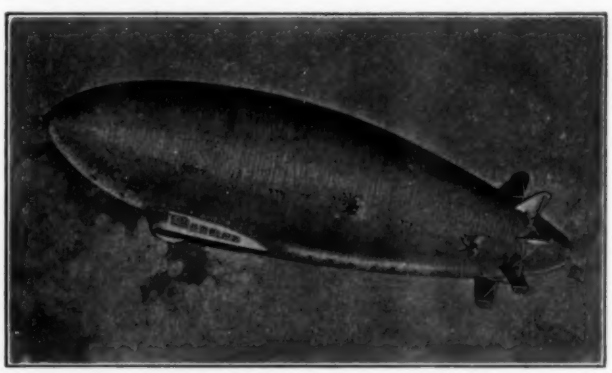

FIG. 3 PROPOSED METALCLAD AIRSHIP "MC-25"
(Gross lift, 75 to 90 tons; helium inflated; speed, 100 m.p.h.)

against head winds, which conforms to standard practice in the older forms of transportation. On the other hand, the flying boat used in the comparison carries only 21 per cent fuel reserve. If it should be loaded with a 50 per cent fuel reserve, not only would it be devoid of pay cargo, but it is doubtful if it would be able to get off the water under the most favorable conditions.

CONCLUSION

It is true that the present paper is intended primarily to describe the metalclad airship. However, in discussing the commercial utilization of this type of craft it is possible to do so only by comparing its performance with something with which the general public already has an intimate acquaintanceship. Therefore the flying boat has been used as a yardstick for this purpose. It is clearly realized that both the large flying boat and the large airplane possess practical advantages on shorter routes over which it would not be economical for the large airship to operate. Consequently this comparison should not be interpreted as an attempt to discourage the development of heavier-than-air craft but rather to designate the range of activity in which they can operate most efficiently. It is very clear, therefore, in the face of this staggering array of evidence, that the conquest of the Atlantic and Pacific oceans by commercial aircraft lies within the province of the large dirigible more than in that of the airplane or the flying boat.

Now, the question will be asked, "If all these advantages in favor of the airship are true, why has not its development progressed more rapidly?" This question to some is not easily answered.

In the first place, prior to the World War, practically all rigid-airship development was confined to Germany. At the conclusion of the war the Versailles Treaty halted this excellent development, and for a period of about six years this highly specialized talent remained dormant.

In the second place, a world-wide survey of aircraft activities reveals that for each $50 spent on airplane development only $1 has been spent on airship development. In the United States for each $100 spent on airplane development only $1 has been spent on rigid airships.

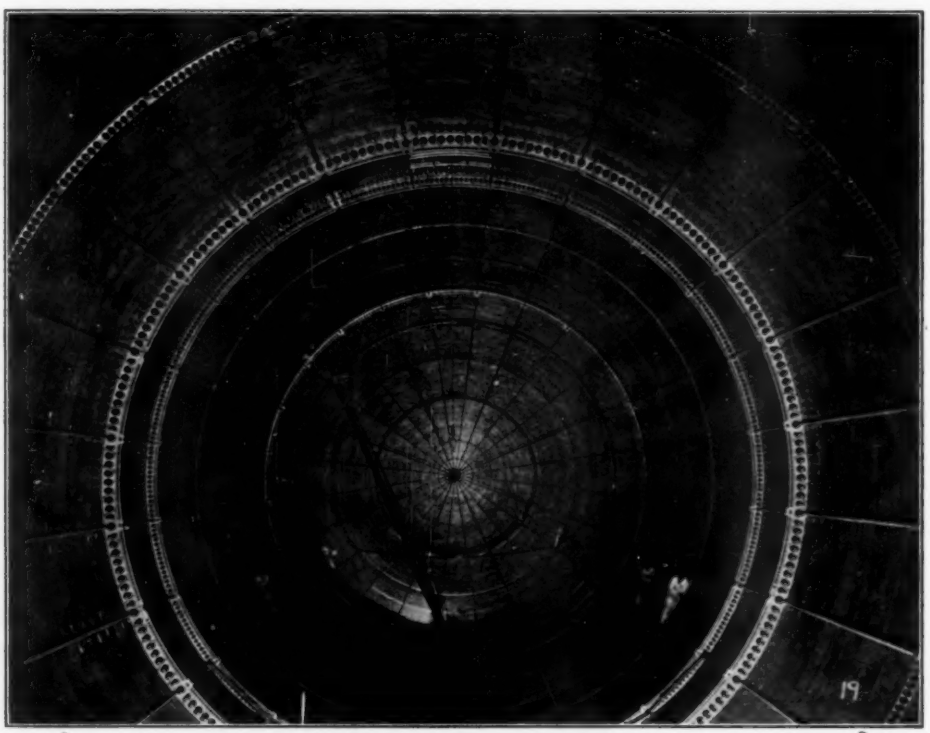

FIG. 4 INTERIOR VIEW OF THE "ZMC-2"
(Note men at work.)

In the third place, when one attempts to develop the rigid airship he must think in terms of millions of dollars instead of thousands for a new type of airplane. His effort must cover a period of years instead of a period of a few months.

In the fourth place, each disaster which has occurred in the experimental development of airships has caused a decided drawback in so far as securing additional funds for prosecuting the work at hand was concerned. The cumulative effect of these disasters has been more serious to airship development than have the most tragic airplane disasters to the development of heavier-than-air craft. This is due to the fact that the enormous size of the airship so captures the public imagination that the influence of any accident is multiplied accordingly.

Finally, the lack of adequate Government support in the past has retarded the development of the airship. However, the early enactment of federal legislation providing for the award of exclusive long-term contracts to commercial-airship companies for the transport of ocean mail at a price that will yield a fair return on the investment, will give the same encouragement to airship development that the air-mail contract act of 1925, as applied to transcontinental service, has given to airplane development.

Coupled with this legislation it would be entirely justifiable to amend the Jones-White Bill, extending its provisions to commercial airships so that the United States Shipping Board will be authorized to loan up to 75 per cent of the construction cost of new commercial airships on the same basis as it is now authorized to loan funds for the purpose of the upbuilding of our merchant marine.

Either phase of this program of legislation will give private capital the courage to go ahead. The full enactment of this program will place the United States in the forefront of all nations probably for generations to come. The goal ahead is the capture of the international trade routes.

TIME DEVOTED TO DEVELOPMENT OF METAL-CLAD AIRSHIP

The equivalent of 65 man-years has been spent by the engineering staff of the Aircraft Development Corporation in solving the problems involved in the design of the *ZMC-2* metalclad airship. The approximate details follow:

	Problems	Man-hours
1	Development of basic theories of stress distribution in metal hull	12,600
2	Extensive original researches made in aerodynamics and static theory of airships	6,090
3	Aid in development of the successful rolling of wide, thin duralumin sheet for hull	2,320
4	Development of suitable practical internal rigid structure of metal-airship hull	2,540
5	Fabrication and testing of many types of lattice and rolled girders	1,780
6	Development of semi-portable automatic riveting machine which sews plating of hull together	9,430
7	Devising practical methods of erecting and inflating metal airships	4,810
8	Development of several different successful sealing compounds for making seams gastight	2,720
9	Development and testing of protective coatings against weathering and corrosion	1,930
10	Fabrication and load testing of fins and various control mechanisms	2,450
11	Construction and testing of first large metal-airship water model	4,310
12	Development of hand method of riveting thin sheet metal	2,400
13	Mooring methods studied and developed	5,390
14	Vibration tests	1,580
15	Development and construction of machine for laying out large radii	800
16	Lightning and fire tests made	590
17	Design and test of all-metal car	7,040
18	Study and development of ballonet and methods of attachment	3,360
19	Seam design	810
20	Detailed design of structure including shop drawings	43,200
21	Building and testing assembled structure	19,400
22	Design and testing inflation methods and equipment	12,300
23	General	10,000
	Total time (man-hours)	157,850

The total given above does not include time devoted to problems by outside cooperating organizations, nor by the Corporation's very able Technical Committee, Messrs. Alex Dow, C. F. Kettering, W. B. Mayo, and Warren Noble, whose seasoned judgment and pioneering faith contributed so much to the success of the enterprise.

Appendix No. 1

DESCRIPTION OF THE "ZMC-2"[4]

The Hull

THE *ZMC-2* hull is 149 ft. 5 in. long from bow to stern, and 52 ft. 8 in. in maximum diameter. Its covering consists of 0.0095-in. thin Alclad alloy sheets sewed together by the Aircraft Development Corporation riveting machine. Each of the rings of sheet metal composing the hull surface has the shape of the frustum of a cone; together the cones closely approximate the curvature of the hull. There are 142 such conical surfaces from bow to stern.

The skin contains lifting gas, consequently the seams and rivets have to be gasproof. This is achieved by a gas-sealing compound which is applied on the seams, is drawn in by capillary action, and seals the lap seam.

Inside the hull the skin is held firmly by rivets to a supporting structure built up of transverse frames and longitudinals. There

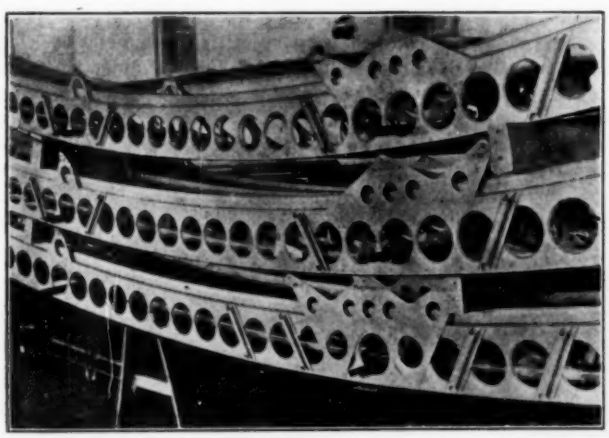

FIG. 5 GIRDERS READY TO BE ASSEMBLED AS PART OF FRAMEWORK

are 24 equally spaced longitudinals running from the bow to frame No. 145, and 16 from this frame to the stern. In the bow and the stern is a rigid ring from which the longitudinals radiate. Incidentally, these rings serve also the purpose of manhole frames, as will be mentioned later.

The cross-section of the longitudinals is of the "capital omega" type (Ω). The flanges of the section are attached to the skin by rivets. Two sizes of sections are used. In the extreme bow and stern, where the longitudinals are crowded, the section is only 1 in. high, while the rest of the hull has longitudinals 2 in. high. The latter are lightened and strengthened by flanged holes.

The thickness of longitudinals varies from 0.014 in. to 0.032 in. according to the intensity of compressive loads in any particular portion of the hull.

Transverse Frames

There are altogether 12 transverse frames, numbered according to their distance from the bow of the hull. Of these, frames Nos. 18, 54, 70, 114, and 122 are of the heavy built-up type, the remainder being of simple triangular cross-section.

[4] Prepared by Vladimir Pavlecka and S. A. U. Rasmussen, Detroit Aircraft Corporation, Detroit, Mich.

The main frames are also of a substantially triangular cross-section, having all three apexes formed by channels and mutually connected by light web plates and a base plate. Flanged holes are used liberally in the channels, webs, and base plates. In cross-section the frames are 8 in. high on center line and from 8 to 10 in. wide at the base, depending on the base slant, which corresponds to the angle of the skin at the location of the frame. The

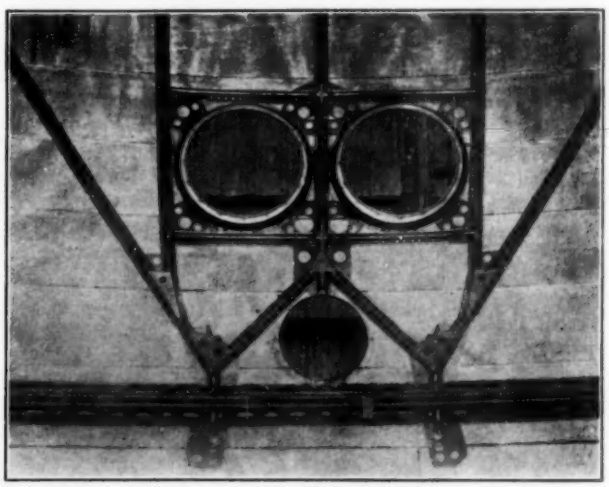

FIG. 6 REINFORCING AROUND VALVE SEATS IN HULL

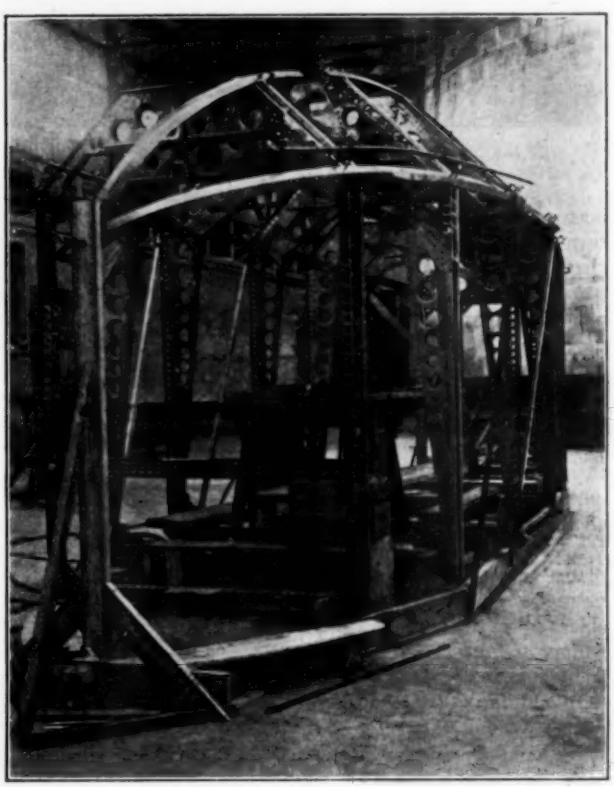

FIG. 7 FRAMEWORK OF CAR

channels are 0.025 in. in thickness, the webs, 0.020 in., and the base plate, 0.014 in.

Each frame is built up of a number of bowed sectors spliced end to end. The main frames take primarily all concentrated loads,

such as landing and handling lines, weight of the car, fin loads, etc. They are diagonally wired by hard-drawn aircraft wire and tie rods. Wires are spliced to eyebolts screwed into Lynite cast-

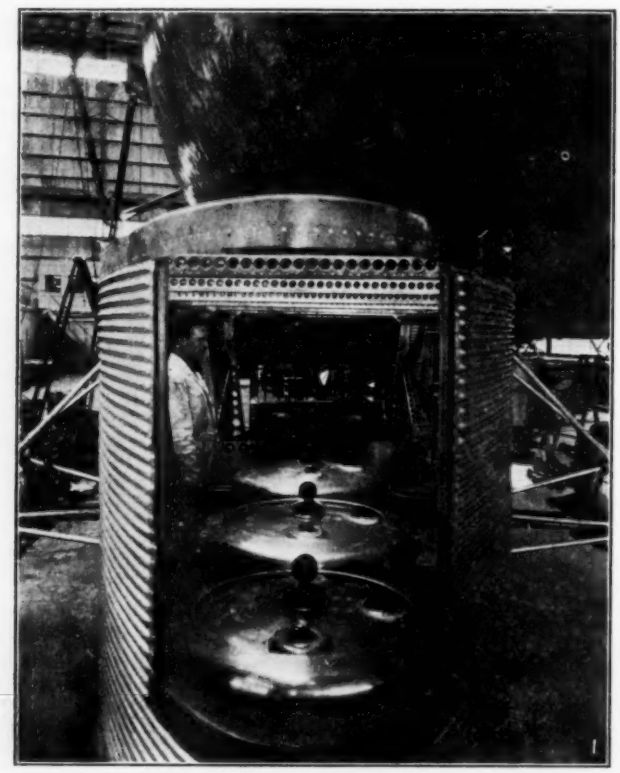

Fig. 8 Interior View of Car

ings as filler blocks, which in turn are anchored in the apex channel of the frames. Gusset plates or, as in the fin attachments, tubular spacers are employed to transmit the external loads from the base of the frames to the apex.

The outer bolts, on which the outside loads are applied, pass through heavy reinforcing plates on the inside of the hull skin; in addition, cast bearing blocks hold the bolts on these base plates against tangential loads. Gastightness at such joints is achieved by a gasket of canton flannel treated with the same compound as the seams.

In addition to the load wiring, frames 54 and 70 have, in their lower halves, auxiliary wiring to take the loads imposed by the ballonet diaphragm.

The frames are continuous, while the longitudinals stop at the frames and are connected through the frames by special straddling splices of formed sheet. In addition to the main longitudinal and transverse structure described above, there are rigid diagonals at places of considerable shear stresses as on the side of the hull, and auxiliary ribs in locations where stiffness is desired, as on the bottom of the hull. All these reinforcements employ a 2-in. channel section, and all are rigidly connected to the rest of the structure by means of base plates and splices.

The average spacing of rivets attaching the skin to the structure is 2 in. Flat-headed rivets of $^3/_{32}$ in. diameter with round edge are used, which eliminates cutting of the skin by the sharp edge of customary round-head rivets. All rivets are of 17ST aluminum alloy.

The bow and stern are fitted with manholes, covered normally with a metal shield plate, screwed down. Similar manholes are placed at all main frames on top of the hull, to facilitate entrance into the hull for adjustment or repairs. These manholes, 5 in all, are provided with a fabric seal against leakage. The rear ballonet can be entered by a similar manhole in the bottom of the hull.

Valves

The hull is equipped with 5 valves, automatically as well as hand operated, of the Gammeter type, 20 in. in diameter and having a 4-in. water column maximum blow-off pressure. Two of the valves are for gas and three for air, the latter being at the bottom of the hull. One of the gas valves is on the port side of the hull and the other in the stern at the bottom of the hull.

Two gas-replenishing connections of 15 in. diameter each are built into the bottom of the hull, one in the bow, the other in the stern. All of these holes and valve seats require secondary structure for local reinforcement, and 2-in. channel is used for this purpose.

The largest unsupported area of the hull skin occurs at the maximum diameter and is 6 ft. wide by 15 ft. long.

Three pairs of glass inspection windows are located in the bow, port side, and the stern of the ship, respectively.

On the underside of the bow is a triangular rip panel, which can be torn open by the pilot in an emergency; it operates on the principle of shearing the skin against the edges of two thick strips.

Control cables to the gas valves run in Bowden casings, securely

Fig. 9 Side View of Car and Motor Mount

cemented to the outside surface of the hull. The air resistance of this type of controls is negligible.

Handling Lines

The *ZMC-2* is equipped with four sets of steel-cable handling lines; each set has two lines, attached to the hull symmetrically to the ship's center line. Each of these lines is designed for 5600 lb. ultimate strength.

One set, on the bow, is intended for landing the ship. Two sets, one on the bow and the other on the stern, are intended for handling the ship on the ground. The last set, located amidships, is designed for holding the ship against rolling when on the ground.

The landing lines are each 40 ft. long, with cotton-rope extensions. In addition, a third landing rope is carried; this is a $^3/_4$-in.-diameter manila, 250 ft. long, which can also be used as a drag rope. This rope is attached to the bottom of the control car and can be dropped at the pilot's will. By a quick-release device it may be swung to a bridle on frame 18 of the hull.

The Car

In plan view the car has a smooth curve, which provides most floor space for the general car dimensions. In cross-sectional view the bottom is a semi-octagon with its vertical sides extended up to the top of the car. The car is 24 ft. long and 6.5 ft. wide at maximum section. With scoops, tanks, controls, radio, drag rope, blower, and a chart table installed inside, it still is quite roomy for two pilots, one mechanic, and about four student pilots.

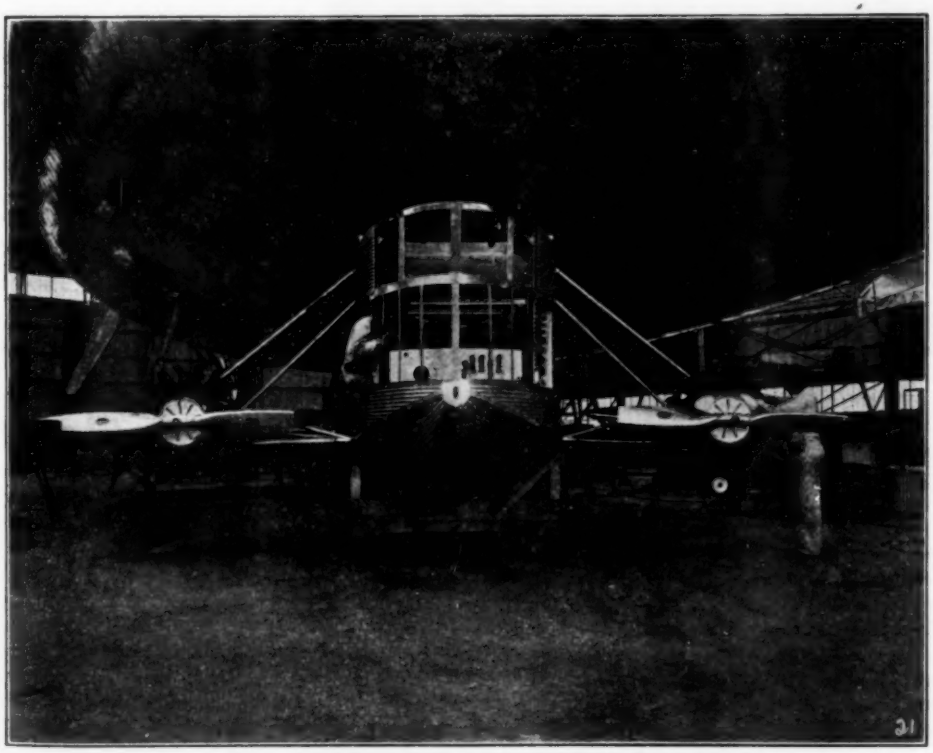

Fig. 10 End View of Car Showing Mounting of the Two 220-Hp. Wright "Whirlwind" J-5 Engines

The structure of the car consists of eight transverse frames, a number of longitudinals, and diagonal braces. It is a bridge-like structure and has been analyzed as such.

The covering is of 0.014-in. corrugated Alclad sheet. The chines, 4 in all, are very rigid, and together with the plating add considerably to the strength of the structure.

All frames are box girders, trussed with inside channels, and each frame is designed for the particular loads it takes. The heaviest frame weighs 33 lb., and the highest load occurring in it is 17,000 lb. compression.

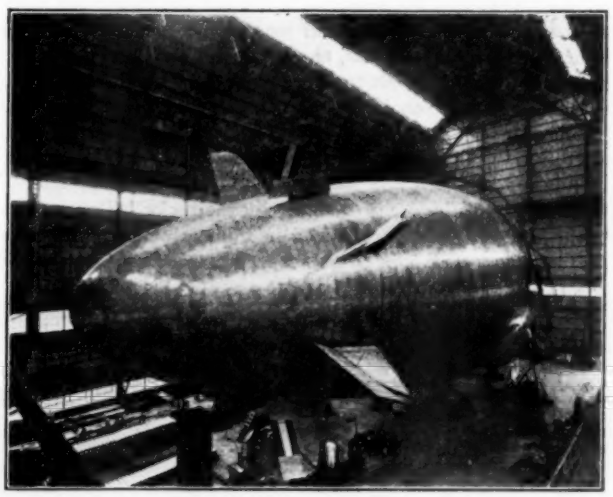

Fig. 11 Showing Series of Control Fins, Embodying a New Feature in Airship Design

The basic rolled section used in the car is a U-channel with flanges, 2 in. wide and $2^1/_2$ in. high. Flanged holes are used profusely in all except the tension members.

The car is suspended to the hull by means of eight attachments; of these four are rigid joints and four streamline rods. Either of these two sets of joints is designed to carry the car independently with all loads in it. Furthermore, the rigid joints are called upon to take the thrust of the power plants. The factor of safety of all joints is 6 on the highest load each joint might ever be required to carry.

The pilots sit side by side in the bow of the car, with all controls and instruments on panel in front of them. Directly above their heads is a compartment containing a dynamic scoop.

The altitude pilot, seated on the port side, can operate a radio set immediately behind him on a desk. The direction pilot, on the starboard side, can read maps on a chart table placed opposite the radio desk.

The engine outriggers are attached to the car aft of the pilots, with the plane of the propellers behind the pilots' seats. In the middle portion of the car are propeller scoops and vertical ducts, one on each side of the car. In this section also is the mechanic's post with a board of engine instruments and controls.

All engine-control rods are carried in the double bottom of the car and are easily accessible.

The pilots can control engine speed by their own set of throttles in addition to the mechanic's controls.

The entrance door is on the starboard side, behind the propeller scoops. Opposite the entrance is a hand air blower for maintaining the hull pressure in an emergency. Besides the main door there are four hatches, one for each pilot and two for the mechanic, to gain access to the engines during flight. A walkway is built on the engine outriggers to connect the car with the nacelles.

Gasoline Tanks on Special Cradles

The stern of the car is occupied by the tanks. Two gasoline tanks, 100 gal. each, are placed in tandem on special cradles. The rearmost tank is of 50 gal. capacity, to be used as a water-ballast container. It can, however, be connected to the fuel system and used as a gasoline tank for long flights.

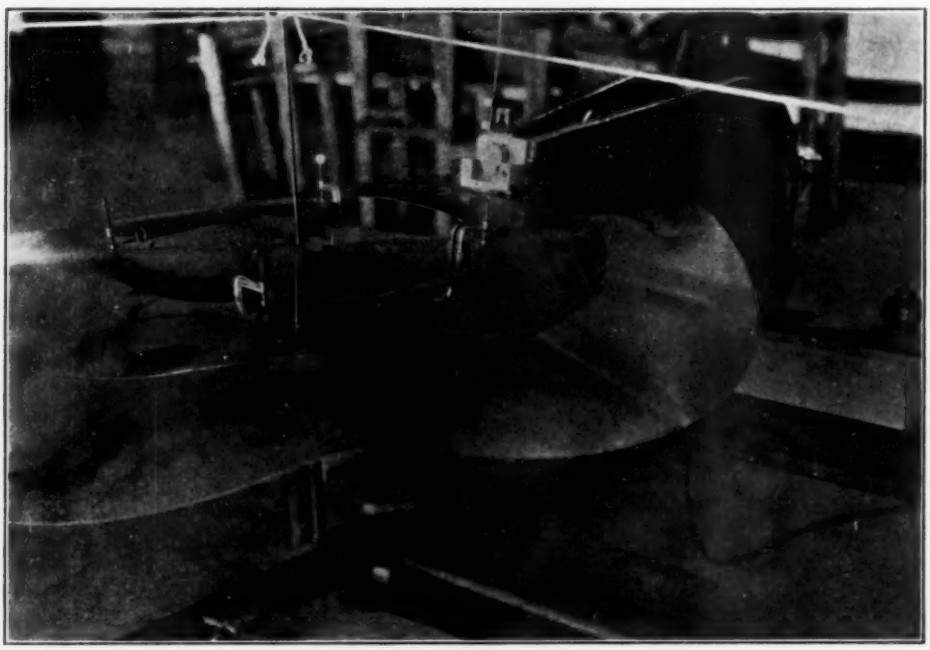

Fig. 12 The First Step in Building the Metalclad Dirigible "ZMC-2"—Riveting the Nose Plates

All tanks have dump valves.

Special balsa plywood flooring is laid in the car and fastened solidly to the structure, except in a few places where it is removable to gain access to control rods and cables.

Electric light is supplied by a 12-volt storage battery.

Power Plants

The engines are carried on tubular outriggers, one on each side of the car. Wright "Whirlwind" J-5-A engines are used, developing a maximum of about 220 hp. each. They operate tractor metal propellers. Each power plant has independent fuel, oil, and ignition systems and controls.

The oil tank, with a glass volume gage, is located inside the streamline nacelle behind each engine. Oil pressure and temperature gages are on the mechanic's board inside the car. All controls, tubes, and ducts to the engines are inside a walkway leading to each engine. A push-and-pull system is used for engine controls.

Each outrigger can be detached from the car by removing four bolts and disconnecting the instrument leads, pipes, and controls from the car. The engines have inertia starters, hand operated from inside the car through the hatches.

The Landing Gear

A bumper bag for taking landing shocks was out of the question in the case of the *ZMC-2*, due to the low position of the engines and excessive height of the car above the ground.

The landing gear is an inverted tripod with one leg as a shock absorber of the Oleo type; the other two legs are streamline duralumin tubes. The impacts are received by a streamline hollow steel shoe at the apex of the tripod.

The streamline struts are calculated for a factor of safety of only 2. In case of a severe shock these struts are expected to collapse, and in doing so check the inertia of the hull, thus eliminating the danger of damaging the car. This appears to be the only practical solution of the problem of protecting the car from ground impact.

The Ballonets

Two ballonets, one of 22,600 cu. ft. and the other of 28,000 cu. ft. capacity, are located between frames 18 and 54, and 70 and 114, respectively. These ballonets are made as complete fabric bags laced to the above-mentioned main frames and also to the longitudinals. The bags are so designed that practically all loads due to surging and to pressure are transmitted to the main frames.

The ballonets are made of two-ply rubberized fabric weighing 9 oz. per sq. yd. The seams are palled $^3/_4$ in.—cemented and taped but not sewed. The ends and sides of the ballonets are attached to the main frames and longitudinals by lacing strips with grommets. The bottoms are tied to the intermediate crossings of longitudinals and frames in order to prevent the possibility of gas getting under the ballonet and lifting it while surging. Around the various openings leading into the ballonets through the bottom of the hull, the ballonets are cemented to the hull with "Vulcalock."

Ballonets Filled by Air Scoops

Air is supplied to the ballonets through a scoop located in the forward end of the car and two propeller scoops. For ordinary conditions of level flying the car scoop should be sufficient, as it automatically increases the air pressure in the ballonets with the increase of the speed of the ship. The scoops are so controlled that air can be let into either ballonet independently or into both ballonets at the same time. An auxiliary hand blower with a maximum capacity of 2200 cu. ft. per min. is provided in the car. This blower should take care of a descent of 250 ft. per min.

One automatic and hand-operated air valve and one automatic emergency air inlet are provided for the forward ballonet and two of each for the rear ballonet. The air valves are standard 20-in.

Gammeter airship valves. The air inlets are inward-opening fabric flaps. To prevent leakage they are sealed with easily ripped fabric covers.

A rip panel is located in the rear end of the forward ballonet and another in the forward end of the rear ballonet, to open ballonets into the gas space.

Fins

A group of eight fins and control surfaces is located at frame No. 122, all surfaces being equally spaced around the hull. The

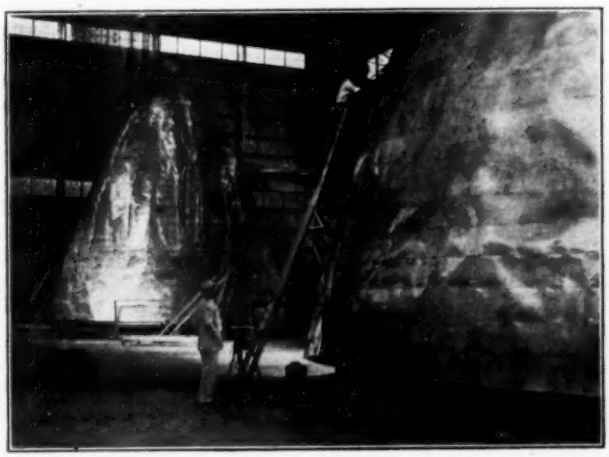

Fig. 13 Partially Completed Sections of "ZMC-2" During Construction in Hangar at Grosse Isle Airport

control surfaces consist of four elevators, two service rudders at the bottom, and two fins. The latter two are normally provided with means of locking rudder and fin together to form a fixed surface, or may be arranged as automatic rudders. All surfaces are mutually interchangeable by means of minor modifications. The elevators are limited to approximately 20 deg. movement, and the lower rudder to 30 deg. each way, by means of stops on the control cables in the car. All movable surfaces are counterbalanced. Each fin is externally braced by a pair of streamline wires.

The fin and control-surface frames are made of aluminum alloy and covered with corrugated Alclad of an average thickness of 0.008 in.

Controls

The rudders as well as the elevators are operated by wheels. To move the elevators from extreme up to extreme down position requires two complete turns of the wheel. The extreme movement of the rudders requires three complete turns. The control cables are brought from the wheels in the forward end of the car beneath the floor to the rear end of the car in such a way that they are easily accessible for inspection. From an outside "pulley bridge" at the rear end of the car the elevator cables lead through Bowden casings to the elevators, while the rudder cables lead over pulleys at the leading edge of the fins direct to the rudders.

TABLE 8 GENERAL WEIGHT STATEMENT, "ZMC-2" AIRSHIP

	Pounds	Pounds
Hull		4,625
Frames	965	
Longitudinals	420	
Skin	2,700	
Seam rivets	30	
Seam dope	70	
Closing seam	30	
Ribs and diagonals	55	
Attachments	355	
Ballonets		780
Fin group		650
Car		1,310
Power plant		1,750
Total weight empty		9,115
Useful load		3,127
Crew	600	
Fuel	1,200	
Oil	200	
Ballast	420	
Cargo and passengers	707	
Gross lift at 92 per cent pure helium at 60 deg. fahr. and 29.92 in. Hg		12,242

The rudder cables from the two rudders are joined together just abaft the car and carried through to the control wheel as a single cable. At the point where they are joined an auxiliary hand line is attached which enables the controls to be operated in case of breakage of cables in the car. As the elevators and rudders on each side of the ship are operated independently (the independent elevator cables being carried right through to the control wheel),

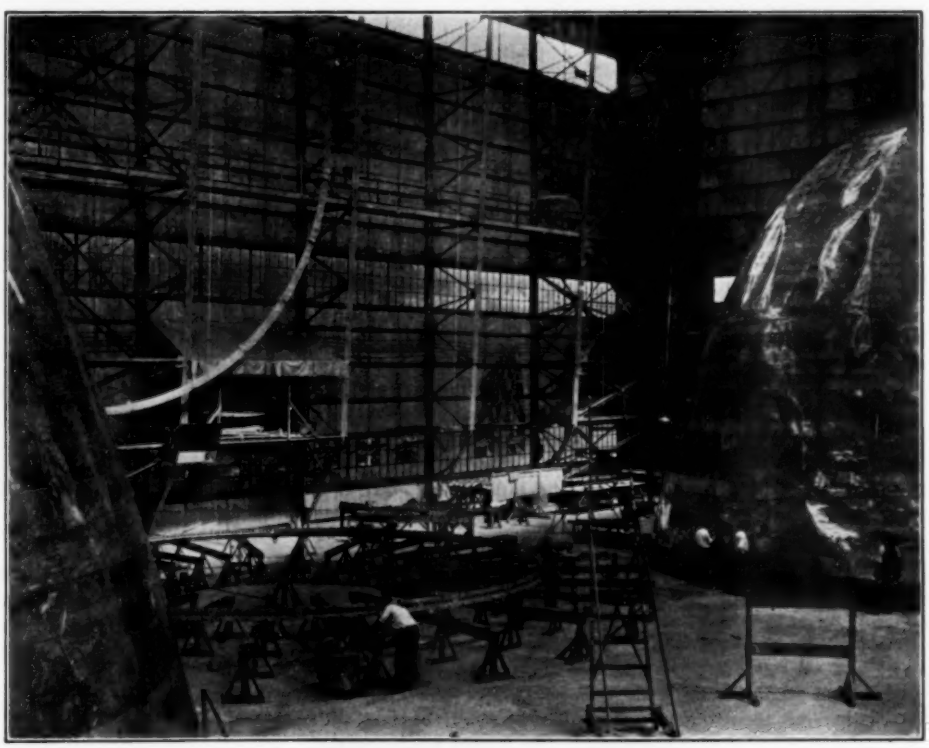

Fig. 14 Assembly of Main Frame Member of "ZMC-2"

the breakage of the cables on one side still allows the ship to be controlled by the surfaces on the other side. The control cables throughout are $^1/_8$-in. diameter, 7 × 19 extra flexible steel cable.

Appendix No. 2

BASIC SHAPE AND STRESS ANALYSIS[5]

THE hull is a double curved surface of revolution based on the geometrical *EH* curve, composed of elliptical and hyperbolic surfaces.

All characteristics of the curve are expressed as functions of

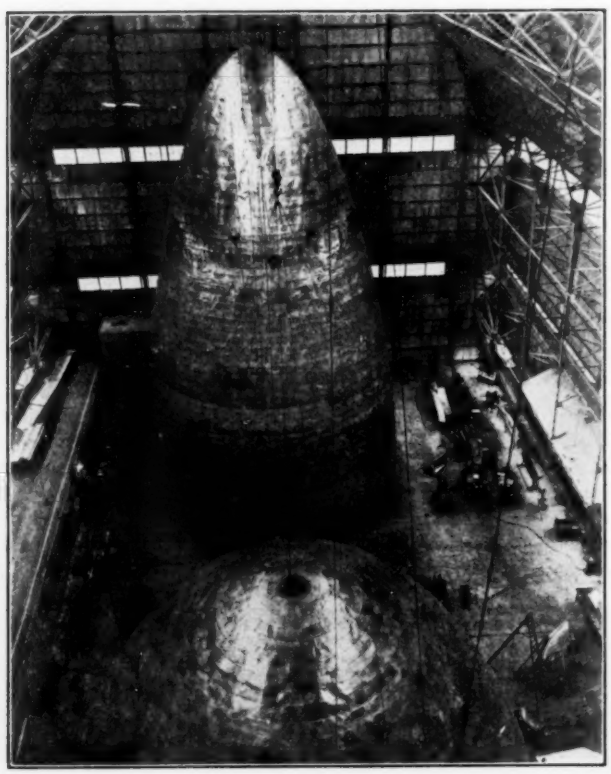

FIG. 15 SHOWING VERTICAL METHODS OF ERECTION USED DURING CONSTRUCTION OF THE "ZMC-2"

the semi-major and semi-minor axes of the bow ellipsoid, and can be easily applied to any volume and fineness ratio.

The particular feature of this purely geometrical curve is that it facilitates the very accurate plotting of elements of the hull structure and allows the determination of aerodynamic loads on the hull, applying the hydrodynamic theory of pressure distribution to the ellipsoidal shapes. This distribution was found to approach very close to the actual condition in the bow, where the aerodynamic loads are most important.

The general load distribution on the hull of the *ZMC-2* is unique because major concentrated loads are carried first to circular transverse frames and from them by pure shear forces into the surface plating. Each of the main frames consists of a rigid continuous girder, riveted directly to the inside of the surface plating and cross-braced by wires in its own plane.

Each frame was analyzed by assuming the concentrated load carried by the frame to be balanced by the system of shear forces, acting tangentially to the hull. For simplicity these tangential forces were assumed to act at the intersection of the ring with internal wiring and the longitudinals. The frames usually carried a system of wiring which was redundant; to simplify the computations the wires which are most liable to be subjected to compressive loads were assumed as not acting, thus making the structure determinate. The maximum load found to be applied at the span of the girder between two wire terminals was taken as the design load for the girder and the girder designed accordingly. The portions of duralumin girders built of rolled shapes, and plates of light gages of the length equal to the arc of the circle between two wire terminals (usually $^1/_{24}$ of circumference) were tested, and finally the present girders were developed. The smallest factor of safety in these girders is 4.7 (disregarding the effect of gas pressure).

It can be shown mathematically that any cylindrical section of a flexible envelope supported in shear by circular bulkheads remains circular at all positive pressures without any tendency to distort, provided the envelope is full of gas and has a uniform weight per square foot. This fact was proved in the *ZMC-2* case by water-model tests. Only secondary forces tend to distort the section from its circular shape, and these are taken care of by the double curvature of the hull's surface and absence of straight elements.

Small longitudinal girders built of rolled sections 2 in. deep of very light gages were introduced to support the skin when the ship is deflated and to take care of compressive stresses occurring in the plating under extreme conditions. The longitudinals were neglected in calculations of general skin stresses, but if compressive loads were found in any direction in the skin, these compressive loads were then investigated and were assumed to be carried by the longitudinals. All these cases, such as bow ribs, suction on lower part of hull, and compressive loads were investigated separately.

EQUATION OF STRESSES

The calculation of stresses in the envelope is based on the

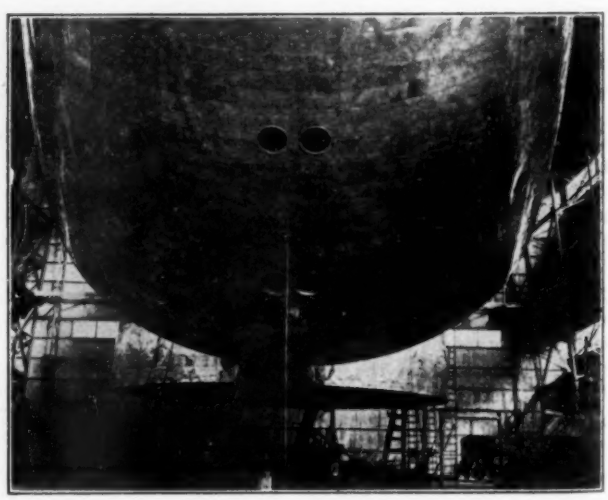

FIG. 16 PLACING HULL SECTION IN POSITION FOR JOINING

fundamental equation of stresses in containers of double curvature subjected to internal pressure, namely,

$$p = \frac{T}{R} + \frac{t}{r}$$

where p = pressure on any section, lb. per sq. ft.
T = longitudinal tension, lb. per lin. ft.
t = transverse (or hoop) tension, lb. per lin. ft.
R = longitudinal radius of curvature, ft.
r = transverse radius of curvature, ft.

This equation is indeterminate, containing two unknown tensions, T and t. Assuming the pure bending theory to apply,

[5] Prepared by W. A. Klikoff, Detroit Aircraft Corporation, Detroit, Mich.

T can be determined from bending-moment theory, making a correction for longitudinal loads. By introducing T in the general equation, t can be determined. The unit value of shear can be computed, and consequently the principal stresses in the skin can be found.

The computation of the skin stresses used was not entirely satisfactory, because the conventional beam conditions were assumed to be applied. The elastic deformations upon which the beam theory is based are small compared to the possible normal deflections, and can even be neglected. The problem was to determine the distribution of stresses in a curved non-extensible surface. A series of formulas of various forces and skin stresses on the whole cross-section of the ship as well as on a small element can be written. The solution of them is a very complicated mathematical problem if all the items are taken in consideration, and as long as the beam theory was found to be closely applicable to the actual practice and the formulas used very simple and easily applied, no complete calculations of these conditions were made but a possibility for further research is left open.

The following limiting conditions were investigated and stresses in the skin in most critical places computed.

Case I. Hull fully inflated; full speed 70 miles per hour; zero yaw and pitch; maximum internal pressure (blow-off pressure at the valve) 100 mm. above the outside air pressure at the valve section.

Case II. Minimum pressure for full speed above atmosphere assumed as one-half of maximum hydrodynamic pressure. Other conditions same as Case I. (Analyzed for nose stiffness only.)

Case III. Speed 50 miles per hour; pitched downward 10 deg. relative to air, but horizontal relative to ground; minimum pressure above atmosphere one-half of maximum hydrodynamic pressure.

Case IV. No power. Hull fully inflated at zero angle; internal pressure at bottom 0 mm.

Case V. Speed 45 miles an hour; pitched upward 10 deg. relative to air, but horizontal relative to ground; (*a*) minimum pressure one-half of maximum hydrodynamic pressure; (*b*) maximum pressure same as Case I.

Case VI. Speed 45 miles per hour; pitched 25 deg. downward relative to ground and 4 deg. downward relative to air. Minimum pressure one-half of maximum hydrodynamic pressure. (This case analyzed for nose stiffness and scoop capacity only; ballonet level full.)

Case VII. Same as Case IV except with ballonet level full (19,000 cu. ft. of air).

Case VIII. Same as Case III except with ship momentarily pitched down by the nose 10 deg. relative to air and 30 deg. relative to the ground.

Case IX. Same as preceding except with ballonet level full.

Case X. Same as Case IV except with surplus load causing descent of 500 ft. per min., plus 500 ft. per min. downward air current.

Case XI. Same as Case IV except with 33,500 cu. ft. of air in ballonet. Upper air level 10.5 ft. below ship's axis. Ballonet diaphragm was assumed to be level across the hull at all sections.

Case XII. Same as Case IV except ship is helium filled.

Case XIII. Same as Case XI except ship is helium filled.

Case XIV. Same as Case II except ship in a gust suddenly pitched 25 deg. down relative to the air, horizontal relative to the ground.

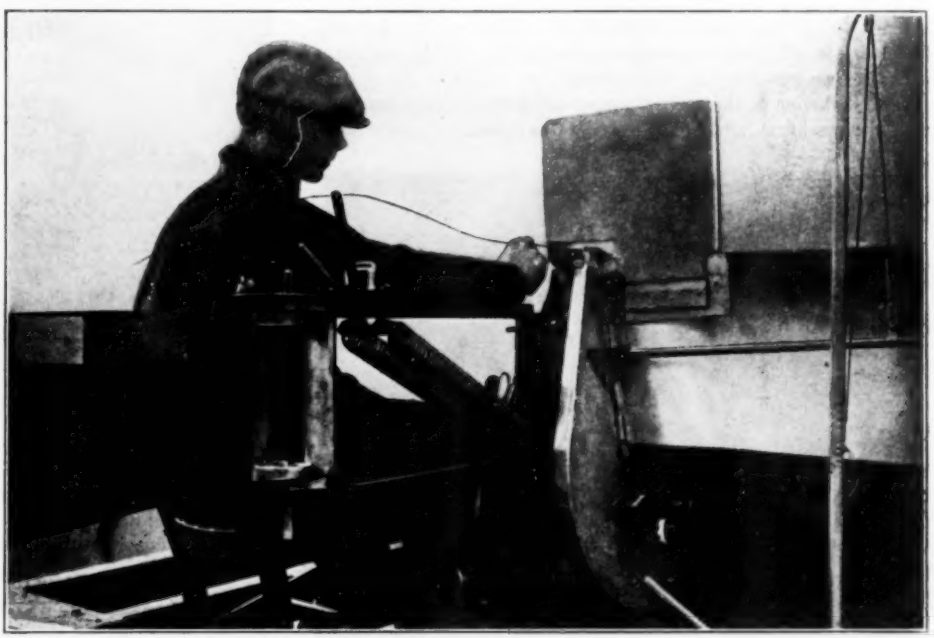

FIG. 17 AUTOMATIC RIVETING MACHINE AT WORK ON HULL OF METALCLAD DIRIGIBLE "ZMC-2"
(This machine "sews" 5000 rivets per hour and put 3,500,000 rivets in the "ZMC-2" during its construction.)

Case XV. Same as Case II except elevators suddenly thrown up 20 deg.

The maximum tension on the skin was found in Case V (*b*) and is equal to 610 lb., giving a factor of safety of 5 on the yield point of the material.

The comparison of the longitudinal strength of the *ZMC-2* with that of long, slender ships like the *Shenandoah* is very favorable. The worst bending moment considered in the design data of the *Shenandoah* was reached at an angle of pitch of 6 deg. relative to the air at a speed of 46 m.p.h., with a blow-off pressure of 10 mm. The factor of safety in the top longitudinal was only 1.68. The *ZMC-2* under the same conditions and blow-off pressure of 100 mm. shows a longitudinal factor of safety of over 10.

A complete analysis was made on the control surfaces and followed by a sand-load test.

The car was analyzed on the same principle as an airplane fuselage under static, flying, and landing conditions.

The capacities of valves, scoops, and all other outlets and inlets were computed. Miscellaneous small computations such as snap diaphragm action and effect of holes and small irregular forces were investigated.

All joints and fittings were carefully investigated with respect to their ability to sustain the loads imposed. Higher safety factors were used in this case than in the main structure.

The various formulas used for calculation of stresses in the skin are given in a paper by R. H. Upson: "Metalclad Rigid Airship

Development," *Journal* of the Society of Automotive Engineers, February, 1926.

Stern-Section Test

Considering all the tests made previous to flight tests, the most instructive one and the one that was done on a larger scale than any other was the leakage, inflation, and side load test on the stern portion of the *ZMC-2* hull.

The metal covering of the hull was changed from duralumin 0.008 in. thick to Alclad 0.0095 in. thick, which necessitated scrapping the work previously done, and it was decided to use the fully completed stern portion 29 ft. high and 34 ft. in diameter at the base for this experiment. This section was embedded in a concrete ring weighing 50,000 lb., which was made airtight by a water seal at the bottom.

The behavior of the section under different internal pressures was observed first, and no air leakage was found.

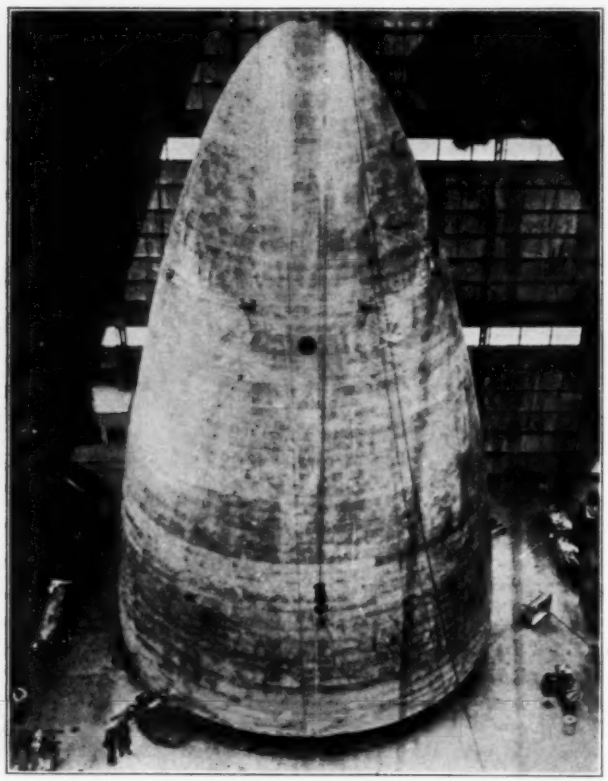

Fig. 18 Showing Vertical Method of Erection, With Automatic Riveting Machine at Work on Hull

After that the section was inflated with carbon dioxide by introducing it at the bottom of the hull and letting the air exhaust at the top. When the section was filled with carbon dioxide, hydrogen was introduced at the top, displacing carbon dioxide flowing out at the bottom. When the exhaust mixture was found to contain 10 per cent of hydrogen it was passed through the scrubbing apparatus, which contained caustic soda solution and absorbed carbon dioxide out of the gas mixture, and the repurified hydrogen gas was forced back into the hull. By continuing this process the hull was filled with pure hydrogen. The reason this method was adopted was the ease with which carbon dioxide is absorbed when mixed with hydrogen, compared with expensive apparatus used to freeze air out of a mixture with hydrogen.

The section filled with hydrogen was allowed to stand for a day, and no loss of purity and no leakage at the seams were observed.

When the gastightness and the correctness of the inflation process had been proved, the hydrogen was then displaced by carbon dioxide and the hull section subjected to a side load equal to 2000 lb. This was done to approximate the condition of bending occurring in the actual ship. The interior pressure was varied from 0.2 in. of water below to 13 in. above atmospheric pressure.

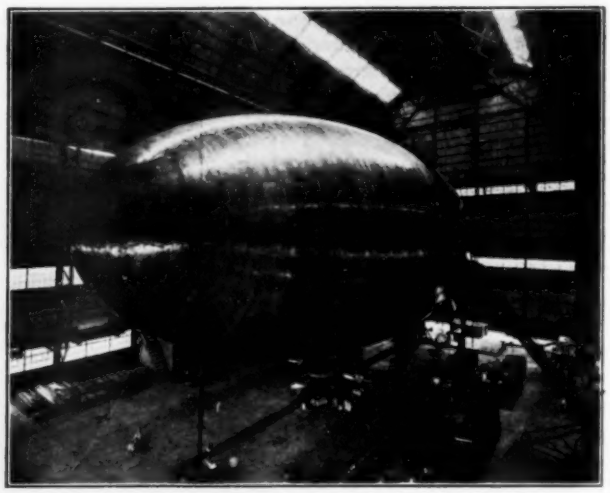

Fig. 19 The "ZMC-2" Ready for Inflation With Helium

At this latter pressure the concrete ring was lifted from the floor, the water seal was broken, and the experiment discontinued.

This test conclusively proved:

1 That an all-metal hull can be made gastight
2 That the method of inflation using carbon dioxide as the intermediate medium is sound
3 That the hull can safely sustain the loads for which it was designed
4 That the hull can stand even pressures slightly below atmospheric.

Appendix No. 3

Construction, Erection, and Assembly of the "ZMC-2"[6]

The assembly and erection methods of the *ZMC-2* were given prime consideration even during the preliminary design of the ship. The building of rigid airships is not only a design problem but a construction problem of the first magnitude. It was not entirely necessary that the ship be constructed with the skin plating and the main seams running transversely; it could have been constructed with the plating and main seams running longitudinally.

The assembly of the metal plating into a gastight hull was accomplished very efficiently by building it in two halves, erecting each half with its major axis vertical to the floor, and then turning them up into a horizontal position and joining them together into a complete hull. The hull plating was built up of a series of transverse rings, each of which was the surface of a frustum of a cone. Each ring was composed of a number of equal panels, the panels being cut to the proper curvature from flat sheets and riveted together end to end to make up a curved band which became one of the transverse rings when riveted in place.

[6] Prepared by Edward J. Hill and Arthur G. Schlosser, Detroit Aircraft Corporation, Detroit, Mich.

A manhole placed at the bow and stern of the hull was the starting point of each half. The first ring of plating was riveted to the manhole by hand and suspended by a single cable through the center of the manhole in such a manner that the manhole and ring were parallel to the floor. The suspension was by means of a winch at the hangar roof so that the height above floor could be easily adjusted.

The automatic riveting machine, described more fully below, was then set up on a carriage. The carriage was mounted on concentric rails which were placed in the floor directly under each half of the hull. The riveting machine was then adjusted to the proper angle of the hull plating. The manhole with the first plating ring attached was then adjusted to the level of the riveting-machine jaws and the second plating ring was riveted to the first, thereby completing the first transverse seam in the hull plating. A gaging device was located on the riveting machine, giving a correct and uniform overlap of the plates. When the transverse seam was completed the two ends of the transverse band of plating were riveted by hand, thus closing the band into a complete ring.

The assembly was then raised by means of the winch, the angle of the riveting machine again adjusted, and the next transverse band was riveted to the last one in a like manner, the shape of the panels with the proper overlap determining the form of the hull.

As the riveted transverse seam emerged from the riveting machine it was inspected and repaired. Any defective rivets were drilled out and replaced with hand rivets. It should be noted that the defective and missed rivets amounted to only about one-third of one per cent of the total number used.

After a thorough check on the seam by an inspector, it was given his approval and the sealing compound applied to the seams to make them gastight.

The Frame Assembly

As one band after another was added, the thin plating was supported by a light falsework of wood until it reached the point where the first transverse frame went in. This frame, having previously been assembled on the radial jig, was expanded tightly into the plating and riveted in its proper place with respect to a given plating ring. After riveting in the transverse frame the longitudinal members connecting the frame to the manhole were forced tightly into the plating and riveted in place. The whole assembly of plating and internal structure was then given a thorough inspection.

The assembly of the plating then commenced again and proceeded down to the point where the next transverse frame was put in, and the longitudinal members connecting it to the previous frame were put in place as before.

Thus the assembly proceeded progressively from frame to frame and as the maximum distance between frames was 18 ft., the work was always within 20 ft. of the floor and all the scaffolding required were ladders about 16 ft. high. All work on the hull was completed and passed by the inspector while in reach of these ladders.

While the structure was being placed in one of the halves, the skin plating was being assembled to the other and vice versa, causing the two operations to dovetail perfectly. There was very little lost time from having one crew wait until the other was out of the way.

As the weight of the assembled hull increased, the suspension was changed from one single cable at the center of the manhole to a bridle which distributed the load from the single cable to eight clips provided for the purpose on one of the main transverse frames. The hull was guyed from the sides of the hangar by cables to prevent it from swaying and turning. The operation of sewing the plating was continued, and main rings and longitudinals were put in place until all plating was riveted. Each half was then completed by the addition of a small angle riveted on with one leg inward.

Joining the Hull Sections

The point at which the two halves were joined together was at the maximum section, 63 ft. from the bow and 86 ft. from the stern. Thus the stern section was 23 ft. longer than the bow section. While still in the vertical position the two sections were given a final inspection, and when passed were ready to be turned into the horizontal position for joining together.

The turning was accomplished by a system of equalizing bridles and winches. Two turning bridles were used for each section, one being attached at the lowest main transverse frame and the other at the highest. The bridles were attached to the frames at four points, and by running over pulleys they equalized the loads. They were then brought up to a single cable which wound on a winch mounted on a trolley on the monorail at the apex of the hangar roof.

Fig. 20 Showing Inflation Tubes Over Top of Hull

By taking up on the bridle connected to the lowest frame, the lower end of the hull section was slowly raised and the upper end in a like manner slowly lowered. The weight of the section was gradually transferred from the original suspension bridles to the two turning bridles. A point occurred in this operation where the center of gravity of the section passed under the upper turning bridle and the total weight of the section was then supported entirely by four points on the one main frame. This was the critical point, and once passed, the lower end was raised and the upper end lowered until it was in a horizontal position.

When the two halves were in the horizontal position they were each suspended by means of the bridles at two of the main frames. The bridles were attached to cables which wound on the winches, which in turn were mounted on trolleys, so that each section could be raised, lowered, tilted, or moved back and forth along the trolley rail into any position, and by this means the two halves were brought together and lined up for the joining.

The Closing Seam

Before any riveting was done on the final joint, the plating was thoroughly clamped in position. It required many clampings and reclampings before a satisfactory job was obtained. In this clamping and subsequent riveting it was necessary for one workman to work inside and one outside at any point on the seam. To accomplish this an opening was cut in the bottom of the hull and an adjustable extension ladder put through this opening up into the inside of the hull. From this it was possible to reach any point on the inside of the seam. For the outside riveting of the final seam a workman was suspended on a sling from the hangar roof over the top of the hull, and from a ladder on the sides and bottom.

When the two halves had been satisfactorily clamped together by the boundary angles the actual riveting of the joining seam began. A lap strip or metal band about two inches wide was laid over the joint and a double row of rivets joined this band to each of the two sections. This was entirely a hand-riveting job and the workmen were given every facility for speeding up the work, yet it took two men the equivalent of two months at eight hours a day to complete the seam, a job which the automatic riveting machine could have done in six hours. After riveting, the seam was sealed and the connecting longitudinal structural members riveted in place.

While the final seam was being riveted, the fins and rudders were bolted to the fittings, which extended out from the main frames designed for that purpose, and the control lines run down to the car through Bowden casings which were cemented to the outside of the hull plating.

The Internal Structure

The internal structure was built up entirely of rolled and flat-plate sections riveted together. The five main transverse frames are of the triangular type having a rolled channel member at each corner riveted to flat plates which make up the sides. The channel members were rolled to fit the circumference of the hull at that point, and the flat-plate sides were cut on the proper curvature to make a complete girder having the required curvature and angle of the hull.

Wooden formers were built for sections of each frame to the exact shape and curvature required, and into them were clamped the channels and plates making up the girders to be riveted together. When completely riveted, the sections rigidly maintained their shape and curvature. They were then taken out of the formers and assembled into a complete ring on the radial jig.

On the radial jig the sections were laid out into a true circle and leveled up. The joints connecting them into a complete ring were then riveted and the radial wiring put in place and adjusted while the frame was perfectly round. The wiring was removed before placing the frame in the hull, and later replaced and adjusted to the exact position it had been in while in the radial jig. This insured the frame's being round.

Longitudinal members were in all cases a single rolled channel section. Each one was rolled to fit a former representing the longitudinal curve of the hull plating. Flanged lightening holes were extensively used in the channel sections and side plates of the frames to lighten and strengthen the structure.

All the material in the internal structure was built of Aluminum Company of America's aluminum alloy 17 ST. All the sections were rolled and worked in the hard state with one exception, namely, where the curvature was so great that heat treating was necessary. The rivet used to build up the structure was the same flat-head rivet that was used to rivet the plating to the structure, the sizes used being mostly $^3/_{32}$ in. in diameter. At joints and highly stressed places $^1/_8$-in. diameter rivets were used, and in a few exceptional places $^3/_{16}$-in. rivets were necessary.

Cutting the Plating Panels

The cutting of the plating panels was done very accurately as the hull was constructed by building from one ring of plating to the other, gaging from the edges of the plating in all cases. Naturally any errors in the cutting of the panels would accumulate. It should be remembered that the shape of the hull was entirely the result of the shape of the panels, and therefore any errors would affect the hull to the extent that the internal structure would not fit.

The panels were cut to various radii, ranging from a few inches at the extreme bow and stern to over three miles at the maximum diameter. For scribing all radii under 20 ft. a specially constructed beam trammel was used. For larger radii recourse was had to an indirect method based on the geometric principle that the locus of all points which jointed to two fixed points form a constant angle, is a circle.

A metal-topped table was constructed with two fixed metal pins spaced 14 ft. apart. Two straight edges 14 ft. long were joined together with a pivoted point, adjustable to any angle. These straight edges were very heavy and were mounted on rolling balls to allow them to roll over the table top freely. With the straight edges rigidly clamped to a given angle, they were rolled across the table with each straight edge in sliding contact with one of the fixed pins. This caused the apex of the angle formed by the two straight edges to scribe the arc of a circle, and the length of the radius of each circle was controlled by setting the angle of the straight edges to the calculated angle.

The sheet to be scribed was clamped to the surface of the table, then the scribing point of the arc machine was brought down in contact with the sheet. The machine was then drawn from left to right by hand operation over the pins until a satisfactory pattern was scribed. The sheet was then removed from the table and trimmed around the scribe line, and the final panels were then made from this pattern.

The Gastight Sealing Compound

The development of the sealing compound was given much thought. A compound had to be found that would adhere to the metal and seal the seams perfectly, yet it had to be a substance that would remain flexible and pliable at winter temperatures and also would not become fluid at the higher summer temperatures. A satisfactory bitumastic compound was finally arrived at. This was applied to the inside of the seams immediately after the riveting had been inspected and approved.

The first coat was thinned out with naphtha until it was very fluid, and was then flowed into the seam between the overlapped plates by means of a rubber-bulb syringe with a very fine nozzle. Capillary action caused the fluid to penetrate into the seam, and in this it was greatly aided by gravity as it was applied in such a manner that it always flowed downward into the seams. This thin application dried very quickly, due to the rapid evaporation of the naphtha, and as soon as shrinkage was apparent, more compound of the same consistency was applied.

In this way the seam was kept full of the fluid until every void was filled by the building up of the sealing compound as the naphtha evaporated. When the minute spaces between the overlapping plates were thus thoroughly filled and no more fluid could be made to flow into the seams, a heavy application of very thick compound was applied over the edge of the plate exposed on the inside of the hull.

This application was thinned by heating to about 200 deg. fahr. This was accomplished by means of an electrically heated pressure gun which forced the heated compound through a nozzle with an opening about $^1/_{16}$ in. in diameter. By this means a ridge of the compound was laid over the inner exposed edge of the plating, covering it completely. This compound cooled very

rapidly in contact with the metal and thus did not fall from the seam of its own weight. While this application was still damp, it was dusted with aluminum powder to facilitate inspection and to harden the "tacky" surface.

The Automatic Riveting Machine

The development and perfection of the automatic riveting machine played a very important part in the construction of the metal hull. It would have been practically impossible to build the hull without such a machine. The machine riveted a very highly efficient seam composed of three rows of staggered rivets, the rows being $^3/_{32}$ in. on centers and the rivets being spaced $^1/_4$ in. in the rows, the overlap of the plating being $^7/_{16}$ in.

Aluminum-alloy wire 0.035 in. in diameter was fed into the riveting machine. The wire was cut to length and forced through the overlapping sheets into hardened steel dies, cutting a clean, round hole. The soft wire was able to punch a hole in the hard sheet because, being confined, it could not expand when the pressure was applied but had to punch through the sheet. When the wire was through the sheet, it was headed first on the under side and then on the top, making a complete rivet. The machine then spaced the next set of rivets automatically.

Three rows of rivets were driven at a time and at the rate of 140 (or 1 ft. of seam) per min. while operating steadily. In actual operation the machine was able to rivet up to 200 ft. (or 28,800 rivets) in eight hours; the greatest number of rivets driven in eight hours was 40,000, not including time for set-up. Concentric circular tracks were laid on the floor, whose common center was at the axis of the hull assembly. A car mounted on these tracks carried the riveting machine around the hull. The riveting machine was mounted on the car by means of an arm with a universal movement and balanced by springs so that it could be easily moved to any position independently of the position of the car, within a limit of about two feet.

The riveting machine automatically pulled itself along the sheet by its own feeding mechanism. A ratchet mechanism conveniently placed for the operator was used to propel the car around the hull. Inasmuch as the forward movements of the riveting machine and car were independent within certain limits, it was not necessary for these two operations to be synchronized.

Appendix No. 4

INFLATION OF THE METALCLAD AIRSHIP "ZMC-2"[7]

DUE to the fact that it is very difficult to separate helium from air, the gas inflation of the *ZMC-2* was carried out in two stages. In the first stage carbon dioxide displaced the air in the ship. The carbon dioxide was let in at the bottom and the air forced out of the top of the hull. In the second stage, the process was reversed. Helium was let in at the top while carbon dioxide was forced out of the bottom of the hull. The carbon dioxide-helium mixture was circulated through a caustic scrubber to remove the carbon dioxide and the purified helium was then returned to a point 10 ft. above the bottom of the hull. Chemical control tests were conducted to show at all times the exact progress of inflation in the various parts of the ship and to give the purity of the gas after inflation.

Gas Sampling and Analysis

The gas was sampled at five stations, at the bow, stern, at each side of the ship, and at the exhaust line. Each station, except the exhaust-line station, controlled three sampling tubes from the top, equator, and bottom of the hull, respectively, and samples from the same level were analyzed at the four stations simultaneously. Samples were drawn through small tubes of rubber. These tubes were always open to insure a fair sample from the ship at all times. The gas was sampled at ten-minute intervals with the result that the time between two successive analyses at any level was one-half hour.

The gas analysis was run by means of A. H. White's modification of the Hempel burette and the carbon dioxide absorbed in a pipette filled with caustic solution in the usual manner. Exactly 100 cc. of gas was drawn into the pipette and the contraction after the gas was run into the caustic pipette was taken as the volume of carbon dioxide. Since exactly 100-cc. samples were always taken, the volume of this contraction is read in percentage of carbon dioxide directly. A sample run follows:

Original sample	100 cc.
After caustic pipette	78 cc.
Contraction	22 cc. or 22 per cent CO_2

During the first stage the carbon dioxide percentage indicated directly the progress of inflation. During the second stage (inflation with helium) the percentage of carbon dioxide subtracted from 100 per cent was taken as the percentage of helium in the ship, as it was impossible to measure the helium directly with the apparatus at hand. This method, undoubtedly, is not very much in error as the final results of the carbon dioxide inflation showed 99.4 per cent of carbon dioxide. Final tests for oxygen were also taken on the inflated ship and showed not over 0.2 per cent oxygen, so undoubtedly the inert gas was very nearly as pure as the helium run in from the containers.

The gas analyses were made by three squads of five men, one squad for each eight-hour shift.

Final tests were made after inflation with the following average results: Per cent oxygen, not over 0.1 per cent; CO_2, 2.3 per cent; carbon monoxide, 0 per cent. This final test was run by means of an Orsat apparatus, absorbing the carbon dioxide in caustic solution, the oxygen in alkaline pyrogallate solution, and the carbon monoxide in cuprous chloride solution in the manner ordinarily used in gas analysis.

Separation of the Carbon Dioxide and Helium

An attempt was made to carry out the inflation in such a manner as to allow one gas such as the carbon dioxide to displace the other gas (air) in the ship without either gas mixing with the other. The chief causes of mixing of the gases were two, namely, diffusion, and turbulent flow of gas from the containers. Turbulent flow is caused mainly by the velocity of flow of the fluid. The velocity of the input of the carbon dioxide was kept within the region of quiet or viscous flow and never exceeded 12,000 cu. ft. per hour. Diffusion depends upon various factors and may be expressed by the following equation:

$$m = \frac{KA(d_2 - d)t}{h}$$

Where m is the mass of substance diffused, K the coefficient of diffusion, A the cross-section through which diffusion takes place, d_2 and d the respective densities of the diffusing substances, t the time, and h the thickness of the diffusing layer.

During the carbon dioxide inflation it was apparent that the amount of diffusion was very small and that stratification of the carbon dioxide and air was quite complete. This was borne out by gas analysis and was visible to some degree from the fact that the moisture in the air condensed on the surface of the cold carbon dioxide as it lay as a level layer of fog which rose as the carbon dioxide rose in the ship. This stratification was probably due, as indicated above, to the slow rate of inflow of carbon

[7] Prepared by Dr. A. R. Carr and E. C. Good, Detroit Aircraft Corporation, Detroit, Mich.

dioxide and to the fact that the differences in density of air and carbon dioxide is not abnormally great.

However, stratification during the second stage of inflation was not nearly so marked. This is also apparent from the gas analysis. The reason for this non-stratification is the fact that the rate of diffusion of helium with carbon dioxide is much greater than that of the carbon dioxide with air as the densities of carbon dioxide and helium are as 44 to 4. Therefore, when over 40 per cent of helium began to appear in the exhaust, the gas from the exhaust was led to the carbon dioxide scrubber.

After the carbon dioxide was scrubbed out the helium was returned from the scrubber to the hull. The proportion of caustic (NaOH) in the scrubbing solution was checked by chemical analysis and kept around 5 or 6 per cent. This checking for

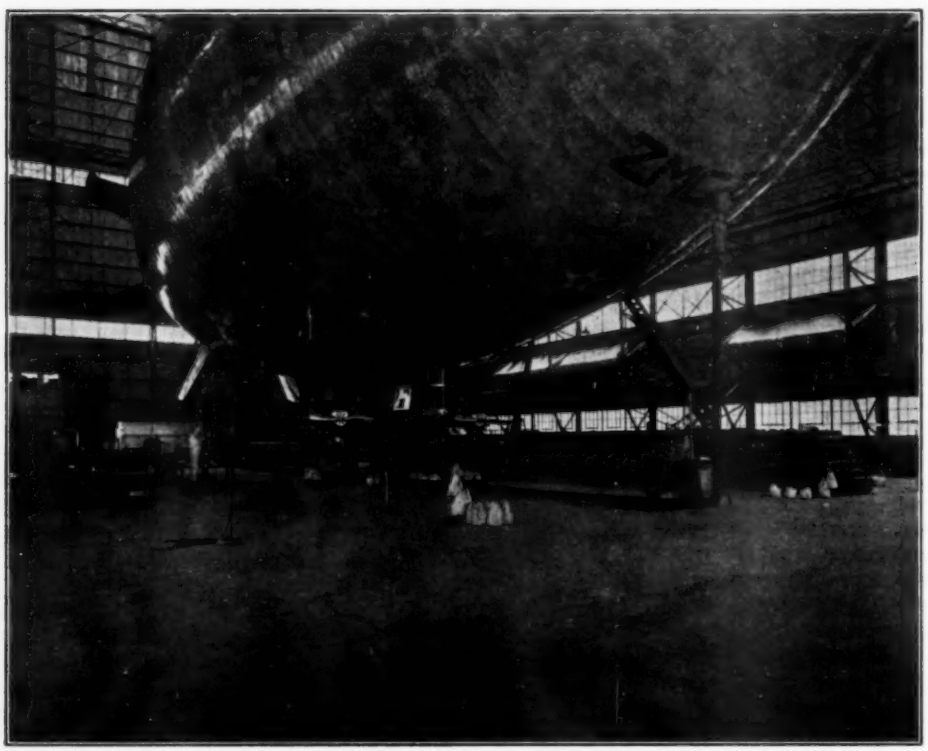

FIG. 21 ARRANGEMENT FOR INFLATION OF DIRIGIBLE WITH HELIUM

NaOH was done by a double titration with standard sulphuric acid, using phenolphthalein as an indicator for the first end point and then continuing to the final end point with methyl orange. This was necessary since the end point for the caustic titration occurred in a basic solution. The first titration gave the amount of caustic plus one-half of the sodium carbonate; the last titration with methyl orange gave the other half of the carbonate. From these two titrations the available hydroxide in the scrubbing solution was calculated and thus controlled. The temperature of the scrubbing solution was kept below 100 deg. fahr., by means of ice placed in the dissolving tank.

Scrubbing of the gas was continued until the content of CO_2 was reduced to 3.4 per cent.

During the scrubbing some moisture was carried over into the hull due to insufficient drying facilities. This was apparent from the water which condensed in the intake pipe and in the ship itself. There was a slight indication of the presence of alkali, as tests showed a faint pink in the presence of phenolphthalein. The condensate, measuring 250 cc. in all, which was drained from the ship at various times was analyzed for total alkalinity. The only means available was by titration with $^1/_{100}$ normal acid. This was of course not an absolutely accurate method, but it gave a very good idea of the magnitude of the total alkalinity. One of the first samples of condensate analyzed 0.0084 per cent NaOH. The second draining gave 0.0031 per cent NaOH. Apparently from the small amount of condensate and also from the very small amount of caustic in the condensate, this should cause little concern.

CONCLUSIONS

The results of the gas analyses show that the two stages of inflation of the *ZMC-2* were successful. In the first stage the carbon dioxide almost completely displaced the air. In the second stage the helium, aided by the carbon dioxide scrubber, displaced the carbon dioxide. The method could be improved by placing a drier in the line from the caustic scrubber. However, the results show that the method employed is a relatively simple, efficient one for inflating this type of ship.

Appendix No. 5

CONCLUSIONS FROM THE TEST FLIGHTS[8]

THE METAL SKIN

THE hull of the *ZMC-2* is an accurately tailored piece of work and unusually free from "stock wrinkles." The patterns give every evidence of having been perfectly cut, and nearly as perfectly joined together.

The rivets and seams are perhaps the most remarkable part of the entire construction. Each line of rivets runs around the ship, acting in a way as a small intermediate transverse ring.

The diffusion during actual operation showed an apparent loss of less than 100 cu. ft. of helium per 24 hours. This is excellent, and indicates that the compound used on the seams is a success.

On the flight to Lakehurst, two punctures occurred. Apparently some one shot a bullet through the hull. Examination of the entry hole showed no signs of enlarging or additional opening beyond what was probably the exact size of the bullet. The exit hole was not round. Rather it might have been a hole made by a flattened soft bullet. If it did enlarge at all the amount was so small as to be negligible, as far as tearing was concerned. The pressure ran as high as $3^1/_2$ in. with these holes in the hull. In fact, the ship at one time was nosed down at an angle of 22 deg., which would put at least 4 in. of pressure on the skin in the vicinity of the holes. Therefore the holes afforded an excellent test of possible tear and opening from an accidental skin break. The result justifies the conclusion that no alarm need be felt over this possibility.

The strength of the metal skin is of course very much greater than that of a fabric covering. The best evidence of this was

[8] Prepared by Capt. William E. Kepner, U. S. A.; Test Pilot.

when, with 0.5 in. pressure, 17 workmen were inside and supported by the skin between frames 54 and 70 before inflation. Needless to say, it is a great satisfaction for the pilot to be able to realize that there is comparatively no danger in letting the pressure run too high.

With a reasonable amount of air in the ship the ballonets act very well for trimming, even at high speed. The damper doors must be forcibly held shut and locked as the elastics tend to pull each door half open, thus equalizing the air in both ballonets, with the consequence that this particular air system can be made to act as a single ballonet, while it is in fact a two-ballonet system. This makes the automatic-pressure idea a thoroughly practicable one, because a ship with a single ballonet is always in a natural static trim.

The air-system controls are easily worked and, once understood, are fairly simple.

The opening for regular entry and inspection of the ballonets is not necessary, as it is much easier for a man to enter the distribution chamber through one of the air-riser ports. This also makes an excellent place to enter the helium compartment, and this on several occasions has been done. This ability to get into the helium compartment and inspect the interior of the ship is a valuable feature, and the apparatus developed by the Aircraft Development Corporation which permits it, adds much to the efficient operation of airships.

The air breathers are at present sealed and are equipped with a pulling-rip cord, that is, a cord that can be pulled from the car should the ship ever approach zero pressure. This has been tested and found perfectly safe.

Only one place has shown any skin flutter, and that was directly in the plane and above the right propeller. It was fixed by putting in a small lattice. In all flying so far there has been no evidence of snap diaphragm action.

Transverse Rings

The main transverse ring frames at Nos. 18, 54, 70, 114, and 122 are held rigidly by radial wiring. The wiring apparently holds these rings to a positively true form whether on the ground or in the air, as far as can be judged from visual observation.

Longitudinals

The convergence of the longitudinals makes a very stiff nose, and even at the lower pressure, i.e., $\frac{1}{2}$ in., the shape is always good from frame 18 forward and from frame 114 back. The nose will undoubtedly stand considerable external pressure, even with very little pressure inside. However, the ship should always be flown at some pressure unless in case of an emergency. This rigidity is simply a safety factor. The recommended flying pressure is 2 in. for an air speed of 50 miles; at higher speeds than 60 miles, $2\frac{1}{2}$ in. to 3 in. is recommended.

Fineness Ratio

The feature of an extremely low fineness ratio affords an excellent opportunity for a practical test of this new shape. The *ZMC-2* is satisfactory as to stability, but it is believed that larger ships flying at higher speeds will have more inherent stability if the fineness ratio is increased.

Controls

Not enough flying has been done yet to determine the exact value of the eight fins and controls. However, it is certain that on this particular ship four fins would not work nearly so well as the present arrangement of eight.

The present set of eight fins, together with the low fineness ratio, make the *ZMC-2* the most maneuverable ship the writer has ever flown. The elevators quickly take care of the most violent angles and in smooth air hold the altitude exceptionally steady. They also force the ship into very quick descent and ascent when so used. The rudders turn the ship in approximately one-half the area necessary for a "TC" or "J" ship.

The Car

The motors furnish plenty of power and the maximum speed is probably 68 to 70 miles an hour. It has been estimated that on the three-hour endurance flight at 1740 r.p.m. the air speed was about 65 miles per hour, which is in excess of contract requirements.

The outriggers are satisfactory and apparently absorb a major portion of the engine vibration.

Sundry Conclusions

There is very little vibration anywhere in the car, and the general arrangement of the interior is very satisfactory.

The air scoops are excellent and, once understood, are easy to operate; in fact, much easier than the conventional drop-pipe scoop. The dynamic scoop is excellent for automatic pressure at speeds of about 1500 r.p.m.

The hand blower is perfectly satisfactory from the standpoint of efficiency. It is particularly valuable for maintaining pressure while the ship is being maneuvered in and out of the hangar.

The fuel system functions satisfactorily.

The handling lines required care to avoid hitting the propellers when letting them out. But throttling the motor on one side while the line is put out on that side, takes care of this. The drag rope functions properly.

The landing skid has excellent shock-absorbing qualities. Probably a wheel would be much better.

The suspension cables are apparently all right; they do not seem to vibrate at all.

The thrust-point fittings are fitted snugly, and show no signs of vibration.

The general location of miscellaneous articles such as tables, stools, seats, fuel pumps, motor power controls, fire extinguishers, shut-off cocks, control cables, handles, etc., seems satisfactory, though each pilot's opinion will differ on this subject.

The writer's general impression is that as an experimental development this ship should have an enthusiastic reception and careful consideration. He for one will follow its operating career with the greatest of professional interest, and believes it to be the forerunner of a long line of super airships.

Discussion

J. C. Hunsaker.[9] The author has made a very competent and stimulating study of the commercial uses of airships and airplanes, but naturally in an airship paper he must choose a 2000-mile route where the two types of aircraft are not at all competitive. For long voyages, and particularly overseas, the airship appears clearly to have only the steamship as competitor. Here the airship offers speed and the steamship comfort. The safety and reliability of airships will eventually be established. Steamships have had a century to reach their present state of development and airships about a quarter of that time. Nevertheless steamships have even today reached only what the writer would call a "commercial degree" of safety. The *Vestris* accident and the deliberations of the International Conference for Safety of Life at Sea now going forward in London, serve to remind us that absolute safety is yet to be reached.

As regards comfort, the writer doubts whether the airship can really compete with the steamship. Large airships will be more

[9] Vice-President, Goodyear Zeppelin Corporation, Akron, Ohio.

comfortable than small steamers or very fast steamers from the point of view of those liable to sea sickness, but if a few knots speed be sacrificed, steamships of reasonable size can be built of extreme comfort and steadiness. Again, airships cannot economically compete with steamships for the transport either of large numbers of passengers or quantities of freight.

Consequently the writer looks upon airships as a new transportation medium that competes neither with the airplane nor the steamship but offers a high-speed service, for a price, to a relatively small quantity of passengers, mails, and express. The speed of the airship cannot be met by steamers, and the carrying capacity and duration of non-stop flight cannot be met by the airplane. For short distances, the airship cannot compete with the airplane (or flying boat) any more than the *Leviathan* could compete successfully on a New York-Boston run with the Sound steamers. Terminal charges and cost of turn around are too great.

For overland work, the airship can carry passengers non-stop in comfort for a long voyage, while the airplane can carry them in considerably less comfort with intermediate stops. For this phase of competition one thinks of the relative comfort of motor buses and railways for long trips.

In general, the picture as we see it now shows airships as offering a super first-class service overseas as a supplement to existing steamship services. A few passengers, first-class mails, and urgent express matter would make up the pay load. The volume of passengers, mail, and freight going by steamer will not be reduced, but will rather tend to increase by virtue of the stimulus to international business afforded by more rapid communications.

The airships likewise supplement the continental and coastal airplane services, for whose routes they provide the necessary extensions overseas.

The Society is to be congratulated on Mr. Fritsche's paper, which contains so much meat. The description of his metalclad airship is most interesting, and is suggestive of the improvements in the art which American ingenuity and skill always bring forward when commercial conditions make development work possible.

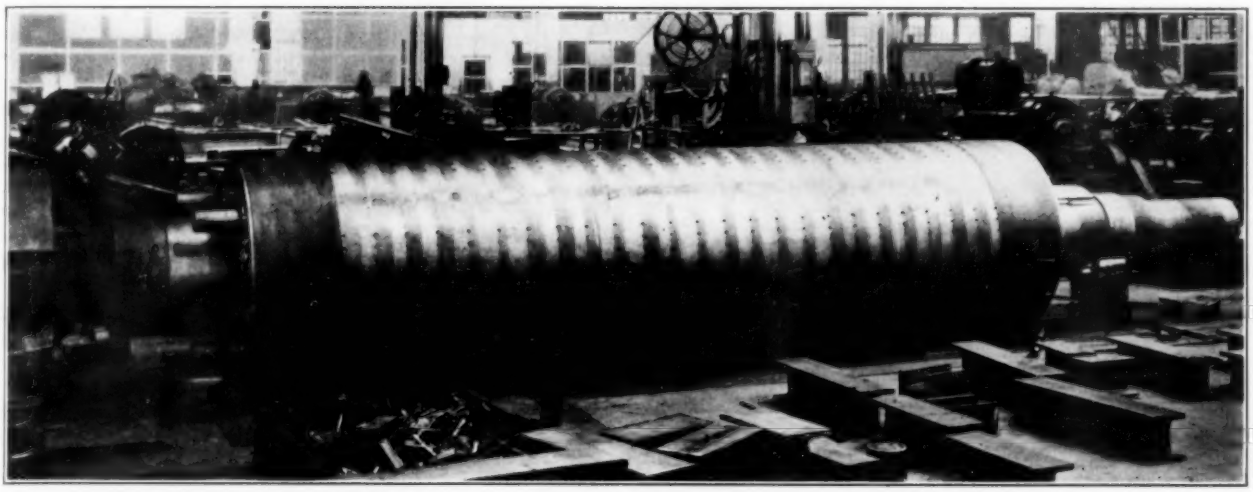

FIG. 1 PLATE ROTOR

The Mechanics of Plate Rotors for Turbo Generators

BY J. P. DEN HARTOG,[1] EAST PITTSBURGH, PA.

With the rapid development of turbo-generators during the last five years, the length of the rotors has practically been doubled. More or less elaborate mechanical calculations, especially of the "plate rotors," have been evolved and experiments have been carried out in order to place the design of this apparatus on a rational basis. In this paper some of the mechanical problems which have come up in connection with this development are discussed in detail.

THIS paper deals with some of the mechanical problems which were encountered during the past few years in the construction of plate rotors. By "plate rotor" is meant a particular construction which the Westinghouse Electric and Manufacturing Company uses for its turbo-generator rotors and which was initiated by Behrend and Field.[2] It consists of a stack of plates between two end-forgings held together tightly by means of four or six heavy bolts (Figs. 1 and 2). These bolts are stressed to about 40,000 lb. per sq. in., so that the stack of plates forms a rigid body.

The advantages of this construction as compared to solid forgings are as follows:

1 For the largest machines of the present time single-piece forgings cannot be bought from the steel companies, so that the rotor has to be made up of several pieces.

2 Better material can be obtained in plate form than in large solid forgings. This is of great importance, since large stresses, due to centrifugal forces, are set up at the roots of the teeth.

3 The ventilation of the rotor can be effected in a simple manner by machining down four sections in every plate (*A* in Fig. 3). This offers greater difficulties for a solid forging. Either circumferential grooves have to be machined, which diminishes the bending rigidity considerably, or recourse has to be taken to drilling holes from the outside into the rotor, which does not secure as good a ventilation.

The material of the plate rotor is more efficiently utilized, so that its bending rigidity is even larger than for a solid rotor. Though the plate rotor has been in use successfully for over 15 years, it is only comparatively recently that refined mechanical calculations on it have become necessary, due to the phenomenal increase in its size.

The investigations dealt with in this paper cover only such subjects as are peculiar to the plate rotor, as distinguished from the solid rotor, namely: 1 stresses and deformations of the structure due to bending under its own weight, 2 the stresses in the bolts and their screwthread, and 3 the effect of centrifugal forces on the bolts. These three aspects of the problem will now be discussed in detail.

THE PLATE ROTOR IN BENDING

Before investigating the stresses appearing in the rotor due to bending, it will first be seen what the stresses in the structure are before any outside loading is imposed on it.

Fig. 3 represents a typical plate of a four-pole generator designed to run at 1800 r.p.m. The shaded area shows the existence of direct contact between neighboring plates. Without bending from outside, this area will be subjected to a uniform compressive stress. The four bolts will carry a certain tensile stress, such that the product of stress and cross-sectional area for the bolts equals that of the plates.

When the structure is bent, this relation remains valid, though both the stresses in the bolts and the pressure between plates cease to be uniform over the section. For the calculation two assumptions have been made:

1 Plane cross-sections remain plane after bending (which is the usual assumption for bending).

2 There is no longitudinal friction between bolts and plates.

---

Contributed by the Applied Mechanics Division and presented at the New England Industries Meeting, Boston, Mass., October 1 to 3, 1928, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

From the second assumption it follows that the stress in any bolt must be constant over its entire length. The bending moment taken by the bolts, therefore, also has to be constant along the rotor.

Fig. 4 shows the bending moment diagram of the rotor, due to its own weight. This bending moment M is taken partly by the bolts M_b and partly by the plates M_p. The magnitude of M_b will be found from the condition that the total elongation of the

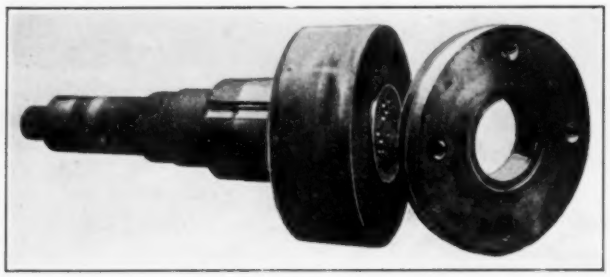

FIG. 2 END FORGING AND PLATE

bolt, due to the bending stresses, is equal to the elongation of the corresponding fibers of the plates at the same location.

The elastic elongation of the bolts can be calculated from its stress very simply. However, for the plates, this is another question.

A stack of plates is compressed more under a certain load than a solid piece of the same size and material under the same load (Fig. 5).

Tests have been carried out in the laboratory on test-pieces of the same thickness, 2 in., and of the same surface finish as the actual rotor plates.

It was found that the first load-compression curve differs considerably from the second and following cyclic curves (Fig. 6). The difference between the second and third loading curves and also between the up-going and down-going branches of these curves is very small. This change in character of the curve is due to microscopic plastic deformations at the contact surfaces. After the first cyclic loading, the unevennesses of the surfaces match fairly well. It was also found that taking the blocks apart and loading them up again produces the "first loading curve," independent of the previous history of the plates. It is evident that, after restacking, the test pieces have undergone a change in relative position, which, however small it may be, is always great in comparison with the unevennesses of the surface. The tests were made on material of three different heat treatments, but the influence of this on the load compression curves was found to be negligible.

The average load-compression curve after permanent set had fully taken place (the third loading curve) is shown in Fig. 7.

If the stack is compressed to a certain stress, and this stress varies in a cyclic manner by a small amount, the corresponding elongation or contraction is determined by the *slope* of the load-deflection curve at that stress.

In this manner the modulus of elasticity of a stack of plates was determined. It was found that this modulus increases with the pressure on the plates, so that it is desirable to have the plate pressure fairly high in order to secure a modulus of elasticity which is not far removed from 30×10^6 lb. per sq. in.

With this in mind, the area of contact between the plates was purposely diminished. The four areas A in Fig. 3 serve ventilation purposes, and the inside circle, which does not add appreciably to the section modulus but decreases the unit pressure between the plates, has been entirely relieved.

Until 1926 all rotor plates were made 2 in. thick. At the present time, however, this practice has been abandoned in favor of 8-in. thick plates, since a metallurgical procedure has been worked out which secures uniform material of good properties and without internal stresses.[3]

The 8-in. plates have the additional advantage of raising the modulus of elasticity of the stack.

In Fig. 7, AB is the compression in the solid material and BC the compression due to the surfaces of the touching plates. With the 8-in. plates no compression tests have been carried out, but since the number of faces is one-fourth of that with the 2-in. plates, it can be concluded that the deformation BD due to this also will be 25 per cent of BC.

Then if E_s and E_2 denote the moduli for a solid piece and for a stack of 2-in. plates, the modulus for the 8-in. plates E_8 can be calculated from

$$E_8 = \frac{4\,E_2 E_s}{3\,E_2 + E_s} \qquad [1]$$

STRESSES IN THE BOLTS

Until a few years ago the bolts of the plate rotors were tightened by means of a wrench of about 4 ft. length, pulled by a crane

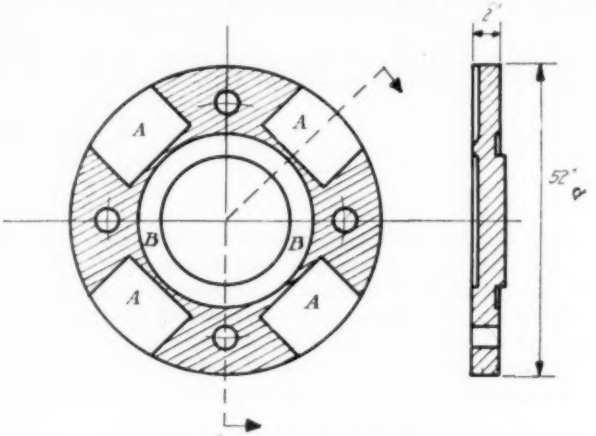

FIG. 3 TYPICAL PLATE

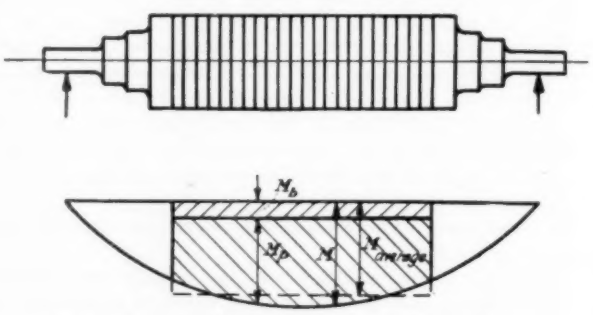

FIG. 4 BENDING MOMENT DIAGRAM OF PLATE ROTOR

overhead. The force with which the crane pulled was read on a spring scale and taken as an indication for the bolt stress. Later the stress in the bolt was not judged by this torque, but determined by measuring the overall length of the bolt.

The torque exerted by the wrench on the nut overcomes friction, which is located partly in the threads of the nut and partly under its seat. If r be the mean radius of the bolt thread, R the mean radius of the seat, f_t and f_s the coefficients of friction in the thread and under the seat, we have for the torque exerted by the wrench

[3] W. J. Merten, Trans. A.S.S.T., 1928, vol. 13, p. 18 ff., annual convention.

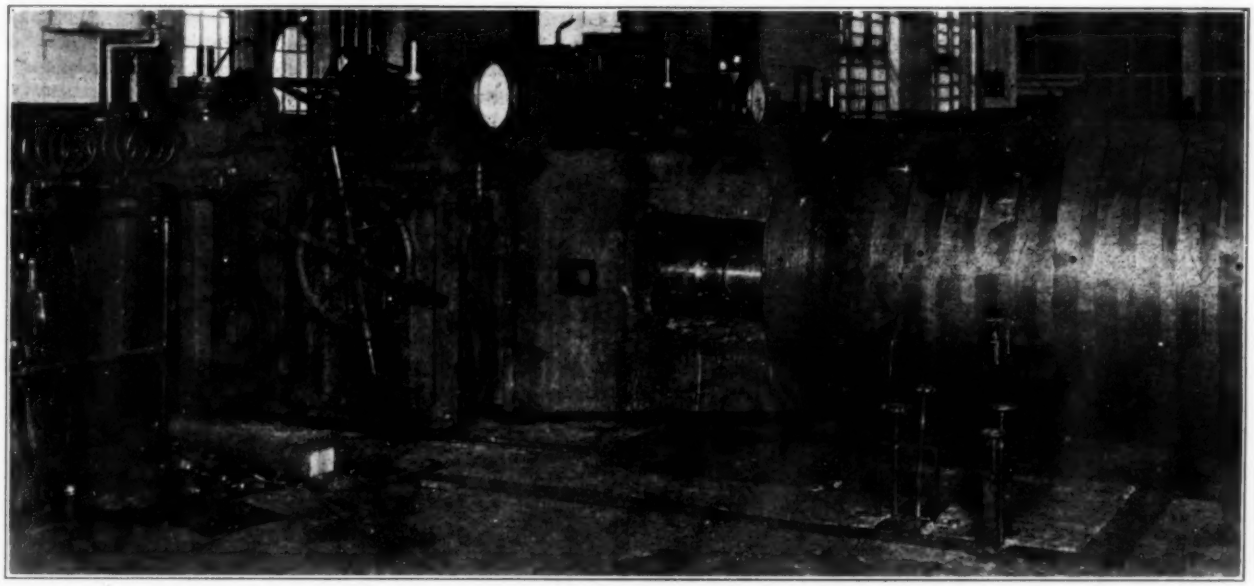

FIG. 8 PULLING MACHINE

$$M = f_t Pr + f_s PR \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

In this equation the coefficient f_t is supposed to include the effects of the shape of thread used. The second term in [2] may under certain conditions gall the seat of the nut; the first term transmits a part of the torque into the bolt. The ratio between f_t and f_s is not known, but it is a reasonable assumption that M is divided about equally over the seat and the threads of the nut. The torque M in one of the rotors was measured to be 6000 lb. × 4 ft. = 288,000 inch-pounds. It is assumed that 144,000 inch-pounds was transmitted into the bolt. The diameter of this bolt was 5 in., so that an extra shear stress of 6000 lb. per sq. in. was imposed.

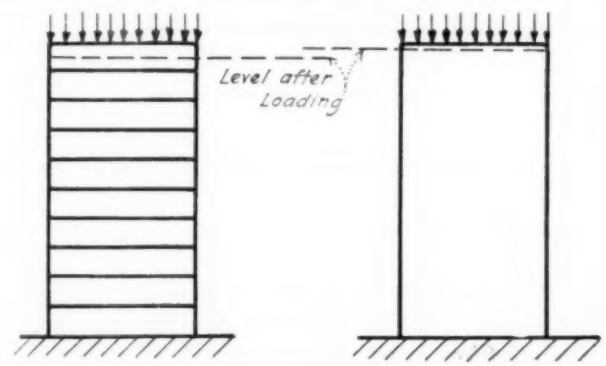

FIG. 5 COMPRESSIBILITY OF A STACK OF PLATES AND OF A SOLID BODY

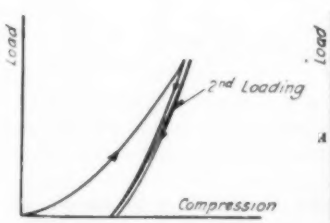

FIG. 6 LOAD-COMPRESSION CURVES FOR STACK OF PLATES

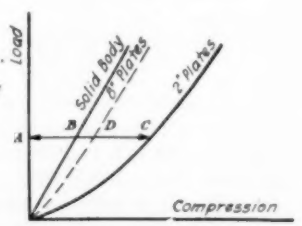

FIG. 7 LOAD-COMPRESSION CURVES AFTER THE PERMANENT SET

This is not a high figure, especially when considered in conjunction with the tension of 40,000 lb. per sq. in., existing in the bolt, but nevertheless it represents an undesirable increase in stress.

In order to avoid this and also to prevent galling of the thread or the seat of the nut, the plate rotors now are assembled by means of a hydraulic pulling machine, suggested by G. M. Eaton. The rotor is first stacked up horizontally and assembled with temporary bolts. One of the bolts is removed and the hole reamed very accurately. The final bolt is put in place and tightened by two men. This is done with all the bolts successively, whereupon the rotor goes to the pulling machine (Fig. 8). Two diametrically opposite bolts are stretched hydraulically, the reaction being applied toward compressing the plates. The two nuts which have become loose due to this are now tightened with a hand-wrench as far as they will go and the hydraulic pull is released. The greater part of the stress in the bolt will remain and be carried by the nut. The rotor is then turned 90 deg., and the operation is repeated for the two other bolts. The stress in the first two bolts is then increased, and so on, going from one to the other in several steps. The stress existing in the bolts after each pulling is measured by a depth gage. Since the pulling machine grabs one end of the bolt, it is not possible to measure its overall length. Therefore, a fairly long hole of small diameter is drilled in the other end of the bolt, in which the depth gage is inserted.

The last pulling brings the bolt stress up to about 45,000 lb. per sq. in., which when the nut is run on and the hydraulic pull is released comes down to about 40,000 lb. per sq. in. This is the usual stress in operation. The material of the bolts is a molybdenum nickel steel with a yield point of over 100,000 lb. per sq. in. It is clear that this method of assembling avoids both galling the threads or the seat of the nut and imposing a torsional stress on the bolt.

STRESS CONCENTRATION IN THE THREADS OF BOLT AND NUT

If a bolt and a nut of equal pitch are loaded in the ordinary manner, so that the bolt is in tension and the nut in compression, the bolt will elongate and the nut will shorten, with the obvious

result that the pitches are not the same any more when loaded. This remark raises a suspicion that the load will be rather unequally distributed over the various threads. Since the bolt threads are a vital part of the rotor construction, an analysis and some tests were made in order to find the stress distribution. The analysis, which is given fully in Appendix No. 2, shows that

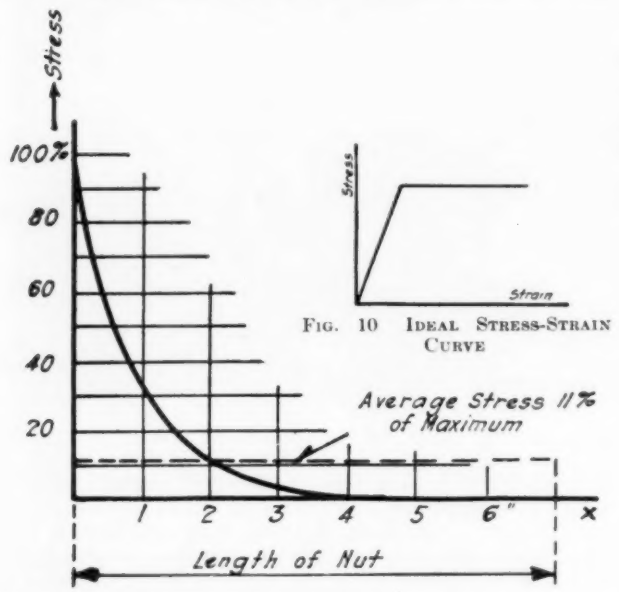

FIG. 9 STRESS DISTRIBUTION ALONG THREADS, SHOWING LARGE STRESS AT SEAT OF NUT

FIG. 10 IDEAL STRESS-STRAIN CURVE

the stress distribution in the threads can be represented by the formula

$$\text{stress} = S = Ce^{-Bx} \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

where x is the distance from the seat of the nut and B is a constant depending on the dimensions of the bolt, nut, and thread.

For a particular bolt and nut of 5 in. diameter and 7 in. length, as used on the rotor, the result [3] is shown in Fig. 9. It was calculated under the assumption of a non-yielding material that the peak stress at the seat of the nut is nine times as large as the "average stress," that is, the stress calculated under the assumption of an equal-load distribution along the bolt. The first two turns of the thread ($^1/_7$-in. bolt length) take 45 per cent of the load. It is clear that this is a case of very pronounced stress concentration. The maximum stress at the first thread is hardly increased by shortening the nut considerably. Since it does not affect the maximum stress whether the nut is 7 in. or 5 in. long, the first result of the analysis was to reduce the length of the nut by 2 in.

However, the derivation underlying the result [3] is based on the assumption that the proportional limit of the material is not exceeded. Now, with such an enormous stress concentration this will happen in practically every existing screw connection. The material in the highest stressed threads will then yield, so that the more remote threads can carry more of the load. If we assume an idealized stress-strain curve as shown in Fig. 10, it is seen that a definite maximum is imposed on the stress, so that the diagram of Fig. 9 is replaced by the one shown in Fig. 11.

Instead of the stress, the ordinates represent the quantity q, that is the load carried by 1 in. length of the bolt, which is proportional to the stress. The part AB follows the law [3]

$$q = q_{\text{yield}}\, e^{-Bx}$$

and is the same as the original curve CD shifted to the right.

The depth of penetration of the yielding into the nut AF can be found from the consideration that the total area of the curve equals the load P_0. Thus from the condition that

$$\text{area } FAEO = \text{area } HCGO$$

the distance FA can be easily calculated.

The yielding of the threads necessary to change the stress distribution from Fig. 10 to Fig. 12 is exceedingly small. Therefore it does not constitute any dangerous condition; the threads merely change their shape slightly so as to readjust themselves to the new circumstances.

It may be thought that if the pitch of the thread on the bolt be made slightly different from that of the nut, such that the bolt when stretched has the same pitch as the unloaded nut, a more

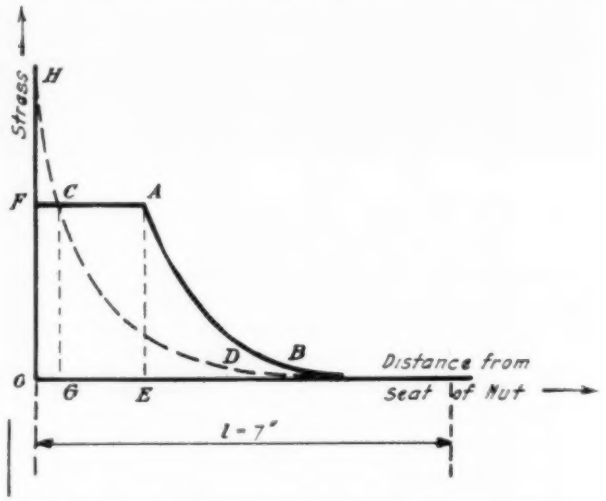

FIG. 11 STRESS DISTRIBUTION IN THREADS AFTER YIELDING

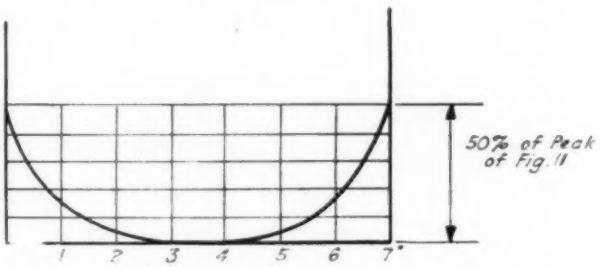

FIG. 12 STRESS DISTRIBUTION ALONG THREADS OF BOLT AND NUT WITH DIFFERENT PITCH

favorable distribution will be the result. This is true to a certain extent; an analysis of this case shows that the maximum stress is cut in half and that two peaks appear at the two extremities of the nut (Fig. 12).

Though this is quite an improvement, it is by far not ideal yet. It is shown in Appendix No. 2 that a perfectly uniform stress distribution along the length of the nut can be obtained by shaping the nut parabolically at the inside.

EXPERIMENTS WITH BOLTS

An experimental confirmation of the result [3] has been obtained with the photoelastic method by Mr. R. V. Baud. A celluloid model of the shape shown in Fig. 13 was very carefully machined and subjected to tension. The two lower "threads" were seen to take nearly the entire load, while the upper

ones were practically not stressed at all. Other tests were made with steel bolts of 1 in. diameter. These bolts were pulled, and the strain was measured directly between a section of the bolt very near to the nut and the seat of the nut by means of the very sensitive Martens extensometer. Though the yield in the first thread was calculated by [3] to occur at a pull of about 7000 lb., no curvature in the stress-strain curve could be detected below 28,000 lb. This confirms that the effect of local yielding in the threads is of such a small magnitude that it cannot be detected on the bolt structure itself. The tests were made with various lengths of nut. No appreciable difference in the yield load was found for nut lengths ranging from $^3/_4$ to $1^1/_2$ times the bolt diameter.

Finally the bolts were pulled to destruction. For nut lengths above 0.6 times the bolt diameter, failure took place in the bolt. With 0.6 times the diameter of the nut the threads of the bolt

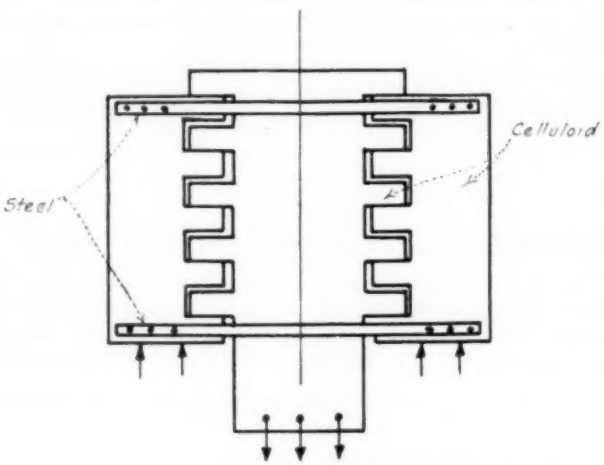

Fig. 13 Celluloid Model for Photoelastic Test

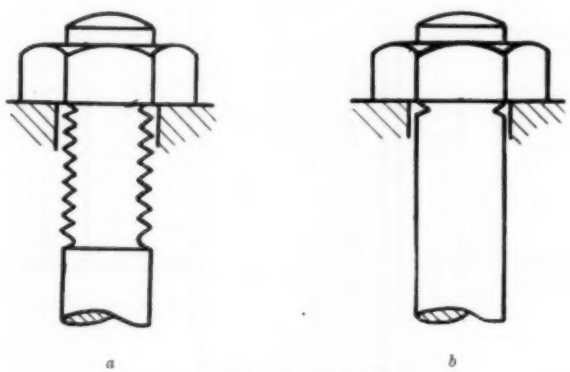

Fig. 14 Diagrams of Bolts Tested

were sheared off. This shows conclusively that in a construction with a nut height of $^3/_4$ times the diameter or more, the weak point is in the bolt rather than in the threads.

The length of the thread under the seat of the nut also has its influence on the final strength and the type of fracture of the bolt. With a sufficient length of nut the construction of Fig. 14*a* will fracture at a slightly lower load than Fig. 14*b*. However, Fig. 14*a* is to be preferred to Fig. 14*b*, since the last construction breaks without hardly any yielding. The fracture looks like that of a brittle material. Fig. 14*a* shows considerable elongation and necking before it fails. The photographs (Fig. 15) show these conditions sufficiently clear. Since a condition as in Fig. 14*b* is particularly dangerous under shock loads, it has been carefully avoided in our plate rotors.

Effect of Centrifugal Force on the Bolts

If there exists some clearance between the bolts and the plates, the bolts will be subjected to bending stresses due to the centrifugal forces acting on them. Let δ be the clearance, that is the

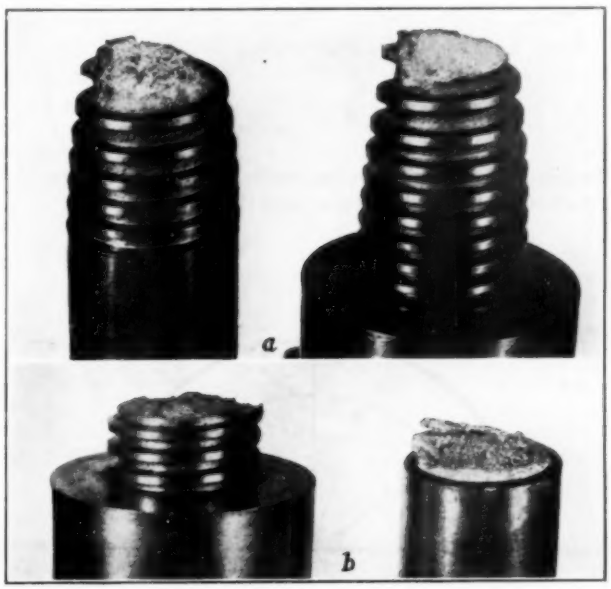

Fig. 15 Types of Fractures of Bolts

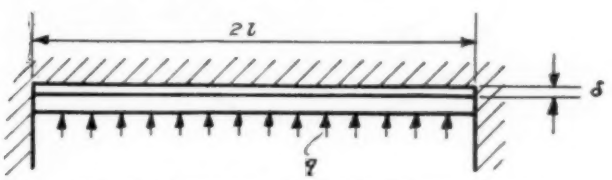

Fig. 16 Rotor Bolt Under Centrifugal Load

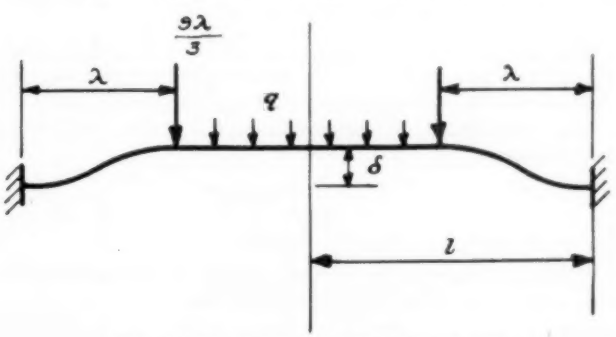

Fig. 17 Reaction From Plates on Bolt

difference between the diameters of the hole in the plate and of the bolt. The most unfavorable case which may happen is that the clearance for *all* the plates is situated on the outside of the rotor. Then there is the problem of a bolt or beam clamped at both ends parallel to a rigid wall (of plates) at a distance from it (Fig. 16) and loaded with a uniform (centrifugal) load of q lb. per in.

At very low speeds, when q is sufficiently small the bolt will not touch the plates at all on the outside. When q becomes larger than $24EI\ \delta/l^4$, the deflection in the middle would become

larger than the wall permits, consequently there will be a point contact between the wall and the bolt there. With increasing q, the reaction of the plate in the middle increases, and the curvature and bending moment of the bolt at that point decrease gradually. This bending moment can be easily calculated to

$$M_0 = \frac{6EI\delta}{l^2} - \frac{ql^2}{12}$$

When this becomes zero, that is when

$$q = \frac{72EI\delta}{l^4}$$

the bolt is again straight in the middle. For larger q's than this a part of the bolt will lie flat against the plate (Fig. 17).

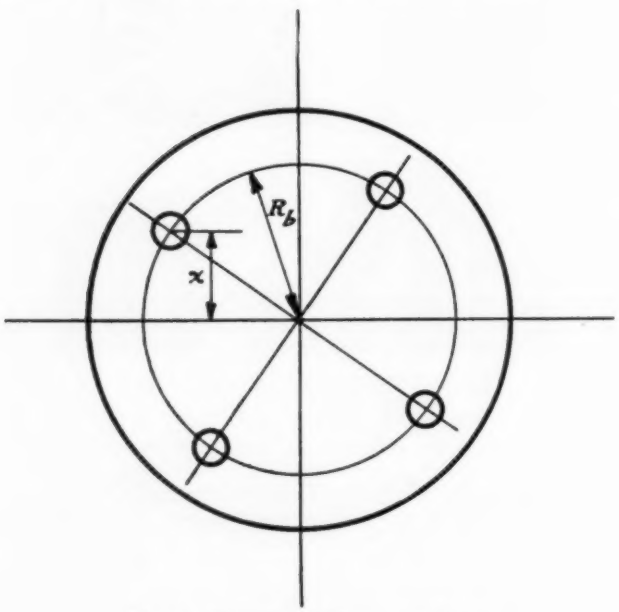

FIG. 18 POSITION OF HOLES FOR BOLTS

The reaction from the plates is calculated to consist of a uniformly distributed reaction q on the straight part and two concentrated forces $q\lambda/3$ on the extremities of the straight part.

The "free" length will diminish when q increases, the relation being expressed by

$$\lambda = \sqrt[4]{\frac{72EI\delta}{q}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

The maximum bending moment appears at the clamped section at the end of the bolt and has the value

$$M_{max} = \sqrt{2EIq\delta} \quad \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

It has been calculated that for a clearance equal to 0.004 in. at a speed of 1800 r.p.m. for the usual construction, this bending moment causes a stress of 22,000 lb. per sq. in. It should be noted that the underlying assumptions of the calculation are excessively severe. The condition of clamping at the end will be only partly fulfilled. Then in case the clearance is all on the outside, the centrifugal force acting on the bolt and nut will overcome the friction under the seat of the nut and slip the bolt so that the clearance shifts to the inside of the rotor.

At any rate this fairly high-stress figure points to the desirability of small clearances in the bolt holes and of an overspeed run to shift these clearances to the inside. Therefore, it is practice to ream the bolt holes in the (temporarily) assembled rotor accurately with 0.004 in. clearance.

After final assembling and machining, the rotor is given a run with 20 per cent overspeed, which will overcome the friction under the nut seat and create a condition in which hardly any stresses, due to centrifugal action on the bolts, can exist.

CONCLUSIONS AND ACKNOWLEDGMENT

The various problems regarding stresses and deformations characteristic of plate rotors are discussed in this paper. It is shown that, in bending, the stiffness can be calculated from some test data on the compressibility of stacks of plates. This stiffness is hardly less than with solid rotors. Various angles of the problem of the stress distribution in the bolts are reviewed, and it is shown that the stresses in any part of the structure are kept well below safe limits by means of special assembly methods in the shop.

The author is indebted to Mr. W. F. Shirk for the compressibility tests on plates; to Mr. R. V. Baud for the photoelastic test, and especially to Dr. S. Timoshenko, not only for the analysis of the bending rigidity of the rotors, but more so for many valuable suggestions and personal encouragement.

Appendix No. 1—Bending of the Plate Rotor

In the following analysis the subscripts $_b$ or $_p$ will refer to bolts and plates, respectively. Let e be the unit elongation of a bolt, at a distance R_b from the neutral axis (Fig. 18) due to bending only. The unit elongation of the bolt at any other location x will then be $\frac{x}{R_b} e_b$. Since the stress in the bolts becomes $\frac{x}{R_b} e_b E_b$, the bending moment M_b is

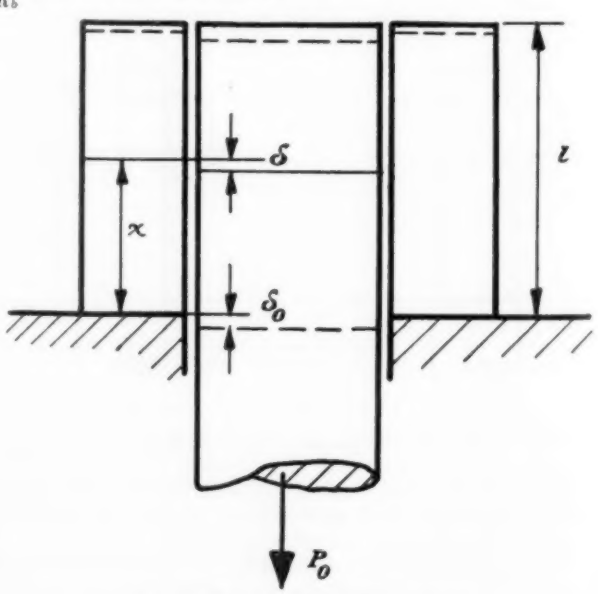

FIG. 19 BOLT AND NUT CONNECTION

$$M_b = \int \left(\frac{x}{R_b} e_b E_b\right) x\, dA = \frac{eE_b}{R_b} \int x^2\, dA = \frac{e_b E_b I_b}{R_b} \ldots [6]$$

where I_b is the moment of inertia of the cross-section of the four bolts with respect to the neutral axis.

In the same manner an equation for the plates can be obtained

$$M_p = \frac{e_p E_p I_p}{R_b} \quad \ldots\ldots\ldots\ldots\ldots\ldots [7]$$

where e_p is the unit elongation in the plates at a distance R_b away from the neutral axis. It should be noted that e_b is constant but that e_p varies along the length of the rotor. The total elongation of a bolt has to be equal to the total elongation of the plates in the same location. Thus

$$e_b l = \int_0^l e_p \, dx$$

Substituting (1) and (2) in this relation, we obtain

$$\frac{M_b R_b}{E_b I_b} l = \frac{R_b}{E_p I_p} \int_0^l M_p \, dx$$

Since $M = M_p + M_b$ and M_b is independent of x, this can be written as

$$M_b = \frac{E_b I_b}{E_b I_b + E_p I_p} \cdot \frac{\int_0^l M dx}{l} \quad \ldots\ldots\ldots\ldots [8]$$

or

$$M_b = \frac{E_b I_b}{E_b I_b + E_p I_p} \cdot M_{\text{average}} \quad \ldots\ldots\ldots\ldots [8a]$$

For the smaller rotors, where the ratio of stack length to overall

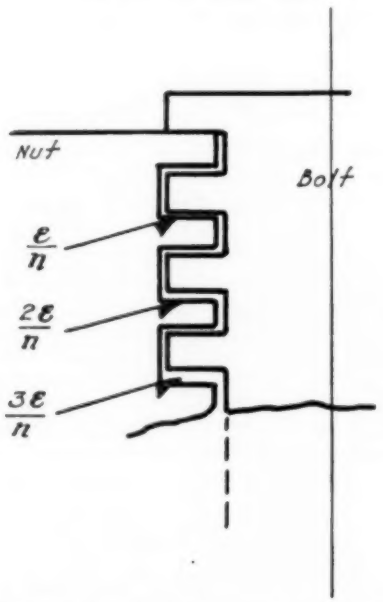

Fig. 20 Bolt and Nut With Different Pitch, Unstressed

length is small, the moment M will not vary much along the stack of plates. In that case we may make the approximation $M = M_{\text{average}}$. Then the moment M_p carried by the plates is also constant, and the central part of the rotor will be bent circularly. We do not need to calculate the plates and bolts separately any more, but may find the deflection as if it were a solid rotor with a stiffness

$$EI = I_b E_b + I_p E_p \quad \ldots\ldots\ldots\ldots\ldots [9]$$

However, for longer rotors, as they are being built now and especially for those which probably will be built in the future, this simplification cannot be made. Then the deflection has to be found graphically. Formula [8] is correct, so that M_p can be found as is shown in Fig. 4. With this moment we construct graphically the deflection curve of a bar with a stiffness of $I_p E_p$.

It will be noticed that even this is only approximate. The bolts, transmitting a constant moment M_b, will bend circularly, while the plates will deform in some other curve. Since, however, the stiffness against bending of the plates is about five times that of the bolts, it is reasonable that the plates will force the bolts in the same deformed shape as they assume themselves. This entails bending stresses in the individual bolts, which, however, are so small as to be entirely negligible.

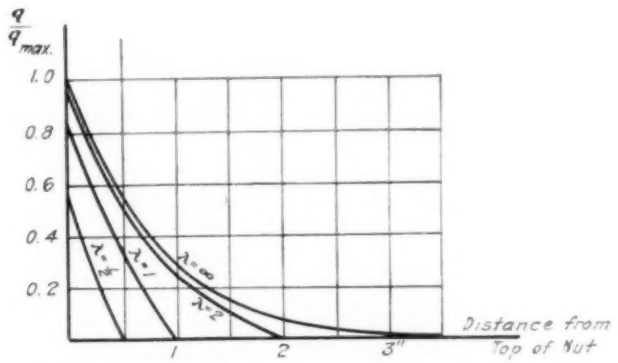

Fig. 21 Stress in Threads for Different Bolt Pulls

The foregoing theory holds only in case the compressive stresses in the plates on the convex side of the rotor do not decrease to a small value, and certainly it will cease to be applicable when these stresses become zero, so that the rotor gaps. However, with the size of rotors now used or under construction, this limit is by far not yet reached.

The periods of natural vibration in bending of a plate rotor, which we want to know in connection with the determination of the critical speeds of operation, are found graphically on the basis of a deflection curve constructed in this manner.

Appendix No. 2—On the Stress Distribution in Screw Threads

Let, in Fig. 19

x = distance from seat of nut
P = tensile force in bolt at any section $P = f_1(x)$
q = force transmitted by the thread from bolt to nut per unit length of the nut $q = f_2(x)$
A_b, A_n = cross-sectional areas of bolt and nut
α = spring constant of the thread, which is the displacement in inches between two originally coinciding cross-sections of bolt and nut, due to unit q.

The total force P in the bolt which is P_0 outside the thread will diminish gradually with increasing x, till for $x = l$, $P = 0$.

The decrease in P is transmitted to the nut, thus

$$\frac{dP}{dx} = -q \quad \ldots\ldots\ldots\ldots\ldots [10]$$

The elongation of an element dx of the bolt due to the tensile force P is

$$\frac{P dx}{A_b E}$$

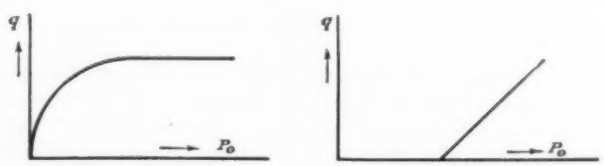
Due to the loading, a cross-section x of the bolt comes down the amount

$$\delta_0 - \int_0^x \frac{P dx}{A_b E}$$

Due to the compression in the nut, a section x of it gets a downward displacement of

$$\int_0^x \frac{P dx}{A_n E}$$

The relative displacement of two initially coinciding sections of bolt and nut therefore is



$$\delta = \int_0^x \frac{P dx}{A_n E} + \int_0^x \frac{P dx}{A_b E} - \delta_0$$

This deflection is taken up by the threads, which can be expressed as $-\alpha q$. Thus

$$\int_0^x \frac{P dx}{A_b E} + \int_0^x \frac{P dx}{A_n E} + \delta_0 = -\alpha q$$

Differentiating this equation, and remembering (10), we get:

$$\frac{d^2P}{dx^2} = \frac{P}{\alpha E}\left(\frac{1}{A_b} + \frac{1}{A_n}\right)$$

a b

FIG. 22 LOADING ON TOP AND BOTTOM THREAD AS FUNCTIONS OF BOLT PULL, DIFFERENT PITCH

a shows the loading on top thread and *b* shows the loading on bottom thread.)

or introducing a constant B, such that

$$B^2 = \frac{1}{\alpha E}\left(\frac{1}{A_b} + \frac{1}{A_n}\right) \quad \ldots\ldots\ldots\ldots [11]$$

the equation becomes

$$\frac{d^2P}{dx^2} = B^2 P$$

Its solution is

$$P = Ae^{Bx} + Be^{-Bx}$$

or with the boundary conditions

$$x = 0, P = 0, \quad \text{and} \quad x = l, P = P_0$$

we have

$$P = P_0 \frac{e^{Bx} - e^{B(2l-x)}}{1 - e^{2Bl}} \quad \ldots\ldots\ldots\ldots [12]$$

Now for the bolts with Acme thread as used in these rotors, the flexibility α was calculated by considering the threads as cantilever beams of variable cross-section. Deformation due to bending and due to shear was considered. In this manner it was found for the value of B: 1.27 inches^{-1}. For any length of nut over 4 in. it is seen that only a very small error is made by writing, instead of [12]

$$P = P_0 e^{-Bx} \quad \ldots\ldots\ldots\ldots [13]$$

The load on the thread and consequently the stress is characterized by q

$$q = \frac{-dP}{dx} = P_0 B e^{-Bx} \quad \ldots\ldots\ldots\ldots [14]$$

which is the same as [3] and is shown in Fig. 9. If the pitches of bolt and nut are slightly different, a similar analysis can be applied; only for simplification it is desirable to measure downward from the top of the nut, and to denote by δ_0 the distance between the bolt and nut sections at the *top* of the nut, instead of at the seat (Fig. 19).

Let ϵ be the difference in pitch of bolt and nut per unit length, the pitch of the nut being greater than that of the bolt. If n be the number of threads per unit length, the clearances between consecutive threads in unstressed conditions are ϵ/n, $2\epsilon/n$, ...

The clearance at x inches from the top in unstressed condition is ϵx.

The load q on the threads becomes

$$q = \frac{1}{\alpha}(\delta - \epsilon x) \quad \ldots\ldots\ldots\ldots [15]$$

which formula holds only for $q > 0$.

The displacement δ between two sections is

$$\delta = \delta_0 + \frac{1}{E}\left(\frac{1}{A_b} + \frac{1}{A_n}\right)\int_0^x P dx \quad \ldots\ldots\ldots\ldots [16]$$

Differentiating (15) and substituting (16), the differential equation becomes

$$\frac{d^2P}{dx^2} = BP - \frac{\epsilon}{\alpha} \quad \ldots\ldots\ldots\ldots [17]$$

the general solution of which is

$$P = Ae^{Bx} + Be^{-Bx} + \frac{\epsilon}{\alpha B_2} \quad \ldots\ldots\ldots\ldots [18]$$

When P increases from zero up, more and more threads will come in contact and will help carry the lead. We denote by λ the length from the top of the nut down, where the threads are in contact. From the derivation of [18] it is evident that it holds only for

$$0 < x < \lambda$$

For determining the arbitrary constants A, B, and λ we have the three boundary conditions

$$x = 0 \qquad P = 0$$
$$x = \lambda \qquad P = P_0$$
$$x = \lambda \qquad \frac{dP}{dx} = 0$$

This leads to

$$P = \frac{\epsilon}{\alpha B_2}\left[1 - \frac{e^{Bx}}{1 + e^{2Bx}} - \frac{e^{-Bx}}{1 + e^{-2Bx}}\right] \quad \ldots\ldots\ldots\ldots [19]$$

and

$$\cosh B\lambda = \frac{\epsilon}{\epsilon - \alpha B^2 P_0} \quad \ldots\ldots\ldots\ldots [20]$$

The maximum value of the thread pressure $q = \frac{dP}{dx}$ occurs at $x = 0$, the top of the nut. Letting this maximum value be q_0, we have from [19]

$$q_0 = \frac{\epsilon}{\alpha B} \cdot \tanh B\lambda \quad \ldots\ldots\ldots\ldots [21]$$

Eliminating λ between [20] and [21] we have the following relation between q_0 and P_0

$$q_0^2 = \frac{2\epsilon}{\alpha} \cdot P_0 - B^2 P_0^2 \quad \ldots\ldots [22]$$

For a certain value of P all the threads along the length of the nut will be in contact ($\lambda = l$). For the conditions prevailing in turbo bolts, $q = \frac{dP}{dx}$, calculated from [17] becomes very nearly equal to

$$q_0 = \frac{\epsilon}{\alpha B} e^{-Bx} \quad \ldots\ldots [23]$$

The relations [19], [20], [21], and [22] have been plotted to curves. Figure 21 shows the pressure distribution for various pulls.

It is seen that the peak pressure does not increase much by increasing the contact λ from 2 in. to 7 in. (or ∞ in.). The curve for $\lambda = \infty$ is represented by [23]. As soon as all clearances have been taken up, the Equations [15] to [23] cease to apply and the conditions expressed by the Equations [12] to [14] prevail. From then on, therefore, pressure starts to be built up from the bottom end of the nut following the law [11], which is the same as [23] except that it slopes down from the bottom of the nut instead of from the top. When P_0 reaches the value $\frac{2\epsilon}{B^2\alpha}$ the peaks at the two ends of the nut become equal (Fig. 12). The most favorable pitch difference at which this happens therefore is

$$\epsilon = \frac{P_0 \alpha B^2}{2} \quad \ldots\ldots [24]$$

The relation between the pull P_0 and the pressure (or stress) q_0 is shown clearly in Fig. 22. Fig. 22*a* represents the stress at the top of the nut and Fig. 22*b* the stress at the bottom of the nut for increasing P_0.

The question may come up whether a bolt can be made in which the pitch varies along its length according to a certain law, such that the stress is distributed uniformly all along the length of the nut. In order to investigate this, let $\epsilon = f(x)$ be the vertical clearance between the threads of bolt and nut both in the unstressed state. At the top of the nut ($x = 0$) the clearance $\epsilon = 0$, it increases when going down. Again x is now measured from the top of the nut down.

The relative displacement between bolt and nut at a section x in this case is

$$\delta = \delta_0 + \frac{1}{E}\left\{\frac{1}{A_b} + \frac{1}{A_n}\right\} \int_0^x P dx$$

This relative displacement is taken up partly by the clearance ϵ and partly by the elastic deformation αq

Thus

$$\epsilon + \alpha q = \delta_0 + \frac{1}{E}\left\{\frac{1}{A_b} + \frac{1}{A_n}\right\} \int_0^x P dx$$

It is desired to have uniform stress distribution, in other words to have $q = \text{constant} = \frac{P_0}{l}$ and $P = P_0 \frac{x}{l}$.

Substituting this in the foregoing equation, integrating and noting that $\delta_0 = \alpha q$, it is found that

$$\epsilon = \frac{P_0}{2El}\left\{\frac{1}{A_b} + \frac{1}{A_n}\right\} x^2 \quad \ldots\ldots [25]$$

in other words, the clearance has to increase parabolically.

Now suppose a bolt and nut fit exactly together without any clearances whatsoever. If the inside diameter of the nut could be increased, it would be easy to create clearances. Then it is clear that by giving the inside of the nut the shape of a paraboloid of revolution, the clearance distribution [25] can be realized.

For the 5-in. diameter Acme-threaded bolts used in the plate rotors, loaded to a stress of 40,000 lb. per sq. in. and equipped with nuts of 5-in. length, the distance a in Fig. 23 was calculated to

$$a = 0.021 \text{ in.}$$

This can be machined by guiding the tool by means of a suitable

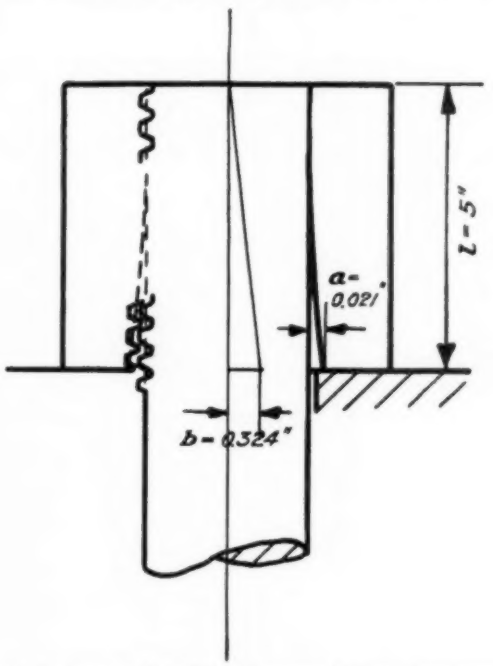


FIG. 23 PARABOLIC NUT WITH UNIFORM STRESS DISTRIBUTION

templet. Since for such small ratios a/l a paraboloid and a hyperboloid are practically coinciding, another method of machining would be by feeding the tool along a generatrix of the hyperboloid. This does not necessitate a templet, and the feed is also much greater ($b = 0.324''$ in Fig. 23). Though this latter method is probably easier to carry out, it has the disadvantage that the *shape* of the thread varies along the nut, due to the fact that the plane of the normal section of the tool does not contain the axis of the nut, but is only parallel to it. Though this change in shape is very small, it has been calculated that it annihilates completely the desired effect on the stress distribution.

Of all these calculations it can be said that they are true only if the machining errors in making the thread are small in comparison to the elastic deformations. With the present state of the art this is not possible as a commercial proposition. Therefore, it was decided not to use the parabolical nuts for the present time, because they represent no improvement when machining errors of 0.0001 in. are possible. The natural ductility of the material takes care automatically that excessive stresses are distributed more uniformly along the length of the bolts.

Discussion

B. A. BEHREND.[4] It may be of interest to recall the reasons which prompted me to propose in 1909 the plate-rotor construc-

[4] Consulting Engineer, Wellesley Hills, Mass. Mem. A.S.M.E.

tion which we developed in the Westinghouse Company and which is now their standard type for all the larger sizes of their turbo-generators.

Twenty years ago, when this work was initiated, large carbon and nickel-steel forgings were very popular. Great stress was laid on the elastic limit and the ultimate strength. The question of ductility of the material was considered of little importance. This state of affairs underwent a change when a number of notable failures called attention to the importance of ductility as measured roughly but most conveniently by the elongation in a 2-in. test bar and by its reduction of area. Another rather old-fashioned but very useful way of getting a conception of the ductility of the material is the cold-bending test in use for boiler plate, which should accompany all conventional tests.

In reviewing the opposition to this construction it is now curious to recall that the importance of the direction in which the test bar was taken from the material could hardly be brought home to the designers and makers. It had been customary to take tests from a small projection of the forging, called the coupon, altogether without regard to the direction in which the material was subjected to stress. We began to call for "radial" and "tangential" test bars, instead of the conventional "axial" tests, and the result of these tests showed very clearly the unsuitability of large forgings, whether of nickel steel or carbon steel, for radially and tangentially stressed rotors.

In the designs as more recently adopted by the Westinghouse Company, there is to be noted a departure from the original design on one salient point. It has been the underlying principle in the designs worked out by A. B. Field and myself to use rolled or comparatively thin forged plates without a hole or other perforation in the center. Such plates were made for these designs on different occasions by the armor-plate department of the Carnegie Steel Company, and it was demonstrated that a small percentage of nickel about one to one and a half per cent greatly improved the plate over plain carbon steel. What excellent results were obtained in this manner has been discussed elsewhere.[5]

Mr. Den Hartog's paper discusses principally the elastic theory of the bolt construction, to which it is a most valuable contribution. In the main I concur with its statements. However, the use of thick forged plates with a large hole in the center appears to me a retrograde step, for two reasons. First, it sacrifices the advantage obtained by a continuous unperforated plate by increasing the stress at the center to about double the stress for the unperforated plate; secondly, mandrel-forged thick plates have, by the very nature of the forging process, better properties axially where they are not required than radially or tangentially, where they are required.

As it has been possible to secure rolled plates with excellent properties, rolled at right angles, if desired, of two or three inches thickness, it would seem deplorable to give up two of the best features of the plate-rotor construction while retaining those features which must be considered the least desirable features of the design which I originated. I should be tempted to consider a solid rotor forging the equal of or superior to a rotor made up of rings of great thickness.

A solid rotor forging with a large central hole has the same radial and tangential stresses as the rotor construction described in the paper. The heat treatment can be carried through in the same manner, as the hole through the center permits this readily. A periscope can be used for inspection of the inside, thus the probability that a flaw may remain undiscovered is likely to be the same in both types. I used to state that the plate rotor as developed by Mr. Field and myself greatly reduced the chance that a flaw would remain undiscovered. Assuming a 2-in. plate and a 100-in. solid rotor, the probability of a flaw remaining undiscovered in the two types is 1 to 2500. This brings home the argument in behalf of the plate construction. Part of this great benefit is lost by going to much thicker plates unless these plates are forged axially of an alloy steel. This latter appears essential to safety in view of the tendency of carbon-steel forgings to develop almost invisible hair cracks.

[5] B. A. Behrend, Trans. A.I.E.E., 1917, p. 883 et seq.

A. L. Kimball.[6] The writer is glad to see that Mr. Behrend has taken up the cause of the solid rotor in single units, because one thing the writer was going to take exception to in this paper is the statement, "For the largest machines of the present time single-piece forgings cannot be bought from the steel companies, so that the rotor has to be made up of several pieces," and the statement, "Better material can be obtained in plate form than in large solid forgings."

The author mentioned among a number of large machines of this type which were built the 100,000-kva. machine which was being built by the General Electric Company. This machine, except for a pair of comparatively small end pieces, is to be made of a single solid forging. The same is true of a 160,000-kva. machine now in the shop. Experienced engineers still use solid forgings, and we have an instance of one of the very largest machines ever built made of such a forging.

Author's Closure

It is particularly gratifying to have a discussion from Mr. B. A. Behrend, the originator of the plate-rotor construction. Mr. Behrend gives a valuable historical review of the development of the rotor and a synopsis of the reasons which led him to propose a plate rotor rather than a solid one as early as 1909. The construction has persisted in its original form for more than 25 years, which certainly is a great tribute to Mr. Behrend's foresight.

However, when the size of the rotors became about three times as large as in 1909 some slight modifications became desirable on account of troubles experienced. It is to two of these modifications that Mr. Behrend takes exception—first, that a hole is made in the plates and, second, that the thickness of the plates is increased.

It is true that the stress at the inside of the plate is increased to more than twice its value due to the influence of the central hole, but since the stress at the roots of the teeth is still higher, this is of no importance. After all, it is only the weakest link in a chain that determines its strength. On the other hand, there are two distinct advantages of the central hole, for which it was adopted, namely, the possibility of a more thorough heat treatment and a superior method of ventilating the rotor. Especially the latter point is of fundamental importance, but since it does not belong to our subject we refer to a very complete paper by S. L. Henderson and C. R. Soderberg, Trans. A.I.E.E., 1928, vol. 47, pp. 549–578.

Mr. Behrend states that the properties of the material in 8-in. plates are necessarily inferior to those of the thinner ones. If that were the case, the Westinghouse Company certainly would have hesitated very much in adopting the thicker plates. Tests have been made showing that in the 8-in. plate the yield point was 65,000 lb. per sq. in., the elongation 25 per cent, and the reduction in area 50 per cent, which is better than anything obtained before with rolled 2-in. plates. These tests were consistent and showed practically no difference between the tangential and radial directions. The behavior of these plates in regard to residual stresses was also far superior to the 2-in. plates

[6] Research Engineer, General Electric Company, Schenectady, N. Y. Assoc. A.S.M.E.

or to solid forgings. The material is more expensive than that of the rolled 2-in. plates, on account of the heat treatment; but this is easily compensated for by the saving in machining obtained by reducing the number of contact surfaces.

Therefore, though Mr. Behrend's discussion has brought out many valuable points, I cannot agree with this view that the latest developments are a "retrograde step," but I am rather inclined to believe that they are a positive step in the direction of improvement.

Mr. Kimball's discussion takes exception to the two opening statements of my paper. The first statement still stands as it is, as Mr. Kimball agrees to himself in the latter part of his discussion. The "comparatively small end pieces" mentioned are equivalent to the end forgings shown in Figs. 1 and 2 of my paper. For the rotor shown in Fig. 1 the end forgings weigh 22,000 lb. each, while the plates together weigh 98,000 lb. The General Electric Company builds its large rotors of three pieces; two end forgings and one central forging taking the place of our plates. The three pieces are joined by means of a shrink connection and a comparatively great number of short bolts. Since such a joint is not easy to make, and since the smaller rotors of the General Electric Company consist of a single forging, it is evident that it was not possible to get a single forging for the larger sizes. In the case of Fig. 1 it would mean the difference between 98,000 lb. and 142,000 lb.

The paragraph in my paper that is questioned should possibly read: "The Westinghouse Company has not been able to secure from any steel manufacturer in the country single solid-rotor forgings of the same quality as obtained in its rotor plates."

APM-51-2

Tests on Belleville Springs by the Ordnance Department, U. S. Army

By D. A. GURNEY,[1] WASHINGTON, D. C.

BELLEVILLE springs are dish-shaped springs, as shown in Fig. 1, which have long been used where relatively large load capacity, small deflection, and a limited closed height are necessitated by other controlling features of design. Recent demands for larger Belleville springs than those previously used disclosed the absence of any reliable design data; and the investigation here presented was undertaken to supply this lack of information. After experimentation and investigation, the following formula was evolved for purposes of design:

$$\delta = \frac{4W}{3\pi Et^3}\left(R_2^2 - R_1^2 + R_2R_1 \log_e \frac{R_2}{R_1}\right) \ldots\ldots\ldots [1]$$

where

δ = deflection, in
W = load, lb.
E = modulus of elasticity, lb. per sq. in.
R_1 = inside radius, in.
R_2 = outside radius, in.
t = thickness, in.

A method of plotting this formula in such a way that designs may be made directly from the plot is given in Fig. 2. Springs may be designed in accordance with this formula and plot; and accurate design is thereby possible with a maximum error of 7 per cent.

The investigators also found that springs made of SAE 6145, which was the steel used throughout these tests, would not be stressed above the elastic limit if designed with the following ratios of outside radius to thickness and with the corresponding dish angles:

$R_2 = 6t$, dish angle = 4 deg.
$R_2 = 9t$, dish angle = 5 deg.
$R_2 = 12t$, dish angle = 6 deg.

where the dish angle is the angle between the sides of the spring and the plane on which it rests. No spring should be made with a ratio of R_2/t less than 6 and a dish angle of 6 deg. is sufficient for any spring.

In addition, the following conclusions were reached after correlation of the results of tests, of mathematical analysis (not here given), and of a photoelastic analysis made by Prof. Paul Heymans of Massachusetts Institute of Technology:

a The maximum compressive fiber stress occurs at the upper inner edge and the maximum tensile fiber stress occurs at the lower outer edge. The former is numerically the greater.

b The neutral axis is about one-third the width of the spring from the inner edge and does not move appreciably during flattening.

c Rotation of lines normal to the surface, which occurs during flattening of the spring, causes most of the stress. This rotation moves the upper surface inward and the lower surface outward.

d The compressive stress due to the sum of this rotation and the radial stress at the inner edge is the limiting stress.

e The upper surface of the spring is under tangential compression throughout.

f Considering a section midway between the inner and outer edges, the resultant tangential strain (top and bottom surfaces) is zero at this point. Inside this point the tangential strain is compression, and outside of it, tension. The radial strains are compression throughout, small at the edges and maximum at the point where the tangential strain is zero. Inside this point both the radial and tangential strains are compression, and this part of the spring tends to remain conical in flattening. Outside this point, radial strain is opposed to tangential, more bending takes place, and the surface becomes warped under load.

g Just before the spring becomes flat the outer point of application of the load moves inward because of this warping, or, in other words, the effective width of the spring is decreased: this explains the shape of the load-deflection curves just before the spring becomes solid.

h Grinding off the surface of a spring decreases very rapidly the load that a spring will carry.

i Grinding off either the inner or outer edge increases this load much less rapidly.

j A relatively thick spring has a straight load-deflection curve until solid height is approached, but the allowable dish is small.

k A relatively thin spring will not have a straight-line load-deflection curve, but the load per unit deflection will drop off as the spring flattens until this curve breaks sharply upward on approaching solid height.

l The load per unit deflection varies as the cube of the thickness.

m Springs of various sizes but of the same proportions obey the following laws:

1 The load per unit deflection varies as the first power of the size ratio.

2 The load at solid height varies as the square of the size ratio.

By making use of these relations, springs of various sizes may be reduced to a unit basis and compared.

n In specifying tests for Belleville springs, loads at two different heights should be given in order to obtain the proper load-deflection rate, or the free height may be specified together with the deflection per spring for a given load. This load should be from two-thirds to three-quarters of the spring capacity. The working load should not exceed two-thirds of the flattening load.

History of Belleville Springs

Belleville springs were used by the Ordnance Department as counter-recoil springs for 7-in. howitzer and 12-in. mortar carriages designed about 1890. The production of these springs at that time proved to be a difficult problem. No private factory would undertake to produce them, and extensive experiments were necessary before the Watertown Arsenal was able to make those necessary for the carriages then under construction. They were finally replaced by helical springs, which were found to be cheaper and easier to fabricate.

During the World War the Ordnance Department obtained

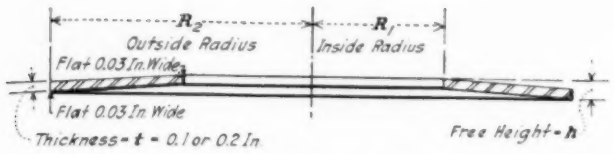

FIG. 1 SHAPE OF BELLEVILLE SPRINGS TESTED FOR DEVELOPMENT OF FORMULA AND DATA

(By arranging these springs in stacks and by alternating them so that two concave and two convex sides are adjacent, almost any desired spring characteristics may be obtained.)

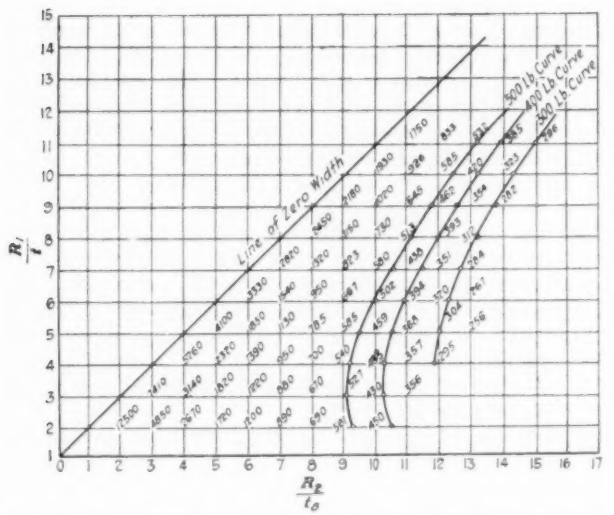

FIG. 2 CURVES OF FORMULA [1] FOR SPRING DEFLECTION PLOTTED FOR USE OF DESIGNERS

(For these curves, t = 0.1 in. and E = 23,300,000. Ordinates are values of R_1/t and abscissas are values of R_2/t. The curves show values of load per 0.01 in. of deflection. To use the plot to find the load per 0.01 in. of deflection for any spring, divide the inside and outside radii of the given spring by the thickness; and, using these values as ordinate and abscissa, respectively, locate the point. By interpolation between curves find the load per 0.01 in. deflection for a spring of unit size, t = 0.1 in. Multiply this value by the ratio of required spring to unit spring to obtain the required result. If the modulus of elasticity is different, i.e., if a different spring steel is used, this result should be corrected in the direct proportion of the two moduli.)

from the French Government designs of gun carriages such as the 75-mm. Puteaux and the 155-mm. G.P.F., in which Belleville springs were used for placing initial compression on the packings which must hold compressed air or nitrogen indefinitely under a pressure of more than 100 atmospheres. This type of spring is admirably suited for this purpose. It therefore became necessary to manufacture great quantities of these springs for use in the recoil mechanisms of these carriages. A considerable number were also used as rebound springs between the frame and chest of caissons for carrying ammunition. Some difficulties were experienced in the manufacture of these springs, but these were overcome and did not delay the manufacturing program. Many of these springs have, however, broken in service and in storage, and there is always the danger that a broken spring may ruin the expensive recoil mechanism in which it is assembled.

After the war, the Department undertook the design of more powerful guns, involving larger recoil mechanisms and consequently Belleville springs having different dimensions and characteristics from those theretofore used. Attempts were made to design the springs by means of a table which had been obtained from the French, with indifferent success. Occasionally a spring would be found to test out as designed, but more often it was necessary to cut and try several times before a satisfactory spring could be produced. A limited amount of research work on these springs was performed during the years 1919 to 1921, and finally, on May 19, 1922, a program for an investigation of the manufacture of Belleville springs was approved. The work has since been carried on in a systematic manner at the Rock Island Arsenal under the supervision of Capt. R. S. Barr, Ord. Dept. U.S.A. A number of partial reports have been submitted, a digest of which is contained in this paper.

Description of Tests

The material used throughout the tests was chrome-vanadium sheet steel SAE 6145, having the following analysis: carbon, 0.43; manganese, 0.62; chromium, 1.10; and vanadium, 0.18. Springs of this material were fabricated by the following operations: shear into square plates; bore inside diameter; turn outside diameter; grind to thickness, 0.1 or 0.2 in.; form hot; heat treat; oil quench from 1650 deg. fahr.; draw at 650 deg. fahr., 30 min. in niter bath. The foregoing heat treatment was found to be best by a number of tests made on strips of the material. The physical properties after heat treatment are: tensile strength, 102,000 lb. per sq. in.; E, 23,300,000; scleroscope hardness, 75 to 80.

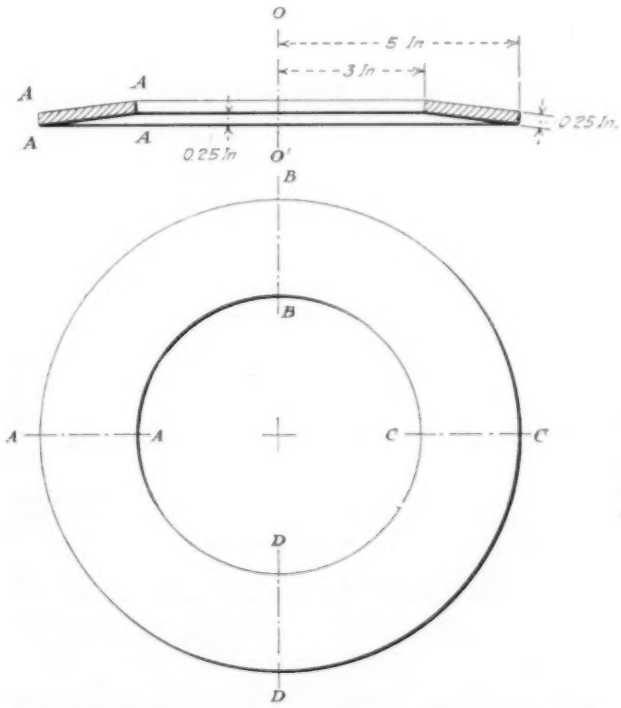

Fig. 9 Celluloid Belleville Spring for Photoelastic Test

In testing, a pair of springs of like dimensions were assembled with their concave sides together and loaded with an initial load of 100 lb. This was used as the starting height or zero point. They were then compressed by successive intervals of 0.01 in. and the load recorded, after which the zero point was again registered and the load noted. In no case were the springs compressed to such a point that the permanent set exceeded 0.001 in. per spring. After completing the test on a pair of springs the

outside diameter was reduced by increments, generally of 0.25 in., by means of Stellite tools, and after each reduction the tests were repeated. This was a great saving in time and labor, and had the advantage of producing sets of springs of varying characteristics and identical material and heat treatments. In most of the tests a dish angle of 7 deg. was used, but a number of springs of varying dimensions were also made and tested having a dish angle of 10 deg. in order to determine the maximum allowable dish. The results of most of the tests are shown graphically in Figs. 3 to 8.

Each radial cross-section (see Fig. 9) is divided into 8 equal parts, point 0 being at the outside radius of the spring and point 8 at the inside radius. All point 8 readings for the inside edge are measured to the top of the loading plate.

A photoelastic stress analysis was also made by Prof. Paul Heymans of Massachusetts Institute of Technology, using a celluloid spring of the dimensions shown in Fig. 9. The distribution of tangential and radial stresses along a radial section (such as *AA* in Fig. 9) of this celluloid model was obtained from the

TABLE 2 THE CHANGE IN DIAMETER FOR FOUR POINTS ON UPPER SURFACE OF THE PHOTOELASTIC MODEL FOR THREE LOADING CONDITIONS

Diameter	Point	Change of diameter in cm. Change of load 0 to 25 lb.	Change of load 25 to 50 lb.
AD	1–1	−0.0019	−0.0083
	3–3	−0.0086	−0.0160
	5–5	−0.0113	−0.0187
	7–7	−0.0144	−0.0206
BC	1–1	−0.0017	−0.0068
	3–3	−0.0055	−0.0119
	5–5	−0.0093	−0.0168
	7–7	−0.0142	−0.0214

The minus sign signifies that the diameter becomes smaller as load is applied. For system of numbering points see Table 1.

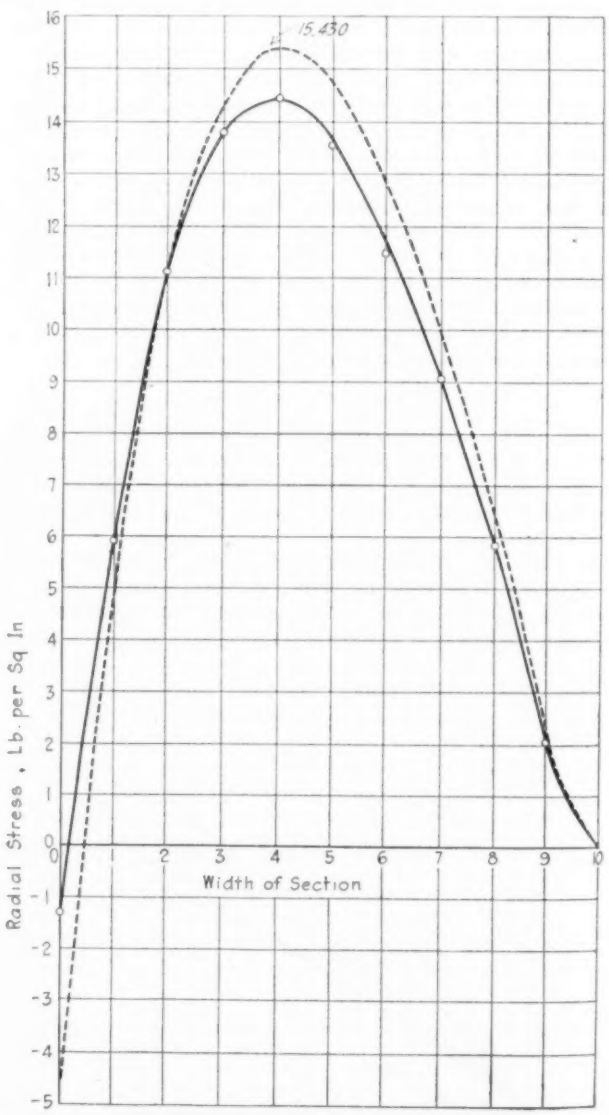

FIG. 11 DISTRIBUTION OF RADIAL STRESS IN RADIAL CROSS-SECTION OF PHOTOELASTIC MODEL

(Abscissas are ten equal divisions of a radial cross-section, the point 0 being at the inside radius of the spring and the point 10 at the outside radius. Solid line shows the stresses caused by change of load from 0 to 25 lb. Dotted line shows stresses caused by change of load from 25 to 50 lb.)

photoelastic measurements and is plotted in Figs. 10 and 11. These stress values were obtained first for a change from zero load to a medium load of 25 lb. and then for a change from 25 lb. to a heavy load of 50 lb. Deflections of various points of the surface of the spring for 25- and 50-lb. loads measured during the photoelastic tests are given in Table 1; and changes of diameter observed during the same tests are listed in Table 2.

Discussion

E. O. Waters.[2] The tests on Belleville springs have interested the writer on account of his having carried on an investigation of stresses in rings for pressure vessels a few years ago. At first sight the problem of the Belleville spring and that of the plain pipe flange or ring might appear to be practically identical, the emphasis being placed on deflection in the one case and stress in the other.

Closer inspection, however, shows certain marked differences. In the first place, the writer found it possible to analyze the stresses and strains in flat pipe flanges according to the classical theory for thick plates set forth by St. Venant, Foppl, Bach, and others, and obtain calculated deflections that agreed perfectly with test results, within the limits of experimental error. This means that the meridian plane, so called, of such flanges underwent no sensible distortion under load. The dish angle, at the point where the extreme fibers began to reach the limit of proportionality, was of the order of 0.5 deg. or less in most of the tests.

On the other hand, the present article specifies possible dish angles of 4 to 6 deg.; this is partly due to the low E of the steel used, but it appears that it is caused chiefly by the thinness of the disks relative to their outside diameter. In other words, the distortion of the meridian plane can no longer be neglected, and the condition becomes one of thin plates rather than thick plates.

So far as the writer is aware, the theory of thin plates, in which the deflection may be of the same order of magnitude as the thickness, has never been discussed at these meetings. He would be interested to know if it was employed in the derivation of Equation [1], or whether the equation was based on the classical thick-plate theory, modified to agree with the tests. It is interesting to note that this equation is identical with the one derived for the classical theory, with the exception of the R function, which is almost one-third less in Equation [1] for all values of R_2/R_1 from 1.4 to 4.0. This is in agreement with two of the pipe-flange tests, where the thickness was only $^1/_{20}$ to $^1/_{15}$ of the outside diameter, and the dish angle at the yield point was twice as great as in the other tests.

Evidently, the thick-plate formula breaks down in the region of high R_2/t, the ring becomes more rigid than called for by the theory, and finally the load-deflection line becomes curved as the ring enters the thin-plate field and a "toggle-joint" action comes into play.

Joseph Kaye Wood.[3] This investigation, which is a result of war-time experience with Belleville springs used in French guns, deserves worthy mention not only as a valuable research work on this particular type of spring, but also as an example of procedure for the investigation of certain other types of springs. Thus the author provides the designer with a deflection formula established by experiment and with the limitations of that formula for a given standardized material, namely, SAE 6145 steel. The competence of the designer with respect to this problem is further increased by providing him with a clear picture of the stress gradient under various loadings as determined by a photoelastic analysis. Mr. Gurney's paper should likewise be commended for its general educational value, since previous to this publication very few engineers in this country knew of the Belleville type of spring as such, either theoretically or practically.

This type of spring is particularly useful in mechanisms which require the storage and release of elastic energy at a relatively large load-deflection rate. It should be of interest and value therefore to know how the Belleville spring compares with other types of springs, particularly those having relatively large load-deflection rates. In making this comparison I shall refer to "A Code of Design for Mechanical Springs"[4] in which I devised a method for determining the efficiency of any general type of spring.

This method uses a bar under pure tensile load as the basis for computing elastic efficiency, it being considered as a theoretical spring of 100 per cent efficiency. A bar under torsion as in a helical spring is about 50 per cent efficient, under uniform flexure is 25 per cent efficient, and under "cantilever" flexure it is only 8 per cent efficient. By this method any type of spring can be rated for stress efficiency provided the form of the stress gradient does not change appreciably under different loads. Since Mr. Gurney has found that the neutral plane in the stress gradient of the Belleville spring does not alter appreciably under different loads, it should be possible with the aid of Figs. 10 and 11 in Mr. Gurney's paper to estimate the general efficiency of this type of spring. I made this estimation and found it to be somewhere between 30 and 35 per cent.

Belleville springs are therefore not as efficient as helical springs, but since a given volume of material in the former may be wholly contained within a smaller space than the same volume of the latter at solid loading, somewhat higher load-deflection rates may be obtained more easily with Belleville springs. Even in the case of the ring[5] type of spring, which approaches very closely to having 100 per cent stress efficiency, it is doubtful whether its overall dimensions are less bulky than those of the Belleville spring at solid loading. The preponderance of efficiency in the ring spring in addition has a large frictional hysteresis loop superimposed on its elastic characteristic.

In computing the efficiency of the Belleville spring it was found that the lever ratio (distance of neutral plane from maximum outside fiber stress to moment arm) was relatively large, which is the reason for the high-load-deflection rate of this type of spring. This fact may be ascertained by referring to Formula [1], page 715, in the code of design previously mentioned.

As a matter of information I would like to know whether the "diameter" designations in Table 2 are correct.

A. L. Kimball.[6] There is a factor which comes into play which tends to prevent the existence of a large difference between the stress in the top and in the bottom sides of the spring, namely, the hoop tensions and compressions in the circular elements of the spring.

Such a spring depends largely for its stiffness upon these hoop tensions and compressions, bending playing only a minor part.

It would seem, therefore, that the photoelastic method should give good results, provided that the springs are relatively thin compared with their diameter.

[6] Research Engineer, General Electric Co., Schenectady, N. Y. Mem. A.S.M.E.

M. F. Sayre.[7] I have been very much interested in this paper with its description of a spring which has been in use for some time past, but which has not been well known. The Belleville spring certainly possesses very attractive features in the form of economy of space; that is, in making it possible to place a very large weight or volume of material in a relatively small space, which is often highly desirable in a spring. I should like to congratulate the author on the very careful and very valuable work which he has done.

There are some questions that I would like to ask. The first is as to the modulus of elasticity, which is given as 23,000,000 lb. per sq. in. Was that obtained from the formula or from tension tests? It seems a surprisingly small value. I have not tested any chrome vanadium steel, but I have tested a good many samples of high-chrome steel and obtained values of about 31,000,000 lb. per sq. in. as the modulus of that material. I do not remember ever having seen any figures on steel that even approached 23,000,000.

Professor Hoadley and I have been carrying on some tests on springs which are to be reported at the December meeting of the Society, and we have been very much interested in the hysteresis question. I should like to know if you have any information on the efficiency of the springs, that is, the per cent of energy returned on the release of the load.

Another question, Were these deflection curves taken on first loading or after the material had been loaded a number of times? I should expect that this would make some difference. Also, judging from the result given by Mr. DenHartog in his paper on "The Mechanics of Plate Rotors for Turbo Generators," I should expect that there would be sufficient yielding at the contact between the successive springs to affect the curve considerably. If, on release of load, the springs shifted on each other even a small distance, a different stress strain would be obtained on the next loading.

J. P. DenHartog.[8] The tests carried out on the Belleville springs are a valuable contribution and should be very useful to design engineers. Some caution has to be exercised, however, in the application of the results of the tests on celluloid models.

Fig. 12

The photoelastic method of investigating stress distributions is inherently applicable only to two-dimensional problems. However, the dished Belleville spring, loaded by forces perpendicular to its plane, certainly is a three-dimensional problem. This is especially clear in the limiting case of a spring with zero dish angle; in other words, a flat plate loaded with a uniformly distributed load along its outer and inner circular boundaries. (See Fig. 12.)

At the inside boundary there will be compression in the tangential fibers at the top of the plate and tension at the fibers at the bottom. The average stress will be zero, and a photoelastic investigation would show zero stress even when the model is nearly failing.

With dished plates these relations will not be so pronounced as with a flat plate; with a sufficient dish angle the tangential stress at the inner boundary will be compressive everywhere, but the compression at the top will always be greater than at the bottom. The photoelastic test gives the average of the two extremes, and the maximum stress will be considerably greater than this average for dish angles of the order of 10 deg.

In connection with this, Mr. Wood's calculations of the efficiency of these springs have to be used cautiously, since they are based on the photoelastic test results. Since the stresses are actually higher than found by this method, Mr. Wood's figures for the efficiency of Belleville springs are too high.

Author's Closure

It is believed that Mr. Kimball's criticisms are in general correct. However, bending may play a considerable part in thin springs.

Professor Sayre is undoubtedly correct in questioning the modulus of elasticity as 23,000,000 lb. per sq. in. The testing facilities at Rock Island Arsenal were not very good, and the Ordnance Department is not entirely satisfied with this figure. There is considerable hysteresis in a Belleville spring, and this was measured in a few cases. All tests were made after working the springs from 20 to 50 times to minimize this effect.

Answering Mr. Waters, the thin-plate theory as given by A. E. Love in chap. xxiv of his "Mathematical Theory of Elasticity" was used in deriving the deflection-load formula. However, an assumption had to be made that lines normal to the surface remain straight and normal under all loads. This is probably inaccurate and accounts in some respects for the difference between the formulas and tests. There is a large shearing action between layers of the spring as the spring flattens. The stress formula derived from this theory was not at all in agreement with the tests for this reason, and the ones given were derived entirely empirically.

Mr. DenHartog is correct, except that the photoelastic test gives the mean stress through the whole thickness of the spring and not the average between the top and bottom.

Mr. Wood's criticism compares the efficiency of the Belleville springs with other springs based on the results of the photoelastic tests. Unfortunately the data obtained from the celluloid spring tested by Professor Heymans are not conclusive because the stresses were very small. Celluloid has a modulus of elasticity in the neighborhood of one one-hundredth of that of steel, and accordingly a celluloid Belleville spring to be stressed close to the yield point would require a much steeper dish angle. In answer to Mr. Wood's question in regard to the data given in Table 2 of the original paper, these data appear to be correct.

Journal Running Positions

By H. A. S. HOWARTH,[1] PHILADELPHIA, PA.

The classic theory of bearing lubrication propounded by Reynolds and extended by Sommerfeld has shown that when a journal runs in a full bearing with a complete film, the journal center will run opposite the center of the bearing when the journal load acts directly downward against the bearing. The classic theory has, the author believes, also shown that the journal will never rise higher than opposite the bearing center, if the bearing measures 180 deg. long and if the load line bisects that angle.

Consequently the impression has gained ground that under no circumstances will the journal rise higher than the bearing center in any clearance bearing—if the classic theory is correct. The present investigation was therefore undertaken to find out whether that current impression was reasonable. A study of journal running positions was undertaken for clearance bearings whose resultant pressures do not bisect the bearing angle.

The 120-deg. bearing was chosen for the present study because it approximates the bearings widely used in steam turbines. Other angular lengths will be studied later if the results of the present study indicate that an extension of the work is desirable, much of the preliminary work already having been done.

The result of our analysis proves that the current impression is erroneous. The journal may run with its center higher than that of the bearing, if the load, speed, viscosity, clearance ratio, and α/β ratio are compatible therewith. This must be so if the classical theory is correct.

The present analysis indicates that the load direction upon a partial bearing has an amazing influence upon the running position of the journal. It also indicates that no matter how high above the bearing center the journal may run at any finite speed, it will return to run concentric with the bearing at infinite speed.

This study disclosed other interesting phenomena that are explained in the text. Side leakage was neglected. The viscosity was assumed constant. Influence of friction upon the direction of the resultant pressure was estimated. Consequently the present work is readily comparable with that of Reynolds, Sommerfeld, Harrison, and with previous work of the author.

FOR SEVERAL years past the question of the stability of the running position of the journal upon its film has been in my mind as a problem deserving further study. It has presented itself in the form of these questions: (1) Can the journal run with its center above the center of the bearing, that is, with its center above a horizontal line through the center of the bearing, assuming the direction of the load is such that the journal presses vertically downward against the bearing? (2) Is there more than one stable running position for the journal for any one combination of load, speed, viscosity, and running clearance? (3) Along what path does the axis of a journal rise from rest to its running position as its speed increases?

In order to answer these questions, we examined our previous analytical work[2] on journal bearings to see what light, if any, it would throw thereon. A 120-deg. partial bearing was chosen for study because it is so commonly used. Such a bearing is illustrated in Fig. 1. It was assumed to be provided with running clearance.

Symbols Employed

The center of the journal in every figure is at O, while that of the bearing is at O'. The symbols used in the figures and formulas are listed below. Lengths are in inches.

- a = radius of journal
- $a + \eta$ = radius of bearing when provided with running clearance
- c = eccentricity factor
- $c\eta$ = eccentricity at which journal runs in a bearing provided with running clearance
- h = film thickness at angle θ
- h_1 = film thickness at point of maximum pressure
- l = axial width of bearing
- N = r.p.m. of journal
- P = w, which see
- q = vertical lift of journal from lowest position to running position
- R = resultant pressure of journal against bearing film
- R' = resultant pressure of bearing against film
- w = $R/2a = W/2al$ = load on bearing in pounds per inch of journal diameter and per inch of axial width of bearing
- W = total load on journal (lb.) = $Rl = 2wal$
- Z = viscosity of the lubricating film in centipoises
- α = angle from leading edge of partial bearing to position of resultant pressure R measured in direction of journal rotation
- β = angular (circumferential) length of partial bearing
- ϵ = eccentricity at which journal runs in a fitted bearing
- η = radial clearance
- θ = angle to point where film thickness is h and pressure is P
- θ_1 = angle to point of maximum pressure
- μ = coefficient of viscosity (absolute), inches, pounds, seconds
- ϕ = angle from line of action of resultant pressure R to line passing through the centers of bearing and journal, measured in direction of rotation of journal.

The path of the journal center as the journal increases its speed of rotation from rest can be determined if we assume the bearing position to be fixed with respect to the load direction and if we also assume the film to be complete from end to end. Under these conditions the ratio α/β of the leading angle to the bearing arc (see Fig. 1) must be constant. Our previous work gives the data on only one such bearing, that for $\alpha/\beta = 0.5$. It is true that we studied another set of bearings called the offset series, but that series does not have a constant α/β.

This present analysis, like our previous work, has the same limitations as the work of Reynolds, Sommerfeld, and Harrison, namely, it is based upon constant viscosity, no side leakage, and neglect of the initial pressure that would be present at the leading edge of a high-speed bearing. It also neglects the influence of friction upon the direction of the resultant pressure. All conclusions drawn from this analysis are subject to these limitations. Experimental verification is needed for the purpose of obtaining correction factors.

The question at once arose as to how the data should be plotted in order to visualize fully what takes place. It appeared that

Contributed by the Special Research Committee on Lubrication and presented at the Annual Meeting, New York, N. Y., December 3 to 7, 1928, of The American Society of Mechanical Engineers.

the journal positions could profitably be plotted in a circle having as radius the radial clearance η, i.e., the difference of radius between the bearing and its journal. On such a figure concentric circles could be drawn to show the values of the eccentricity factor c from zero to 1.0, or even higher if such a running position should be found. Fig. 2 illustrates such a chart. The vertical line through the center O' of the circles represents the line of action of the bearing pressure R', whereas the journal pressure R

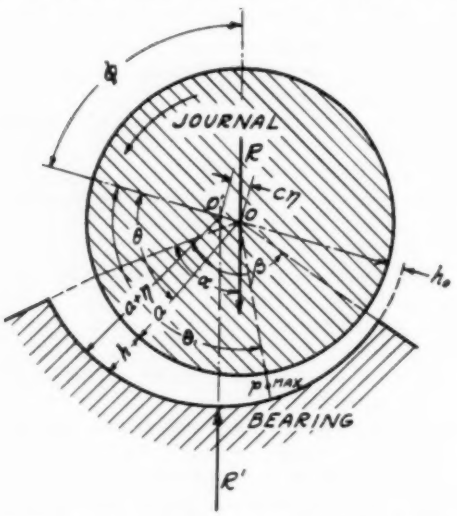

FIG. 1 SET-UP OF 120-DEG. BEARING WITH SYMBOLS USED IN TEXT

acts downward through point O against the bearing. The bearing arc is represented by GH. The running position of the journal is at some point O. If the journal runs concentric with the bearing both centers would be at O'. If metallic contact takes place the journal center would usually be somewhere on arc GDH. When the journal runs at any point O the diameter through $O'O$ makes an angle ϕ with the load line $O'D$. The angle ϕ is measured from the load line in the direction of journal rotation. The curved arrow in Fig. 2 represents the rotation of the journal. Hence the coordinates of point O on the chart Fig. 2 will be known when the eccentricity factor c and the angle ϕ are both known.

Curve B on Fig. 2 was drawn to show the path of the center of the journal for the central bearing, in which $\alpha/\beta = 0.5$. There is also drawn the curve A to show running positions for the offset series, in which α/β is a variable. Curve B therefore represents the only true path of the journal in Fig. 2.

When the journal speeds up from rest in such a 120-deg. central ($\alpha/\beta = 0.5$) partial bearing, its center presumably starts at D directly below the bearing center O'. Before the film is formed the journal will roll around inside the bearing until its center reaches some point E, determined by the coefficient of starting friction. Slip will then take place and if the acceleration is rapid a thin film will form at once. The journal center will at the same time slip over to some point near F. Its exact location has not been determined, because at this time we were more concerned with the journal path at the higher speeds.

When this slip takes place the coefficient of friction will fall off to a very low value, and there may be some oscillation of the journal across its normal position for the speed at which it is rotating. As the journal gathers speed this oscillation should cease and the journal center should rise along a path like curve B toward the bearing center O, as the oil film thickens. Our analysis indicates that at infinite speed the journal and bearing centers will coincide. This statement appears to be true if the effect of friction upon the direction of the resultant pressure be neglected. We have not yet completed our study of the influence

of friction upon the resultant pressure direction, and therefore cannot yet say definitely whether concentricity is the ultimate position when friction is taken into account. (See p. 9, however.)

Bearings are not all of the central type discussed above. Hence it is desirable to obtain data on the path of the journal for values of α/β other than 0.5. The inadequacy of our available data became evident when it was plotted on a chart like Fig. 3 whose coordinates are w/N and ϕ. Upon this chart we built up curves for constant θ_1, constant eccentricity factor c, and constant α/β, as far as they could be drawn from data underlying the "Graphical Study of Journal Lubrication,"[2] published in 1923, 1924, and 1925. Upon such a chart we could also show the influence of friction upon the position of the resultant pressure with respect to the bearing, if such data were available. The curves in Fig. 3 were so few, so uncertain, and so limited as to be obviously inadequate for the purpose of the present study.

In order to get the additional data required, it was necessary to go back to Harrison's fundamental Equation [20] (see "A Graphical Analysis of Journal Bearing Lubrication"[3]) and to plot curves like Figs. 38 and 39 of that analysis, for a wide range of values of c and θ_1. This necessitated an immense amount of careful graphical and tabulating work, extending over a period of nearly a year. This work was done by S. J. Needs, who aided the author so materially with similar work in the preparation of Parts II and III of "A Graphical Study of Journal Lubrication."[2] Up to the present time we have investigated the field covered by Fig. 4. This extends from the upper line marked "Beginning of Negative Pressure at Trailing End" to the lower line marked "Beginning of Negative Pressures at Leading End." Between these limits the film pressures are always positive. How far Fig. 3 fell short of our present needs is seen by comparing it with Fig. 4, on which we have plotted all the important data thus far obtained.

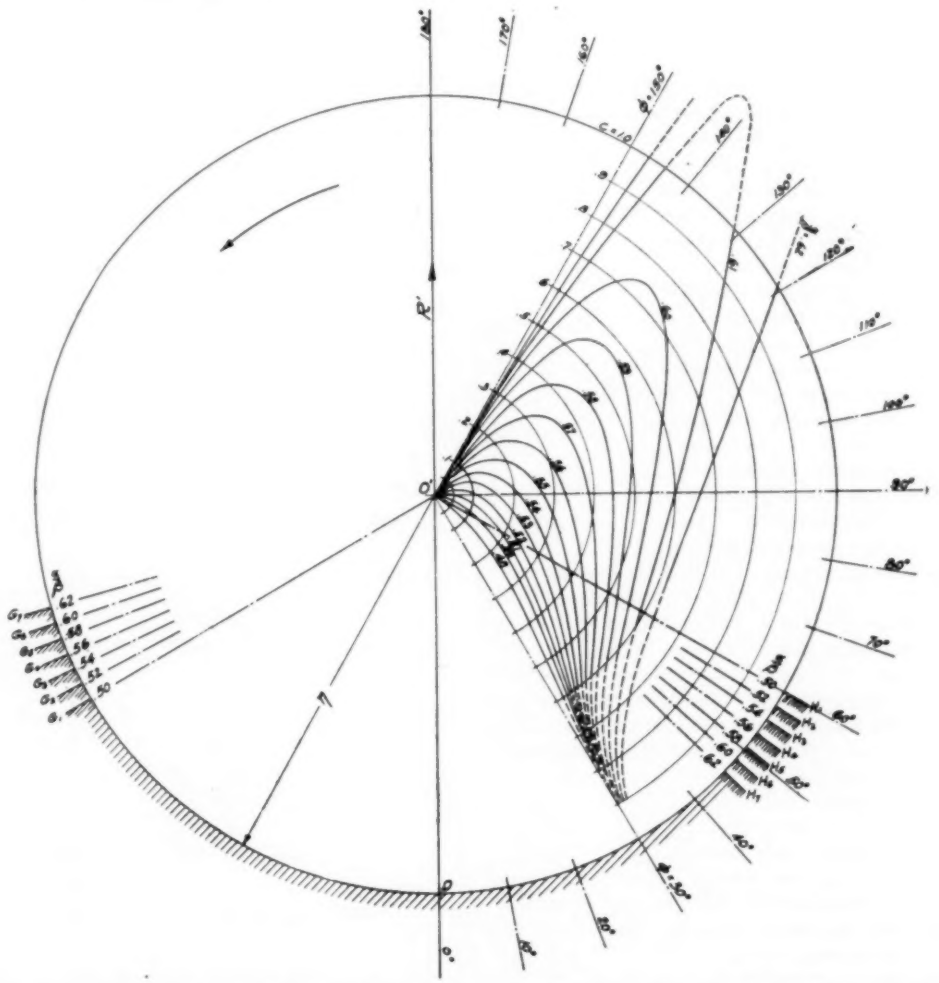

FIG. 5 CLEARANCE CIRCLE SHOWING JOURNAL RUNNING POSITION LOCI FOR DIFFERENT LEADING-ANGLE RATIOS FOR 120-DEG. BEARING

On Fig. 4 there are constant α/β lines for values ranging from below 0.50 to above 0.60. There are also constant maximum-pressure lines ranging from $\theta_1 = 50$ deg. to $\theta_1 = 140$ deg. The constant eccentricity factor lines vary from $c = 0.05$ to $c = 1.0$. In Fig. 4 therefore a much larger field of bearing running conditions is shown than has heretofore been available.

For convenience in working with Fig. 4 there are four horizontal scales. One for $(P/ZN)(\eta/a)^2$ is placed at the top. Just below it there is a scale for $(w/\mu N)(\eta/a)^2$. At the bottom there are two scales for w/N alone, assuming $\mu = 3.4 \times 10^{-6}$. The lower one covers bearings in which $\eta/a = 0.001$, while the upper of the two covers those in which $\eta/a = 0.002$.

From Fig. 4 and an intermediate Fig. 4*a* it is now a simple matter to plot Fig. 5 which, similar to Fig. 2, shows the path of

[3] This pamphlet, published by the Society in 1926, combines parts I, II, and III of the "Graphical Study of Journal Lubrication" in a form better suited for convenient reference.

the journal center within a circle whose radius is η. Fig. 5 can be interpreted in connection with Figs. 4 and 4*a*, and vice versa, referring both to Fig. 1. The dotted portions of the curves on Fig. 5 have not yet been fully verified. They show, however, the general character of the journal paths.

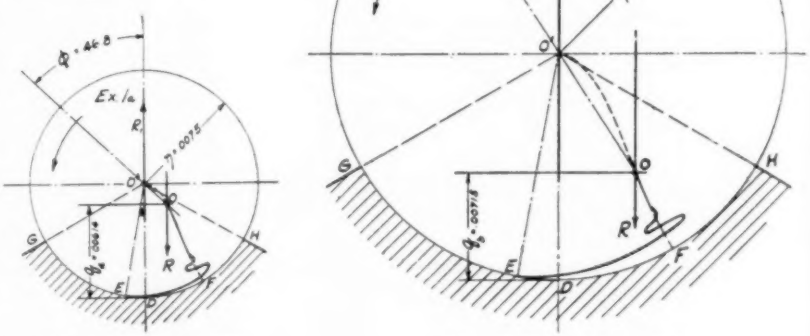
On the lower half of the circle whose radius is η we have marked at the left with G_1 to G_7 the leading edges of the bearing for different values of α/β. At the right the corresponding trailing edges are marked H_1 to H_7. The angular length of each bearing is 120 deg. Hence it is possible to visualize the position of the bearing with respect to the load line for each proportion being examined.

Practical Applications

The above analysis of the 120-deg. clearance bearing has given us Figs. 4, 4*a*, and 5 for use in seeking practical application of the results. There may be added to this material such data on the 120-deg. and other fitted bearings as are contained in Fig. 14 of "A Graphical Analysis of Journal Bearing Lubrication."[3] This figure is reproduced herein with same number for convenience.

The direction of the load against a bearing is usually known in the case of important machinery, such as horizontal steam turbo-generators. In these the load is vertical, if we assume perfect mechanical and electrical balance. With geared or belted machinery the bearing-load direction is not so obvious. In the case of motor drives through belts, chains, or gears, the load direction cannot be predicted by the motor manufacturer. Therefore, no matter what the bearing maker may expect, it is quite possible in some cases that the bearing will be called upon to take its load in an unexpected direction. These facts make it necessary to examine the unfavorable as well as the favorable running conditions.

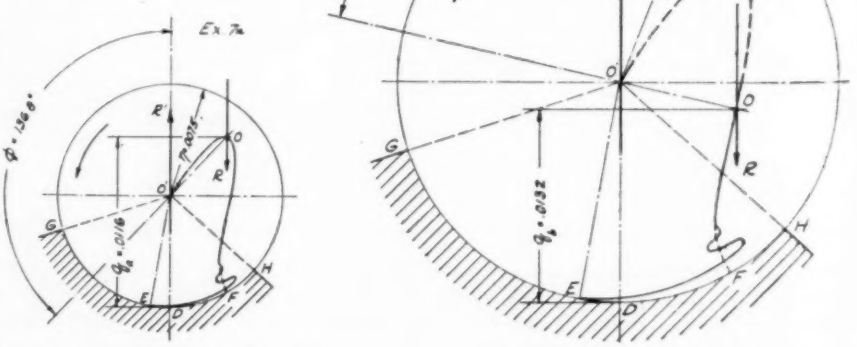
The running position of a journal with relation to its bearing will depend upon the bearing design, its load, the viscosity of the oil, and the speed. Under "bearing design" we must consider (*a*) whether it is full or partial; (*b*) the position of the bearing surface with respect to the load line; (*c*) the running clearance provided on the working bearing face; (*d*) the clearance, shape, and position of the bearing cap; and (*e*) the method of applying the lubricant. The following bearings will be studied in the examples discussed below:



(1) 120-deg. fitted bearing, (*a*) without cap; (*b*) with caps of various designs.

(2) 120-deg. clearance bearing, (*a*) without cap; (*b*) with caps of various designs.

Example 1. A turbine journal, 15 in. in diameter and 30 in. long, exerting a vertical load of 67,500 lb., runs at 1500 r.p.m. in a 120-deg. clearance bearing, central type ($\alpha/\beta = 0.5$), *without a cap*. What will be the running position on a light oil (S.U.V. = 150 sec. at 100 deg. fahr.) whose operating temperature is 130 deg. fahr., assuming (*a*) the clearance ratio $\eta/a = 0.001$, and (*b*) the clearance ratio $\eta/a = 0.002$?



Example 2. Same as 1, except that load is 33,750 lb.

Example 3. Same as 1 except that a medium oil is used, S.U.V. = 300 sec. at 100 deg. fahr.

$\alpha/\beta = 0.50$; $\eta/a = 0.0001$ $\alpha/\beta = 0.50$; $\eta/a = 0.002$

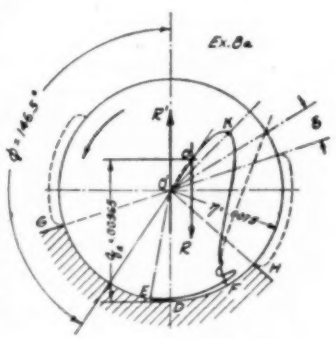
Example 4. Same as 2 except that a medium oil is used, S.U.V. = 300 sec. at 100 deg. fahr.
Example 5. Same as 1, except $\alpha/\beta = 0.60$
Example 6. Same as 2, except $\alpha/\beta = 0.60$
Example 7. Same as 3, except $\alpha/\beta = 0.60$
Example 8. Same as 4, except $\alpha/\beta = 0.60$

Solution of Example 1.



$$w_1 = \frac{67{,}500}{15 \times 30} = 150 \qquad \frac{w_1}{N_1} = \frac{150}{1500} = 0.1$$

The oil viscosity at operating temperature (130 deg. fahr.) will be approximately 85 S.U.V. ($\mu_1 = 1.87 \times 10^{-6}$). Since the scale of chart Fig. 4 is based on a viscosity of 3.4×10^{-6} we must enter it with $w/N = 3.4 \times 0.1/1.87 = 0.182$. Hence from Fig. 4 we find (for $\eta/a = 0.001$) that $\phi = 46.8$, $c = 0.266$, and $\theta_1 = 134.6$. If $\eta/a = 0.002$ we find that $\phi = 32.6$, $c = 0.62$, and $\theta_1 = 153.5$. Therefore the two running positions will be as indicated in Figs. 6 and 7, by points O. The lifts vertically from rest position D would be $q = \eta(1 - c\cos\phi)$. Lift (a) will then be $q_a = 0.00614$ (see Fig. 6); $q_b = 0.00715$ (see Fig. 7).

Solution of Example 7.

15 in. × 30 in. journal, $\alpha/\beta = 0.6$, $w_1/N_1 = 0.1$, S.U.V. = 300 at 100 deg. fahr., S.U.V. at 130 deg. fahr. will be 150 sec. = 3.4×10^{-6}. Enter Fig. 4 with $w/N = 0.1$ and find that $\phi = 136.8$, $\theta_1 = 57.5$ deg., and $c = 0.75$ or greater. Enter with $w/N = 0.1$ when $\eta/a = 0.002$ and get $\phi = 77$ deg., $\theta_1 = 118$ deg., $c = 0.54$. The lifts will be as follows:

$$q_a = 0.001 \times 7.5 \times (0.75 \times 0.731 + 1) = 0.0116$$
$$q_b = 0.002 \times 7.5\,(1 - 0.54 \times 0.225) = 0.0132$$

$a/\beta = 0.60$; $\eta/a = 0.001$

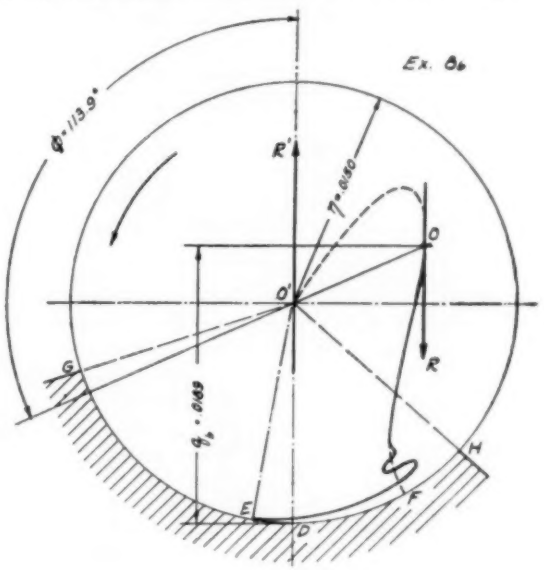


Fig. 11

FIGS. 10 AND 11 PLOTS OF JOURNAL RUNNING POSITION FOR EXAMPLE 8

Solution of Example 8.

This will have maximum lift because of the lighter load and higher viscosity. 15 in. × 30 in. journal, $\alpha/\beta = 0.6$, $w/N_1 = 0.05$, S.U.V. at 100 deg. fahr. = 300 sec., S.U.V. at 130 deg. fahr. = 150 sec., $\mu_1 = 3.4 \times 10^{-6} = \mu$. Entering Fig. 4 with $w/N = 0.05$ we find that $\phi = 146.5$, $c = 0.34$, $\theta_1 = 43$ deg., for $\eta/a = 0.001$; while for $\eta/a = 0.002$ we find $\phi = 113.9$ deg., $c = 0.64$, $\theta_1 = 82.2$ deg.

$$q_a = 1 - (-284) = 1.284 \times 0.0075 = 0.00965$$
$$q_b = 1 - (-261) = 1.261 \times 0.015 = 0.0189$$

But in getting to $q_a = 0.00965$ the journal has to pass over a point whose lift is about 0.0116.

When examining the tabulated data and results for examples 1 to 8, it must be remembered that certain data are the same throughout, for example, journal diameter = 15 in. × 30 in.; speed = 1500 r.p.m.; operating temperature = 130 deg. fahr.; and the bearing has no cap.

The above eight examples refer to bearings without caps or those whose caps are provided with extra clearance so that no appreciable interference may be expected from them.

When the running clearance of the bearing is $\eta/a = 0.001$ the radial clearance will be 0.0075. Hence "over center" running would occur in examples 5*a*, 6*a*, 7*a* (see Fig. 8) and 8*a*, whereas practically "opposite center" running would occur for examples 2*a*, 3*a*, and 4*a*. For the larger clearance ($\eta/a = 0.002$) over center running occurs only for example 8*b*, whereas practically "opposite center" running occurs for example 4*b*, 6*b*, and 7*b* (see Fig. 9).

Comparing only the *lifts*, we find in example 1 about the same lift for both clearances, as will be clear from Figs. 6 and 7. This is also approximately true for examples 5, 6, and 7.

Hence for a given bearing the lift will be increased if the load is reduced, or the oil viscosity increased, except in cases where the running position O lies on the curve at the left of the point of maximum lift (see Fig. 5) as it does for example 8*a* (see Fig. 10).

Clearance Bearings With Caps

Bearing-cap construction and position both play an important part in the operation of the journal. The cap clearance should be partly determined by the method of applying oil to the bearing. The cap may exert pressures upon the journal that will partly determine its running position. Three distinct types of caps will be considered.

Cap *A*. The surface of this cap is concentric with the bearing.

Cap *B*. The surface of this cap is concentric with running position of the journal.

Cap *C*. The surface of this cap is offset and not concentric with either the bearing or journal.

We shall examine these three types of caps with reference to a 120-deg. partial bearing for which $\alpha/\beta = 0.6$ and whose running clearance is $\eta/a = 0.001$. We shall assume that the cap is also 120 deg. long and that the oil channels at the sides are each 60 deg. long.

Cap *A*. This problem is illustrated by Fig. 12. The load, speed, and viscosity are assumed to be such that the journal would run at O if there were no cap. If a cap is then placed in position, and it has the same radius as the bearing, pressures would be set up in the cap film. Their net effect would be to draw the journal toward the cap provided the natural negative pressures in the film are not impossibly high. Presumably the negative pressures could not exceed 14.7 lb. per sq. in. If not, the film under the cap would break when that negative value was reached, and then the positive pressures under the cap might dominate, thereby opposing closer approach of the journal. Obviously this needs experimental verification.

Cap *B*. This problem is illustrated by Fig. 13. The natural running position of the journal is assumed to be at O if no cap is used. In this case if a cap is added and so set that its center

is also at O, no pressures would be set up in the cap film if the cap radius exceeded that of the journal.

Cap C. This problem is illustrated by Fig. 15. Obviously if it is desirable to reduce the natural lift of the journal a cap could be so placed as to generate only positive pressures that would oppose the normal lift. Fig. 15 is therefore made by shifting the cap sideways to some position such that with zero load the journal would run halfway between the bearing and cap. To better illustrate this case we shall solve the following problem.

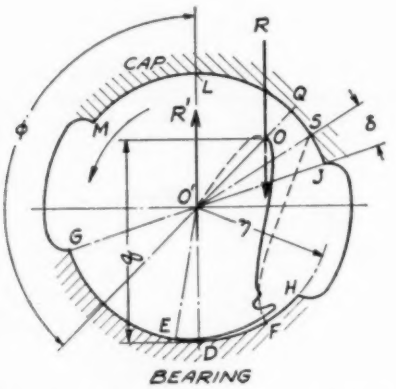

FIG. 12 CLEARANCE-CIRCLE REPRESENTATION OF 120-DEG. BEARING AND CAP, CONCENTRIC AND WITH SAME RADIUS

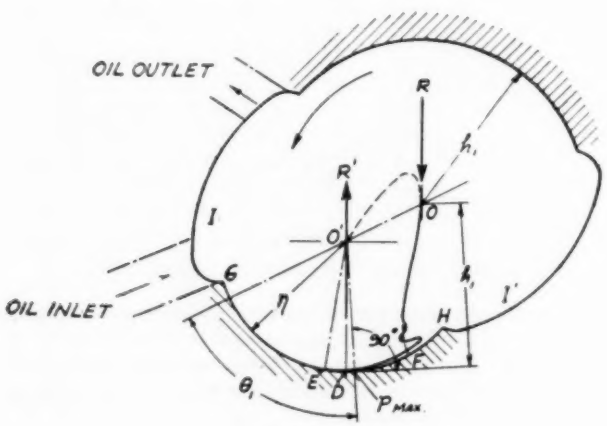

Fig. 13 Cap B

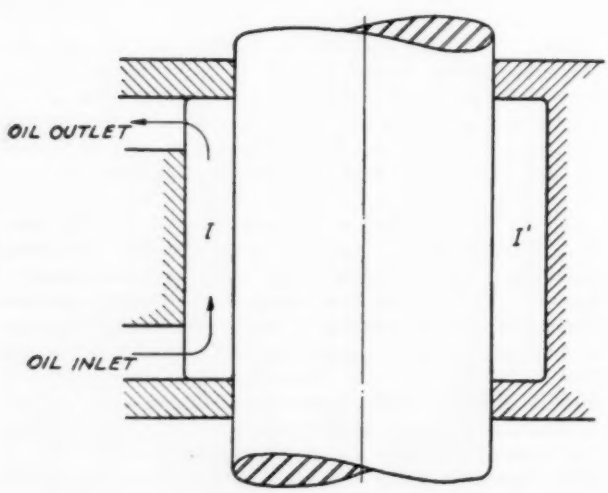

Fig. 13a

FIGS. 13 AND 13a CLEARANCE-CIRCLE REPRESENTATION OF 120-½DEG. BEARING WITH CAP SET OVER TO BE CONCENTRIC WITH RUNNING POSITION OF JOURNAL

Example 9.

How far to the right should the cap be shifted in order that its downward pressure will so balance the lifting force of the bearing film that the journal will never rise above the horizontal line $O_B'O_C'$ through the bearing center? Example data are the same as in example 8, except that $\alpha/\beta = 0.62$ and $\eta/a = 0.001$. In Fig. 15 the cap has been assumed to be as effective as the bearing; and the journal path with respect to it, if the load were upward, has been shifted with the cap toward the right until it coincides approximately with the path of the journal with respect to the bearing. The w/N values were marked on both curves and then projected horizontally to scale from a vertical line PQ. The lower half of the line representing w/N for the bearing is ST, and that representing w/N for the cap is TV. They cross at T on the line of centers $O_B'O_C'$. The horizontal distances between lines TV and ST show net upward capacities (w/N) of this bearing-cap combination for different lifts of the journal. The lift is measured from the horizontal line through D on which the w/N scale is laid off for curves ST and VT.

For a net value of $w/N = 0.2$ the lift of the journal in this shifted cap bearing will be only to point O_2 which gives $q_2 = 0.0065$ as compared with $q_1 = 0.0105$ when the cap was not shifted and the journal ran at O_1.

The side shifts of the cap to bring about this increased stability of the journal would be $S = 0.0093$.

FITTED BEARINGS WITH AND WITHOUT CAPS

When consideration is given to the *fitted bearing* without a cap, it is found that α/β cannot be less than $77.4/120 = 0.645$. In fact the only data we have on fitted partial bearings cover this case. The running clearance is zero in a fitted bearing. Hence the circle of radius η used heretofore would become a point. Fig. 16 represents a fitted 120-deg. partial bearing. Line $O'O$ represents the path of the journal center. Just where the journal center will lie for a given set of data can be found from chart, Fig. 14.

Example 10.

Taking the same data as for example 7, but with $\eta/a = 0$ and $\alpha/\beta = 0.645$, we have $w_1/N_1 = 0.1 = w/N$. Hence $\epsilon/a = 0.0031$. $\epsilon = 7.5 \times 0.0031 = 0.0232$. The lift will be $q = \epsilon\cos(180 - \phi)$ which for this case becomes $0.0232 \times 0.85 = 0.0197$. This lift is much more than we had in example 7, e.g., 0.0116

TABLE 2 COMPARISON OF CHARACTERISTICS OF 120-DEG. BEARINGS WITH AND WITHOUT THE INFLUENCE OF FRICTION THEREON

		Without friction	With friction
Partial bearing	ϕ	65.7°	65.357°
$c = 0.095$	α	60°	60.343°
$\beta = 120$ deg.	α/β	0.50	0.5029
	w/N	0.0602	0.06049
Partial bearing	ϕ	51.5°	51.313°
$c = 0.2$	α	60°	60.187°
$\beta = 120$ deg.	α/β	0.50	0.5016
	w/N	0.1272	0.127013
Partial bearing	ϕ	77.80°	77.64°
$c = 0.2$	α	63.70°	63.86°
$\beta = 120$ deg.	α/β	0.5308	0.5322
	w/N	0.140	0.14007
Partial bearing	ϕ	84.0°	83.68°
$c = 0.1$	α	61.8°	62.12°
$\beta = 120$ deg.	α/β	0.5150	0.5177
	w/N	0.0692	0.06924
Partial bearing	ϕ	139.28°	138.906°
$\beta = 120$ deg.	α	68.72°	69.094°
$c = 0.2$	α/β	0.5727	0.5758
$\theta_1 = 50$ deg.	w/N	0.0531	0.053213

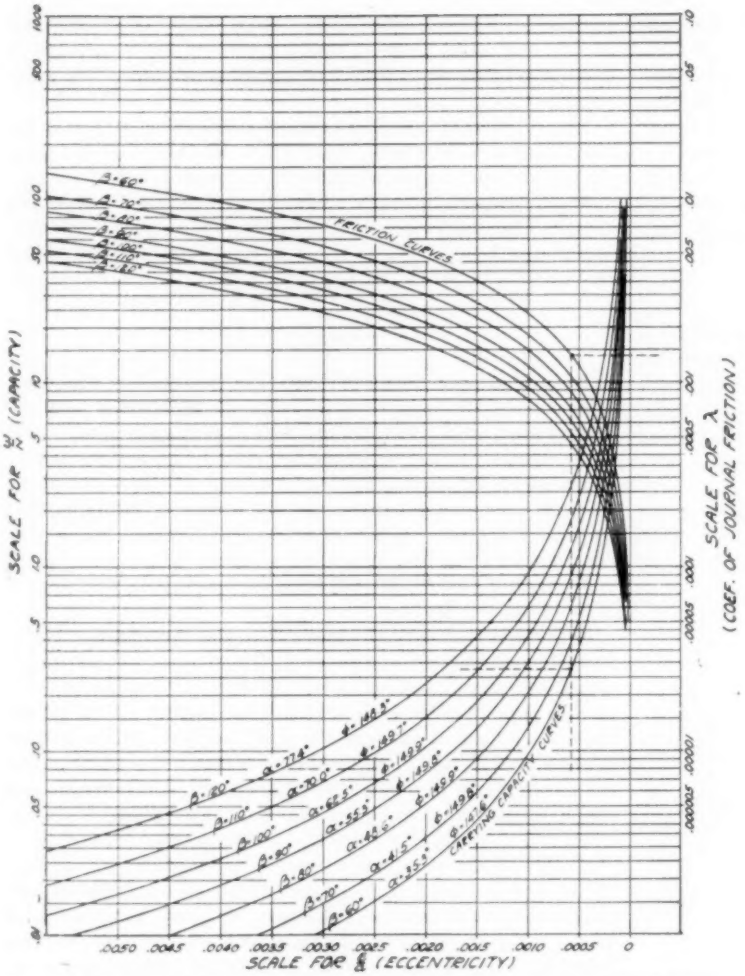

FIG. 14 CHARACTERISTICS OF FITTED PARTIAL BEARINGS OF MINIMUM FRICTION $\mu = 3.4 \times 10^{-6}$

and 0.0132. If, however, the curves for the clearance bearings were extended to a value of $\alpha/\beta = 0.645$, it is quite likely that the lift for such a case would not be far different than for the fitted bearing.

It is very evident that the cap of a fitted 120-deg. bearing, if of types *A* or *B*, would have to be bored with large clearance so as not to interfere with the natural running position of the journal. Otherwise instability might result. It is obvious also that the cap might be made of type *C* so as to reduce the journal lift to a desired minimum.

OIL SUPPLY FOR CAPPED BEARINGS

Assuming the bearing to have a cap of type *B*, let us examine the available locations of oil inlet and outlet for the bearing. Since we know the running position of the journal, the place where the pressure is maximum, and the film thickness there, we can estimate the volume of oil passing through the working film. We must be able to supply this amount at the leading end of the bearing and to get rid of it at the trailing end. For a bearing like Figs. 13 and 13*a*, the cap clearance should equal or exceed the film thickness at the point of maximum pressure, if the oil passing through the film is to return to the starting point without setting up a pressure in channel *Z*. Any increase in the cap clearance will reduce the friction. Any decrease in cap clearance would increase the friction and at the same time set up pressure in channel *Z* that would disturb the running position and require a new estimate thereof.

If the channel at *Z* were connected with the discharge line and the inlet were left at *I*, the cap clearance would have no material influence upon the journal position. If the inlet were at *Z* and the outlet at *I*, all the oil for the film would have to pass through the cap clearance before it reached the bearing. Then after passing through the film it would have to pass under the cap again before being discharged. In that event the cap clearance would have to be twice the film thickness at point of minimum pressure. The discharge opening would preferably be restricted.

If the inlet were at one end of *Z* and the outlet at the other end, the cap clearance would only need to be equal to the film thickness at point of maximum pressure, to avoid disturbing the assumed equilibrium.

EFFECT OF FRICTION ON RESULTANT PRESSURE DIRECTION

The influence of friction on the position and value of the resultant pressure upon the bearing for a given film has been studied for a few critical positions, with the results set forth in Table 2.

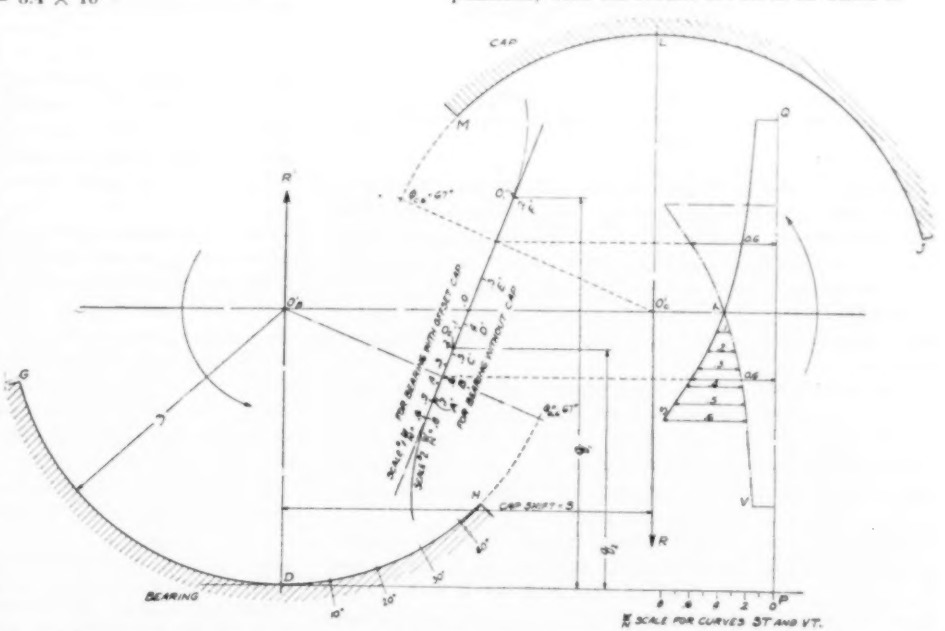

FIG. 15 CLEARANCE-CIRCLE REPRESENTATION OF CHARACTERISTICS OF BEARING WITH ITS CAP SET OVER SO AS TO PRODUCE COUNTER PRESSURES THAT WILL REDUCE THE JOURNAL LIFT IN A 120-DEG. BEARING

These points corrected for friction are shown in Fig. 4 by x's connected by small dotted lines with the uncorrected points. It is interesting to note that the positions of the x's vary but little from the points previously placed upon Fig. 4. The influence of friction upon the α/β lines is more pronounced, however. We have therefore drawn, with reference to these x-points, corrected curves for α/β. These calculations prove that we were justified in neglecting the influence of friction upon resultant position throughout the range of the present investigation.

Conclusion

Having applied these new charts to the solution of several hypothetical problems, one will realize that it is a serious handicap to have charts only for the 120-deg. bearing. We shall therefore endeavor to have this analytical work extended to include bearings with different angular lengths. The amount of labor required for this extension will be much less per bearing than for the first one covered by this paper, because much of the preliminary work has now been done.

The present paper indicates that the journal lift, under adverse conditions, may be much greater than generally expected. This

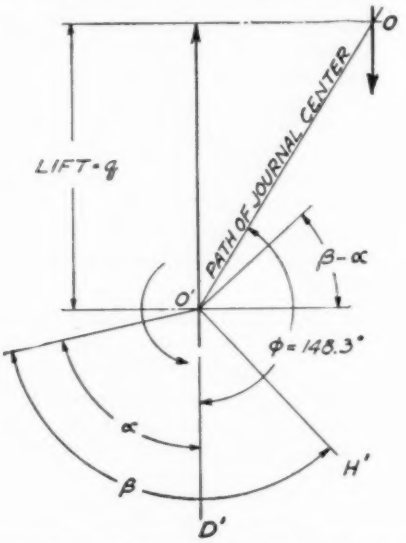

Fig. 16 Path of Journal Center, as Speed Increases in a Fitted Partial Bearing of Series Whose Characteristics Are Given in Fig. 14

may result in rubbing against the cap. The design of the bearing cap therefore becomes important. The methods of providing and removing the lubricant are dependent upon the cap design. The cap may be fixed in an offset position so as to maintain a pressure film that will reduce the journal lift. Such a cap would be suitable for one direction of rotation. If made so as to adjust itself automatically it would be suitable for either direction of rotation.

The journal lift will not be serious if the oil is not heavy for the *load-speed-clearance* combination employed. In other words a bearing that is too lightly loaded for the *oil-speed-clearance* combination may give trouble by rubbing against the cap. Again, if the speed is too high for the *oil-load-clearance* combination, similar rubbing may take place.

High-speed bearings will require further study to take into account the initial pressure at the leading end of the bearing. In general it may be expected that high-speed bearings will have journal lifts that correspond with longer bearings of greater α/β value. Hence when a journal runs in a 120-deg. central bearing at high speed its lift will follow more nearly one of the paths for $\alpha/\beta > 0.5$. The greater the speed the higher the value of the equivalent α/β. These predictions are suggestive of what is to be expected from studies taking account of the initial pressure.

The side-leakage effect in journal bearings[4] is still open for rigorous analytical investigation, as is also the influence of viscosity decrease as oil passes through the bearing film.

Much experimental work is under way from which useful factors for designing engineers may result. Important in this class is the work being done by the U. S. Bureau of Standards under the direction of M. D. Hersey.

Discussion

E. O. Waters.[5] The author has pictured in very commendable manner the history of a journal in its bearing from the instant that motion commences until it gets up to speed. The polar diagram certainly brings out clearly the various journal positions for different speeds and loadings, and shows to what a surprising extent the journal may rise when the bearing is offset only a few degrees. It is to be hoped that the study will be continued for partial bearings of other angular lengths, as there is certainly a wide field of application for bearings in the range of β = 160 to 180 deg.

A problem that naturally arises from this investigation is that of the restraining effect of caps. It would seem that the author could well afford to elaborate on this at much more length than he has permitted himself in the present paper. He cites three cases only (caps A, B, and C), and leaves the writer with the impression that the first of these may or may not be stable at low w/N values; the second is somewhat neutral, and to resume real stable running it is desirable to offset the cap a distance equal to twice the horizontal eccentricity of the journal. Needless to say, this would be a very sensitive and difficult adjustment. Actually, however, a much smaller offset would serve just as well. Take the case of cap B as an example. Suppose that the journal is running at O and that there is a small film of uniform thickness between it and the cap. Then, if the speed is increased or the load decreased, it will tend to rise and crush this film. As soon as this occurs and there is actual pressure on the cap, the journal and cap will act as an inverted bearing and the journal center will take up some position in the region between O and O' such that the algebraic sum of the pressures produced in the lower and upper films will equal the external load. At an infinite speed, the journal center would be exactly midway between O and O'. Such being the case, it would seem that the amount of offset for the cap would not be such a sensitive adjustment after all.

The writer regrets that he has not had sufficient time to work out a sample problem to illustrate his point. Briefly outlined, one method of procedure would be to assume the amount of cap offset for a given-sized bearing; then assume arbitrarily a location for the journal center relative to the bearing center, leading edge, and trailing edge. This would also define the journal position relative to the cap center, leading edge, and trailing edge. With these data, previous formulations and charts could be used to determine the magnitude of the carrying capacity and w/N direction of the resultant film pressure between the journal and bearing and the journal and cap; and the vector sum of these carrying capacities would determine the net carrying capacity

[4] A. G. M. Michell's study of side leakage for inclined flat surfaces with rectilinear motion is the only sound analysis at present available. It indicates what may be expected for curved surfaces in short arc partial bearings. See "The Lubrication of Plane Surfaces," by A. G. M. Michell, Melbourne, *Zeitschrift für Mathematik und Physik*.

[5] Assistant Professor of Mechanical Engineering, Yale University, New Haven, Conn. Assoc-Mem. A.S.M.E.

of the capped bearing. By repeating the process for several locations of O, data would be obtained for plotting contour lines of carrying capacity for any given direction of external load.

GEORGE B. KARELITZ.[6] The paper gives a very interesting analytical study of the motion of a shaft in the bearing shell. It would be of importance to arrange for experimental verification of the results obtained. Some measurements of journal positions are on record, and a number of people will probably be engaged in the future in such investigations. A few of the methods of measurement will be mentioned. V. Vieweg (Germany) used a beam of light just skimming the journal. This allowed microscopic measurement of the journal motion; a photographic record was taken on a moving film (*Petroleum Zeit.*, vol. 18, 1922, p. 1405). He found vibrations of the journal during the first moments of rotation, as described by the author. Ch. Hummel (Germany) attached a pivoted mirror to the end of a journal and studied the motion of the shaft by observing the deflection of a beam of light from the mirror (*Forschungsarbeiten*, No. 287, V.D.I., Berlin, 1926). Mr. Schering (Germany) measured the thickness of the oil film by the variation in capacity of the condenser formed by the bearing and journal (*Instrumentenkunde*, June, 1927, p. 286). In our company we made accurate tests in

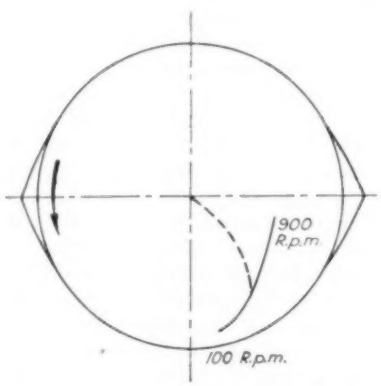

FIG. 17 POSITIONS OF JOURNAL FOR SPEEDS FROM 100 TO 900 R.P.M.

connection with a study of oil-film vibration; the work was done by Mr. M. Stone of our Power Engineering Department. A disk was attached to the shaft of a 9-in. bearing outside the bearing housing. The disk was ground concentric with the journal. Four small electromagnets were placed around the disk, two on the horizontal and two on the vertical diameters, with a very narrow clearance between their armatures and the disk. Motion of the shaft caused electromotive forces in the coils which were recorded by an oscillograph. Proper interpretation of the oscillograms gave a complete picture of the journal movement in the bearing clearance.

Using the clearance circle proposed in the paper, the positions of the journal were found for various speeds from 100 to 900 r.p.m., as approximately shown in Fig. 17. The center of the journal did not approach the center of the bearing, as should be the case for a central-portion bearing. This was caused, no doubt, by an oil pressure on the down side of the journal, as mentioned in the paper, which moved the journal over to the right.

In his investigations Mr. Howarth assumes that there is a positive pressure all over the bearing surface. The writer in his analysis ("Charts for Studying Oil Films in Bearings," Trans. A.S.M.E., 1925) assumed that the pressure is zero at the point of nearest approach, the pressure being also zero in the divergent part of the oil film. This was done on basis of observations on large turbo-generator bearings which are machined with utmost care and accuracy. Invariably from 2 to 6 in. of vacuum is found in the divergent part of the bearing surface; this vacuum is negligible when compared with the pressures existing in the load-carrying oil film, justifying the assumption of zero pressure. Comparing the data in Fig. 4 of the paper and in the diagram Fig. 5 of the above-mentioned "Charts," the values of $(w/\mu N)(\eta/a)^2$ for a 120-deg. bearing are:

Eccentricity c	0.1	0.2	0.3	0.4	0.5	0.6
Value from the paper	0.019	0.038	0.061	0.093	0.132	0.196
Value from the "Charts"	0.019	0.039	0.063	0.091	0.123	0.172

Taking into consideration the inaccuracies of the graphical computations employed, we can say that up to $c = 0.4$ the data coincide, while at higher values of c, i.e., for heavier loads, the carrying capacity of the bearing appears to be less than is represented in Fig. 4 of the paper. It would be very valuable to have reliable experimental work done on this question.

It is interesting to note from Figs. 6 and 7 that an increase of the clearance, all other conditions being equal, affects but little the thickness of the oil film at the point of nearest approach. This appears to be true for all partial bearings of ordinary design.

A. G. M. MICHELL.[7] The writer hopes that the author will extend his investigations to bearings of smaller angular lengths. In the bearing of 120 deg., treated in detail in the paper, there may be considerable portions of the oil film diverging in the direction of relative motion, and such a condition is usually inadmissible in bearings of finite width.

The author's discussion of the possible variations of the position assumed by the journal relatively to the bearing is paralleled to a certain extent in R. O. Boswall's recently published work, "The Theory of Film Lubrication." The criterion for determining the stability of the journal in one or other of such positions does not appear, however, to have been satisfactorily established. The fact brought out by the author that the center of the journal may rise above the center of the bearing surface is not to be regarded as paradoxical. Such a condition necessarily occurs in "pivoted" journal bearings, in which the curvature of the bearing surfaces is made the same as that of the shaft, and the same effect is to be expected, under certain conditions, in bearings formed with a clearance.

M. D. HERSEY.[8] An investigation has recently been completed by R. Wolff in the laboratories of the German Government Railways at Göttingen, in which the optical-interference method was used for measuring displacements of the bearing relative to the journal. This method is extraordinarily sensitive.

The conclusion reached was that the laws of fluid-film lubrication would not fully account for the observed results and that the oiliness of the lubricant must be considered as a rather large factor. It will be interesting, when we can get the details of these experiments, to compare them with Mr. Howarth's curves and results.

To my mind the significance of this German work is the interest that it gives once more to the experimental study of oiliness. We are indebted to Mr. Kingsbury for calling the attention of the profession to the importance of oiliness in a paper presented before the Society in 1902. The Special Research Committee on Lubrication has had on its program, since its organiza-

[6] Research Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Assoc-Mem. A.S.M.E.

tion in 1915, the attempt to study oiliness as thoroughly as the viscous-film effects analyzed by Mr. Howarth.

A. E. Flowers.[9] I want to express heartfelt appreciation for the worth-while theoretical study of lubricated bearings that the author has been conducting. It is particularly important, it seems to me, that it should have been carried out as it has as a theoretical study, because that puts it at once in a form such that designers can make use of it.

Attention should again be called to the research program of the Lubrication Committee and to the fund it is proposed to raise for these research studies. It is hoped that the sum of approximately $25,000 may be raised in the near future in order to conserve the results, the equipment, and the personnel that are now available for actively prosecuting these studies, and particularly for prosecuting the highly important studies upon the unknown or x-factor of lubrication, called unknown simply because, although we know it is present, we do not know to what it may be due or how it may be controlled.

I think there is no other single project now before our Society or the profession of greater importance or more worth while than the study of the lubrication conditions, and particularly this so-called unknown factor.

Author's Closure

It is certainly gratifying that this paper has provoked so much discussion by such competent persons. It is very interesting indeed to know what Mr. Michell, Mr. Hersey, and Mr. Karelitz have pointed out, that so many investigators are studying experimentally the running position of the shaft in a journal bearing, and it is hoped that these experimenters will be able to show exactly how much the true paths of the journal axis deviate from the theoretical ones shown in the paper.

Mr. Karelitz has plotted a curve representing results of experiments made by him in the Westinghouse Research Laboratory. It is to be hoped that he will continue these experiments and present a paper to the Society giving all the data necessary for a complete understanding of the results obtained. When he compares values obtained from my Fig. 4 with the Fig. 5 taken from his charts,[10] he should state that there is only one point on my Fig. 4 that represents a bearing agreeing with the series covered by his charts. The bearings covered by my curves are assumed to have complete films. Those illustrated by my Fig. 4 are all assumed to have positive pressures in the films. A curve can be drawn on my Fig. 4 representing a series of bearings in which $\phi = \beta - \alpha$. This curve, about straight, would pass approximately through the point where $\phi = 60$ deg. on the curve for $\alpha/\beta = 0.5$, and the point for $\phi = 50$ deg. on the curve for $\alpha/\beta = 0.58$. Bearings of this series would have the ϕ-line, which passes through the journal and bearing centers, coinciding with the trailing end of the bearing. This new curve would represent a series of 120-deg. bearings with complete films, no portions being discarded as ineffective. It would cut the various α/β curves and would have one intersection with each. It would cut the curve for $\alpha/\beta = 0.5$ where $\phi = 60$ deg. and where the eccentricity factor $c = 0.12$. For this point on Fig. 4 the value of $(w/\mu N)(\eta/a)^2$ is about 0.023. Hence in the series of comparisons made by Mr. Karelitz, between his work and mine, one would expect agreement at that point only. This is confirmed by the fact that he shows agreement when the eccentricity factor $c = 0.1$.

For all values of c, other than $c = 0.12$, Mr. Karelitz has made his comparisons with the series represented by my curve $\alpha/\beta = 0.5$, which assumes the oil film to be complete throughout the whole bearing angle β. The series covered by Mr. Karelitz's chart Fig. 5 include only those bearings in which the oil film is assumed to be complete throughout an angle $\alpha + \phi$. Since he neglects pressures between the ϕ-line and the end of the bearing and has determined his resultant position on that assumption, the comparisons between his work and mine merely indicate deviations resulting from different points of view. My work has been rigorously true to the Reynolds theory, whereas Mr. Karelitz has arbitrarily located his point of zero pressure at the point of closest approach where he believes experiments will prove it to lie in bearings where side leakage is taken into account. I believe he has jumped at a conclusion that will not be supported generally by the results of experiments covering the field of practical bearing proportions.

Referring to the comments by Professor Waters, it was not my intention to convey the impression that the journal would be unstable with any particular form of cap, but merely to show that the freedom of the journal to rise along any path, or particularly upon the path determined by the bearing alone, would be interfered with by any cap under which a counter pressure would be generated. His statement that an offset cap need not have as much eccentricity as illustrated by my Fig. 15 does not seem reasonable if one wishes to preserve full films in both the bearing and the cap. For a lesser cap eccentricity than shown, there would undoubtedly be pressures developed under the cap that would oppose the normal lift of the journal from the bearing. It therefore seems most natural and correct to shift the cap until the journal path for it, if the load were upward, would coincide as nearly as possible with the journal path for the bearing, assuming that the load is downward. This assumption avoids the necessity of a detailed analysis for a particular cap and bearing combination with a lesser or a greater cap offset.

I hope we shall find time to extend this investigation to bearings of smaller angular lengths than 120 deg., in accordance with Mr. Michell's suggestion. He is interested in the shorter bearings because of his subdivision of the bearing surface into small sections about 40 deg. long in the pivoted-block journal bearing. If our preliminary investigation of short-arc bearings, comparing them with longer ones,[11] had shown the short arc superior to the longer ones, we would perhaps have made our preliminary study for the shorter ones. It is our belief, however, that the longer-arc bearing is bound to remain superior to the more complex group of shorter ones. We therefore explored the 120-deg. bearing quite fully, as shown in this paper.

I have not yet examined R. O. Boswall's recent book and am therefore not familiar with his discussion of stability of the journal. In Part III of my "Graphical Study," in the discussion of Fig. 44 showing capacity and friction coefficient curves for a 120-deg. fitted-journal bearing, I found a number of pairs of journal running positions for the same load, speed, and viscosity factor—each, however, with a different eccentricity. The friction coefficients were lower for the greater eccentricity than for the lesser. An analytical investigation I conducted at that time led me to conclude that the journal would run in the position where the friction was least.

It seems reasonable enough, now that the investigation has been made, that the journal should be expected under certain conditions to rise above the center of the bearing surface in a bearing with running clearance, especially when the clearance is small. The slant of the path of journal center in Fig. 16 is seen

[9] Engineer in Charge of Development, De Laval Separator Co., Poughkeepsie, N. Y. Mem. A.S.M.E.

[10] "Charts for Studying the Oil Film in Bearings," by George B. Karelitz, presented at the Annual Meeting of the A.S.M.E., December, 1925.

[11] See example 9, part III, "A Graphical Study of Journal Lubrication," presented in December, 1925; and letter entitled "A Graphical Study of Journal Lubrication," published in Mechanical Engineering for April, 1927.

to be quite similar to the slant of the path in Fig. 5 for $\alpha/\beta = 0.62$. When the α/β is the same in both cases, we should expect the corresponding paths in the two figures to approach one another as the clearance ratio approaches zero.

It seems desirable to point out that in the various analytical investigations I have conducted, including the present paper, there is complete consistency in assumptions, methods, and results. That seems to be the best way to lay the foundation for an experimental determination of deviations in actual bearings from conditions that our theoretical study with its limitations would lead us to expect. This experimental check is under way, but is very far from complete. When it is far enough along the time will be ripe for a fuller discussion of certain suggestions made by Mr. Michell and Mr. Karelitz concerning the location of positive and negative pressures in the bearing films, with relation to relative inclinations of the surfaces, and the point of closest approach.

Dr. Flowers has pointed out the need of funds for carrying out the investigations fostered by the Special Research Committee on Lubrication, of which Mr. Hersey is chairman. Several important projects are under way in laboratories that have inadequate funds available; for example, Pennsylvania State College and the U. S. Bureau of Standards. If adequate funds were on hand, important work could be carried forward in those and possibly in other laboratories. Investigation is not standing still, however. For example, some important work is being carried on in the Westinghouse laboratory at East Pittsburgh under the direction of Mr. Karelitz. Further investigations are being conducted under Mr. Kingsbury's supervision at his laboratory in Philadelphia. Neither the Westinghouse nor the Kingsbury laboratory requires financial assistance from the Society. For this reason the Special Research Committee on Lubrication has been able to make a fair showing on very slim appropriations from the Society. Nevertheless the committee's work should not drag along too slowly, and adequate funds are therefore very much needed.

Erratum

Paper No. APM-50-3 ("Measurement of Flow of Air and Gas in Nozzles," by S. A. Moss): In the last equation on page 9, second column, the denominator or in the final parenthesis should be p_1 instead of p_2. As corrected the equation will read

$$\sqrt{1-\left(\frac{D}{D_p}\right)^4\left[1-\frac{2}{k}\left(\frac{p_1-p_2}{p_1}\right)\right]}$$

Combustion at High Pressures[1]

By L. C. LICHTY,[2] NEW HAVEN, CONN.

In the author's experiments hydrogen-air mixtures ranging from 1 H_2 + 0.85 Air to 1 H_2 + 6.5 Air were investigated, first, by varying the length of combustion chamber, holding the initial temperature constant at 80 deg. fahr., and second, by varying the initial temperature from 80 to 400 deg. fahr., holding the length of combustion chamber constant. Records were obtained from which the effect of mixture on maximum pressure was studied, as well as the effect of surface-volume relationships on maximum pressure, effect of mixture on time of pressure rise, rate of flame propagation, heat loss during pressure rise, etc.

THE object of these experiments, which have recently been made at Mason Laboratory, Yale University, was to study the process of combustion. Air-hydrogen mixtures were chosen for the first experiments, due to the rapid rate of combustion of the correct mixture.[3] High pressures were used so that the apparatus when developed would be satisfactory, with small change, for low-pressure experiments.

The investigation is divided into two parts with variables as follows:

a The length of combustion chamber was varied while the initial temperature was held at 80 deg. fahr. for ten mixtures ranging from one explosive limit to the other.

b The initial temperature was varied from 80 deg. fahr. to 400 deg. fahr. while the length of combustion chamber was held constant for eleven mixtures from one explosive limit to the other.

All experiments were conducted at an initial mixture pressure of 1000 lb. per sq. in. gage, the combustion taking place at constant volume.

Description of Apparatus

A Kipp generator with zinc and dilute sulphuric acid was used to obtain the hydrogen. After generation the gas was washed through two warm solutions of potassium permanganate and one solution of lead acetate.

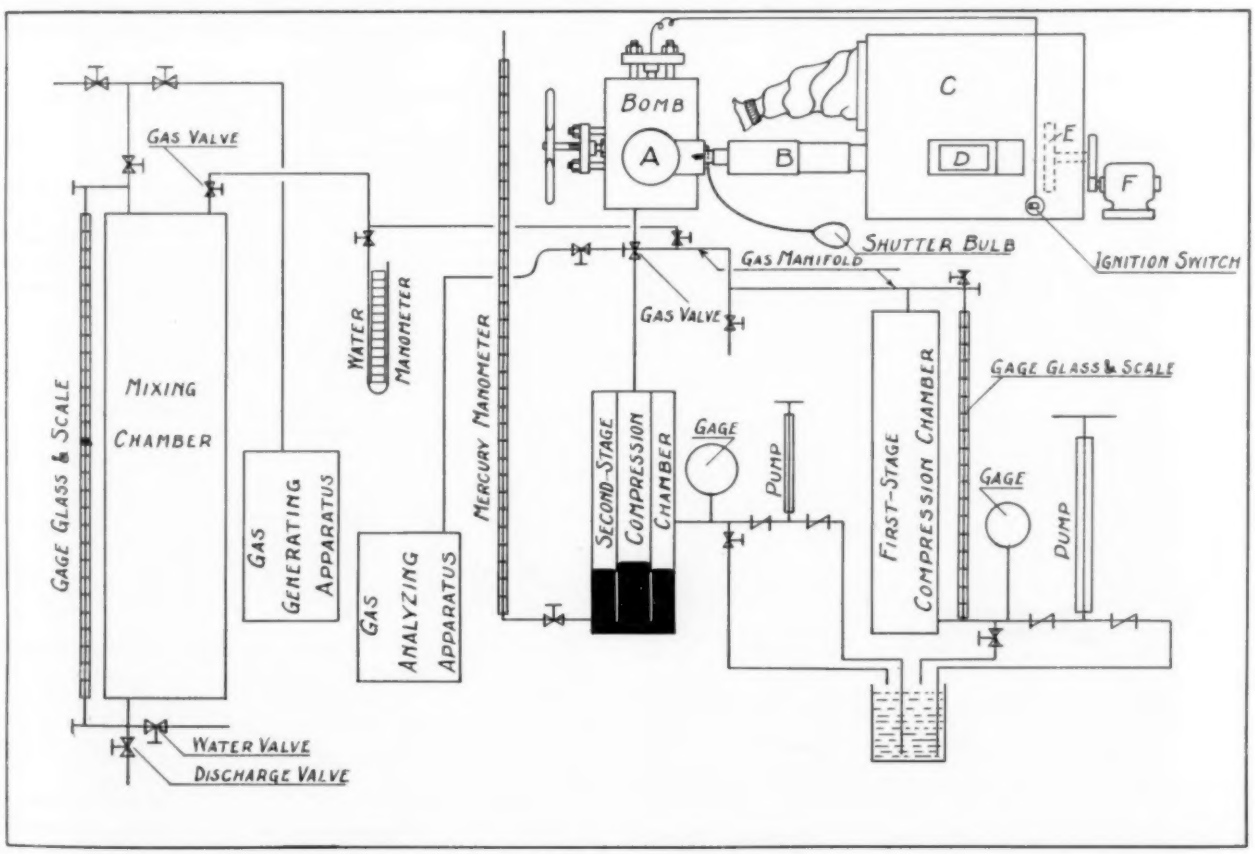

Fig. 1 General Arrangement of Apparatus

The air was washed through a cleaning solution while being drawn into the mixing chamber. The mixing chamber, 10 in. in diameter and $3\frac{1}{2}$ ft. high, provided enough volume for the mixture required for one series of experiments to be completed in one day. A motor-driven fan mixed the gases and maintained uniformity of mixture throughout any series of experiments.

The compression of the combustible mixture was accomplished in two stages. In each stage a hand-operated water pump was used to compress the charge. In the first stage the compression

[1] This work was done under the direction of Prof. Walter J. Wohlenberg.

[2] Assistant Professor of Mechanical Engineering, Sheffield Scientific School, Yale University. Assoc-Mem. A.S.M.E.

[3] The correct mixture is one in which the combining constituents are in the proper proportions (1 H_2 + 2.39 Air).

occurred over water, and in the second, over mercury. (See Fig. 1.)

The combustion chamber was formed inside of a piece of 8-in. shafting. The shape of the combustion chamber was cylindrical except for the upper part, which was conical in form. The cylindrical combustion chamber was chosen since it made possible various volume experiments in which only the length of the flame travel varied. Spherical combustion chambers, while having less heat loss per unit volume, present a changing cross-section to flame travel.

The temperature of the bomb was maintained with an electrical heating element embedded in magnesia and surrounding the bomb.

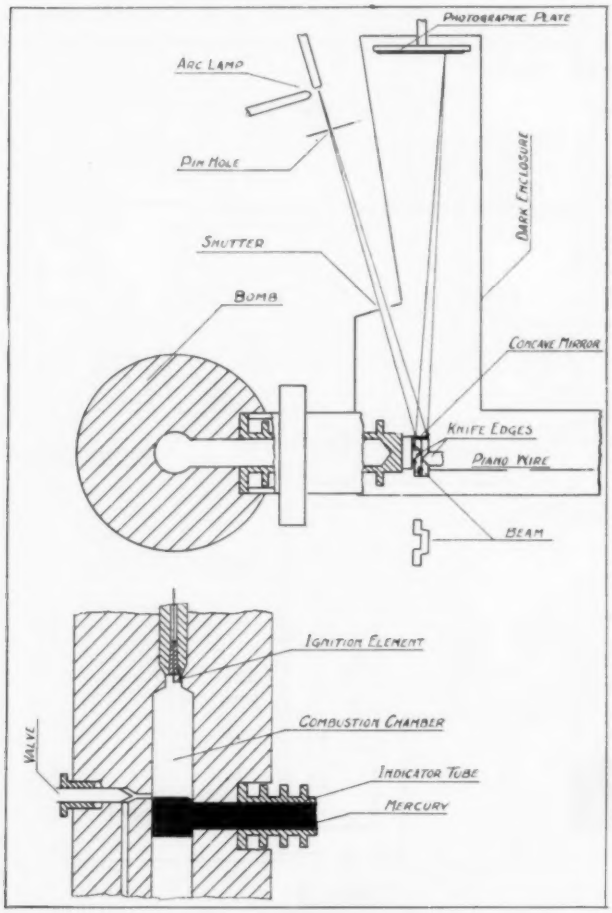

Fig. 2 Bomb and Photographic Apparatus

Three connections were made into the combustion chamber. The lower valve trapped the charge in the chamber. The upper valve contained the ignition element and also permitted the combustion chamber to be scavenged with mercury. The third connection was for the optical indicator.

For low-pressure work the pressure element of an optical indicator is usually a steel diaphragm.[4] The compression of a steel tube has been used extensively for high pressure experiments.[5] The tendency to buckle and to introduce friction to the movement are the two principal disadvantages to this type of element. The pressure element in this work (Fig. 2) was a $3\frac{1}{2}$ per cent nickel-steel tube subjected to tension. With this type of element, friction and buckling were eliminated. The tube was heavily reinforced with integral flanges to make it approximately equally strong both longitudinally and circumferentially.

The movement of the tube is transferred to a beam held between two knife edges by means of a No. 19 piano wire stretched almost to the elastic limit. The outer knife edge and beam are so designed that both knife edges and wire support are in the same plane. A slot in the support of the outer knife edge permits an adjustment whereby the leverage ratio of the magnifying apparatus may be changed.

The optical and photographic apparatus consisted of an arc lamp, shutter, mirror, and revolving plate. Immediately in front of the carbon-arc lamp was located a piece of copper with a minute aperture. This formed the point source of light. The cone of light from this source was directed toward a mirror on the beam of the optical indicator. The light reflected from the mirror was focused on a revolving photographic plate. The camera enclosure surrounded all of the optical apparatus except the point source of light, the light being admitted at the desired time by a photographic shutter.

Experiments With Various Volumes and Mixtures

In this series of experiments ten hydrogen-air mixtures were used, ranging from 1 H_2 + 0.53 Air to 1 H_2 + 7.00 Air.

The photographic records shown in Figs. 3 and 4 are taken from the various mixtures and show the differences in rates of pressure rise and the effect of different lengths of combustion chambers. Table 1 gives information regarding the conditions under which these records were made, along with maximum pressure and time of pressure rise for each record.

TABLE 1

No.	H_2-Air ratio	Vol. of comb. chamber, per cent	Plate speed, r.p.m.	Max. pressure, lb.	Time of pressure rise, sec.
1	1:0.53	40	300	4775	0.1060
2	1:0.57	10	300	5000	0.0280
3	1:0.57	80	300	5125	0.1200
4	1:1.25	100	300	7100	0.0170
5	1:2.41	10	900	6700	0.0015
6	1:2.41	100	900	7900	0.0121
7	1:3.6	100	900	6700	0.0125
8	1:5.0	20	300	4850	0.0090
9	1:5.0	80	300	5300	0.0320
10	1:6.0	40	300	5025	0.0075
11	1:7.0	10	300	2400	0.0394
12	1:7.0	40	300	4400	0.2000

The inner circle of each record represents atmospheric pressure. The circle around it represents the compression pressure of 1000 lb. per sq. in. gage. The beginning of combustion is noted by a line leaving the outer circle and going rather quickly to the maximum pressure, where it merges with the spiral cooling curve.

In general, near both explosive limits the process of combustion appears to be similar, although at the lean end of the mixture a much slower rate of combustion exists. Away from the explosive limits a marked difference is noted. With rich mixtures the rise of pressure ends almost abruptly, while for lean mixtures the end of the pressure rise is well rounded into the cooling curve.

Records Nos. 2 and 3 show the effect of combustion-chamber volume on the process. Being a rich mixture with a slow rate of burning, the process reaches maximum pressure much more quickly with the small volume and in a much different manner.

Record No. 4 is typical of all the records taken with this mixture in which the air supplied was about 50 per cent of that required for the correct mixture.

Record No. 5 shows the effect of inertia of a large mass of mercury in the combustion chamber and should not be thought to represent the combustion process. Record No. 6, with the

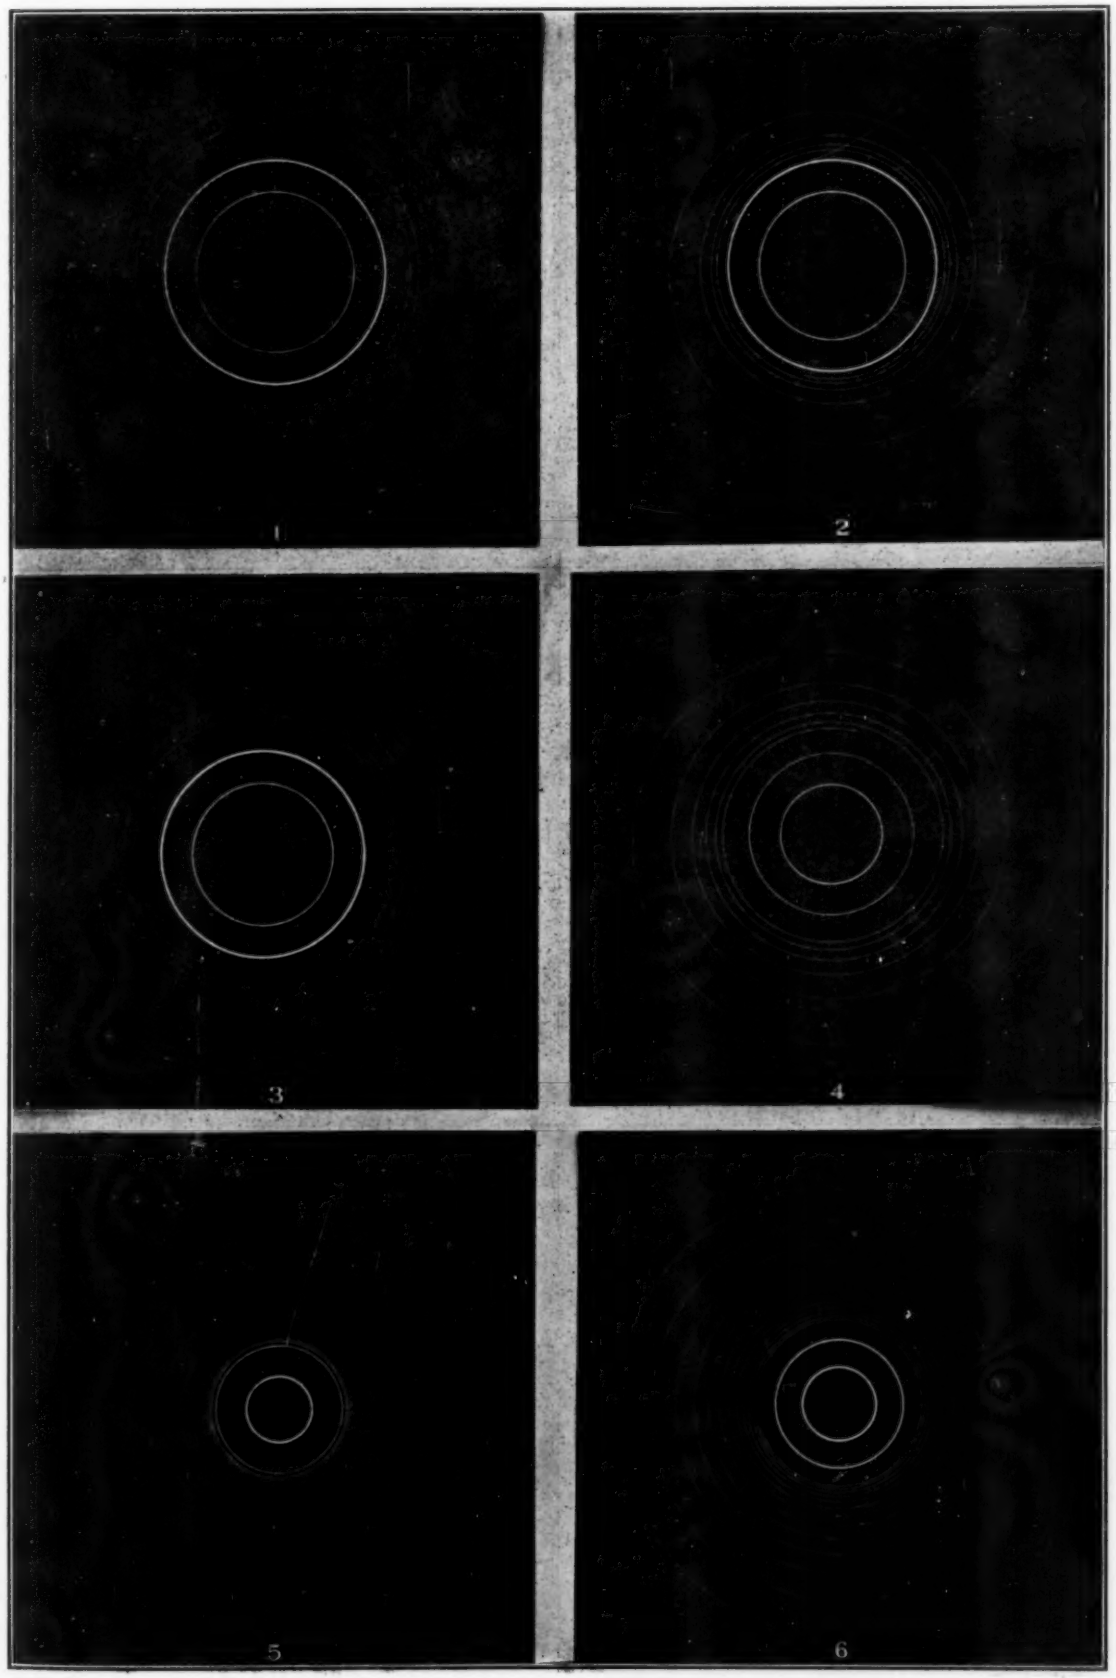

FIG. 3 AIR-HYDROGEN COMBUSTION RECORDS

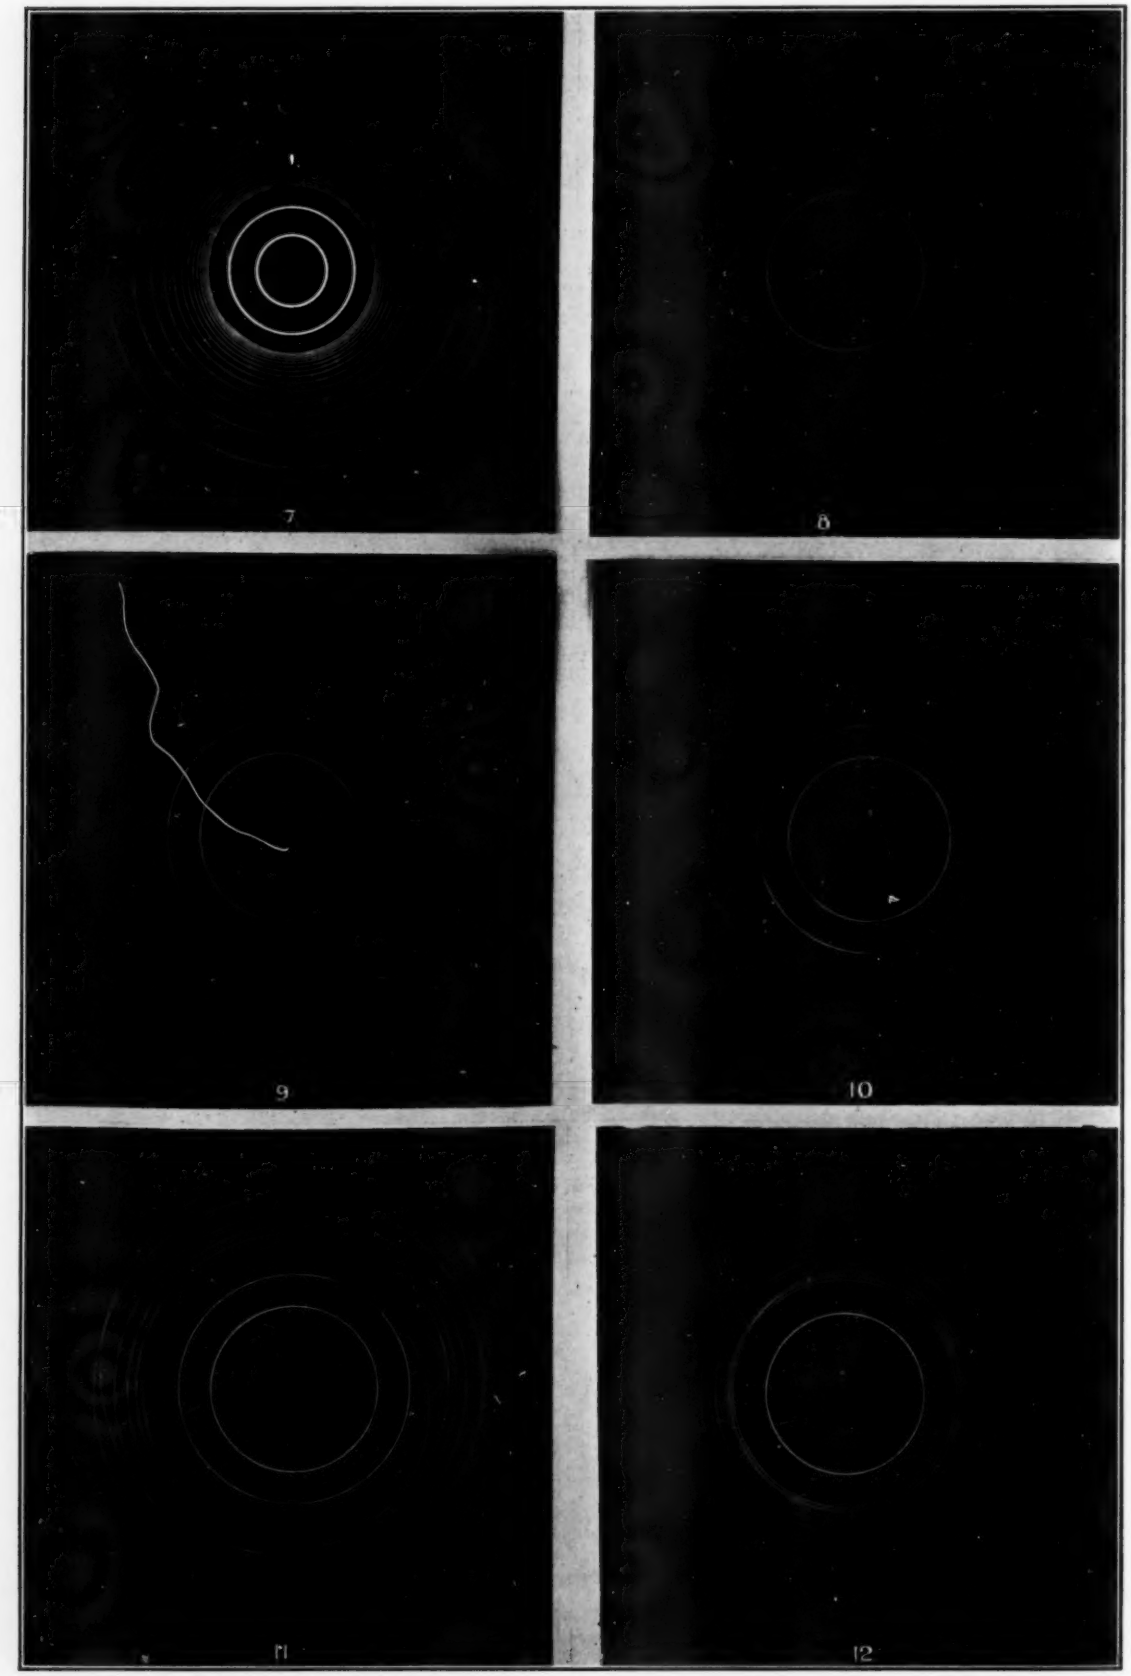

FIG. 4 AIR-HYDROGEN COMBUSTION RECORDS

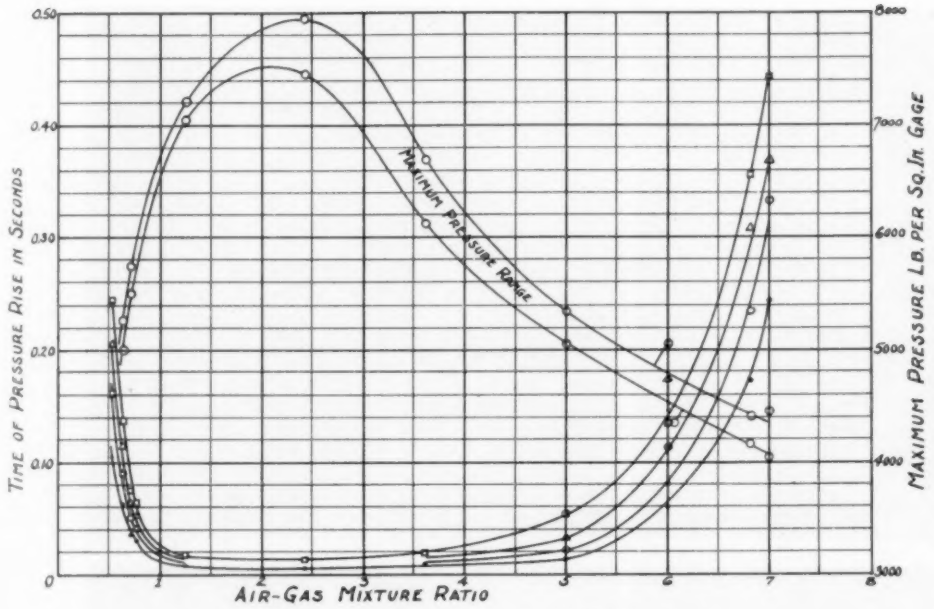

FIG. 5 EFFECT OF MIXTURE ON MAXIMUM PRESSURE

same mixture but with larger combustion chamber, is typical of the other records taken with this mixture. In the original of this record the natural frequency of vibration of the indicator tube could be seen. It appears to be of the order of 6000–7000 vibrations per second.

Record No. 7 shows the speeding-up and slowing-down tendency of the combustion process which occurred with the lean mixtures.

Records Nos. 8 and 9, with the same mixture but with small and large volumes, show the process speeding up in the case of No. 9 until it resulted in detonation, while in No. 8 the process speeded up and slowed down several times without detonation. At no time when detonation occurred did the pressure rise to an abnormal amount.

Record No. 12 is of particular interest, for in this case the rate of energy liberation was not very much greater than that of energy dissipation, with the result that only a small pressure rise resulted. Record No. 11, with the same mixture but with a larger volume, shows a much larger pressure rise.

EFFECT OF MIXTURE ON MAXIMUM PRESSURE

The highest and lowest maximum pressures for each mixture are plotted in Fig. 5, no reference being made to the volume corresponding to the maximum pressure. The maximum pressure occurs with the correct mixture, maximum pressures being considerably lower for leaner and richer mixtures.

EFFECT OF SURFACE-VOLUME RELATIONSHIPS ON MAXIMUM PRESSURE

The maximum pressure for each of the mixtures was not obtained with the same volume. For mixtures near the correct mixture the maximum pressure occurs with large volumes and small surface-volume relationships (Fig. 6). For both the richer and leaner mixtures maximum pressures were obtained with smaller volumes and larger surface-volume relationships. In general, slow-burning mixtures will reach maximum pressures in the smaller combustion chambers where flame travel is shorter, while the faster-burning mixtures will reach maximum pressures in the larger combustion chambers. Thus the combination of the rates of energy liberation and energy dissipation fix the maximum pressure for a given mixture in a definite length of combustion chamber.

This relationship between fuel-air mixture, rate of flame propagation (and resultant energy liberation), and rate of energy dissipation during the combustion process should be considered in the design of the combustion chamber of an internal-combustion engine. These experiments show that no one combustion chamber will result in maximum pressures for all mixtures of fuel and air; and that when the fuel-air mixture is such that the flame propagation is slow it is better to provide a combustion chamber with small flame travel even though the surface-volume relationship is undesirable, from a heat-dissipation standpoint.

EFFECT OF MIXTURE ON TIME OF PRESSURE RISE

The time of burning is low for correct and near-correct mixtures, being below 0.02 sec. for mixtures ranging from 1.25 air to 3.60 air per volume of hydrogen. The correct mixture burned the fastest.[6]

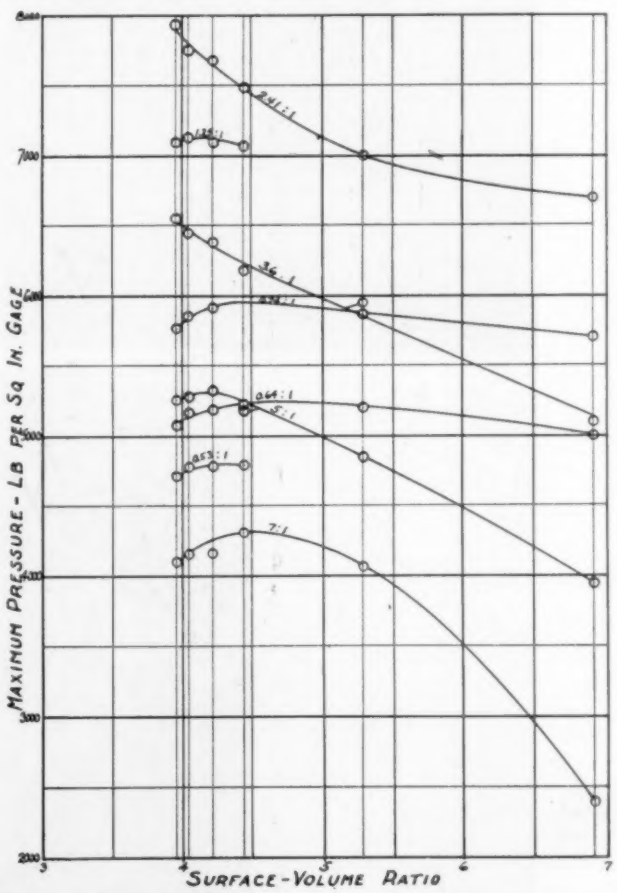

FIG. 6 EFFECT OF SURFACE-VOLUME RATIO ON MAXIMUM PRESSURE

[6] See second set of experiments.

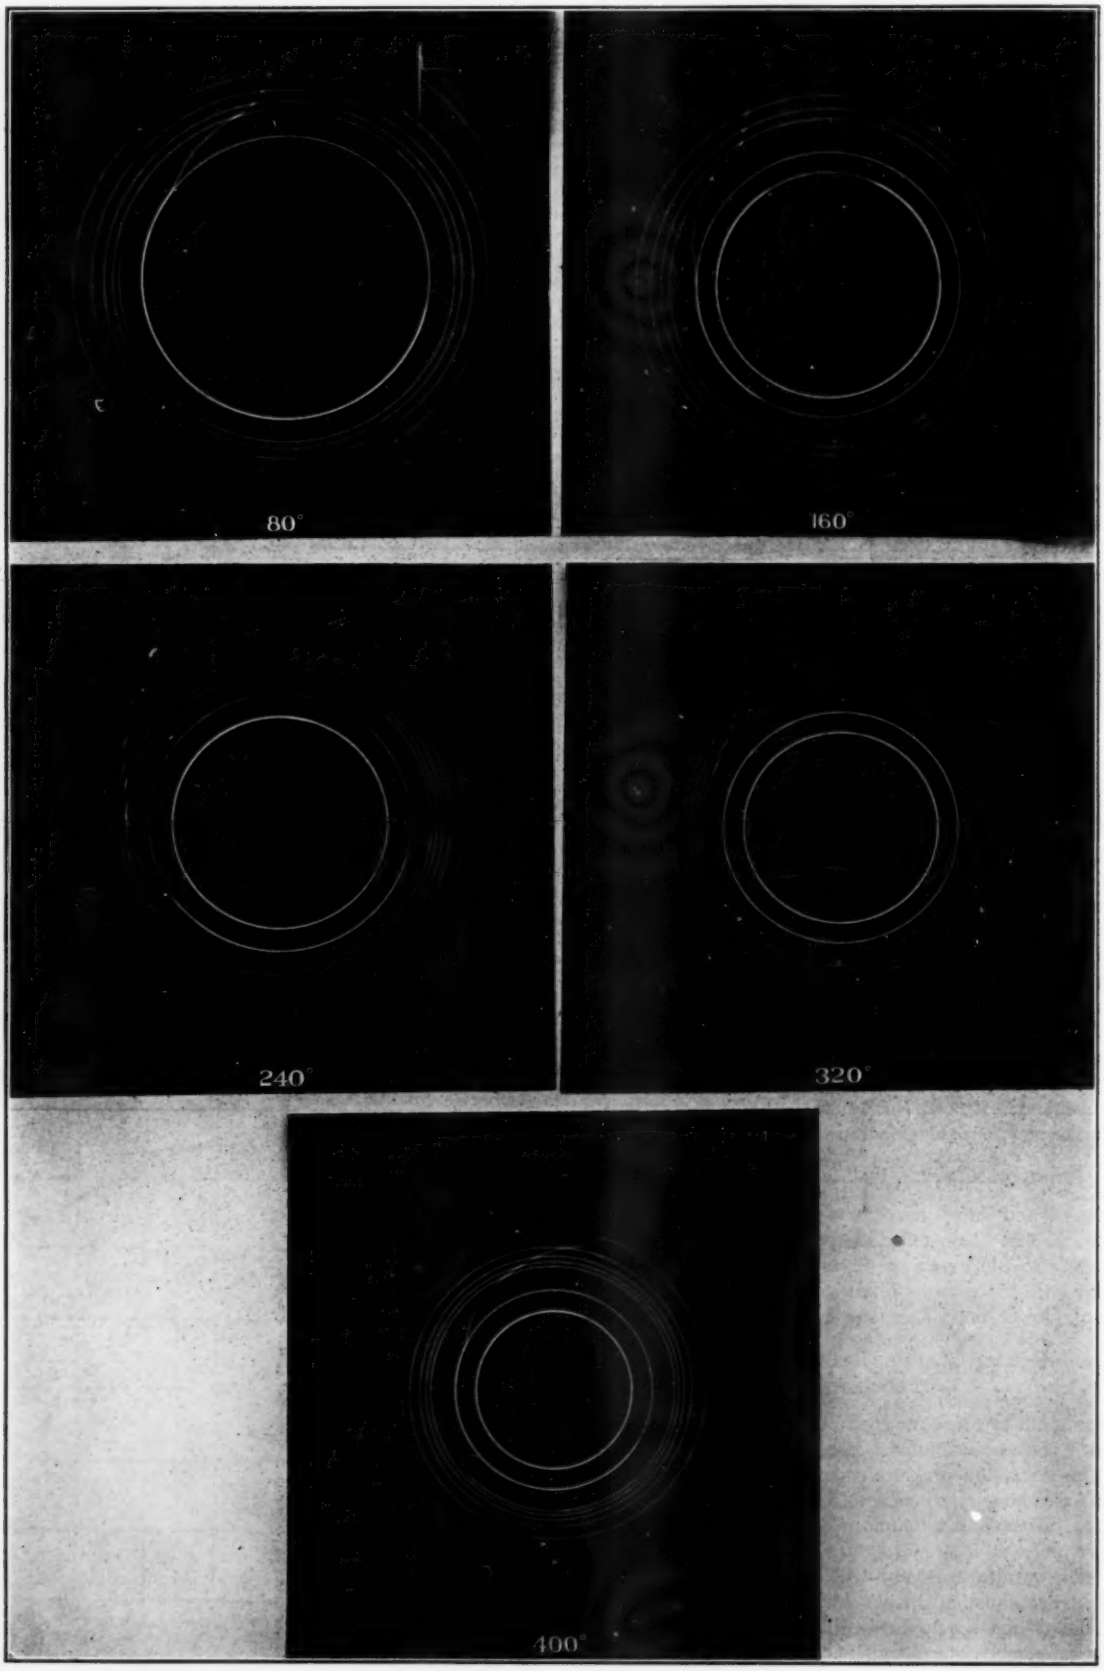

FIG. 7 RECORDS FOR 1 H_2 + 4.78 AIR MIXTURE

For any mixture, the smaller the volume the lower the time of pressure rise, indicating that the length of flame travel directly affects the time of pressure rise.

Explosive Limits

The explosive limit is apparently independent of the volume for this apparatus, and was found to be 1 H_2 + 0.5 Air on the rich side, and to lie between 1 H_2 + 7 Air and 1 H_2 + 8 Air on the lean side, probably quite close to the 1 H_2 + 7 Air.

Flame Propagation

The average rate of flame propagation was determined from the time to reach maximum pressure and the length of flame travel. The lowest rate was 0.11 ft. per sec. with the leanest mixture and the smallest volume, while a rate of over 30 ft. per sec. was found with the correct mixture. The length of flame travel had no apparent effect on the rate of flame propagation in some mixtures, while in others the rate increased or decreased with the length of flame travel.

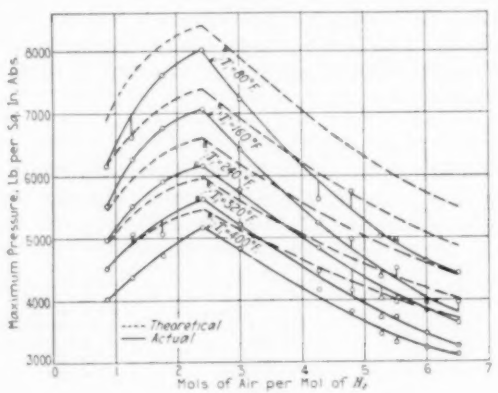

Fig. 8 Maximum Pressures

The average rates of flame propagation are given in Table 2.

TABLE 2 FLAME VELOCITIES, FEET PER SECOND

Length of travel, in.	Air-hydrogen mixture ratios 0.53	0.64	0.74	1.25	2.41	3.6	5.0	6.0	6.8	7.0
0.52	...	1.6	3.3	..	28.9	15.5	4.3	1.0	0.53	0.11

Experiments With Various Initial Temperatures and Mixtures

In this series of experiments eleven hydrogen-air mixtures were used, ranging from 1 H_2 + 0.85 Air to 1 H_2 + 6.5 Air, some of the mixtures being chosen to lie between those used in the first series of experiments. The records taken with 1 H_2 + 4.78 Air are shown in Fig. 7. Attention is called to the type of pressure rise, which is similar to Record No. 8 in Fig. 4, this record being made with approximately the same mixture. The records for the other ten mixtures in this series exhibit pressure rises with the same characteristics as found in the first series for similar mixtures, showing that the mixing of the fuel and air was complete in all cases. The ease with which records could be duplicated was considered rather remarkable.

Theoretical and Actual Results

The results of this series of tests are shown in Figs. 8 and 9. The theoretical results were obtained by an analysis based upon the work of Goodenough and Felbeck.[7] This work takes into account variable specific heats and the effect of dissociation, but does not include correction for the deviation from perfect-gas laws. For this reason, only the shape of the theoretical curves are of particular consequence. The actual pressures attained decrease with an increase in initial temperature of the mixture. This was to be expected, since theoretically

$$\frac{P_0}{P_1} = \frac{T_0}{T_1}$$

and for a practically constant energy liberation the difference between T_1 and To would vary only a small amount, so that

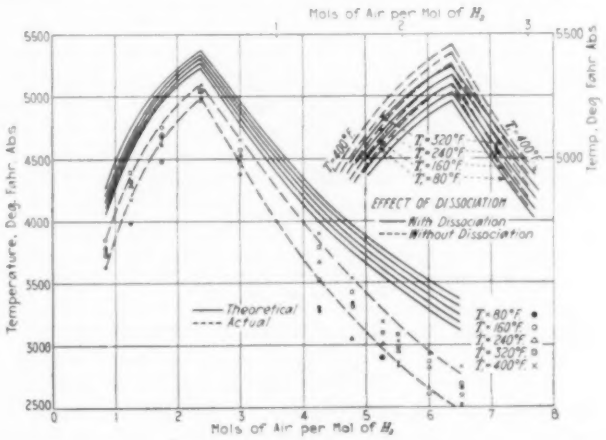

Fig. 9 Maximum Temperatures

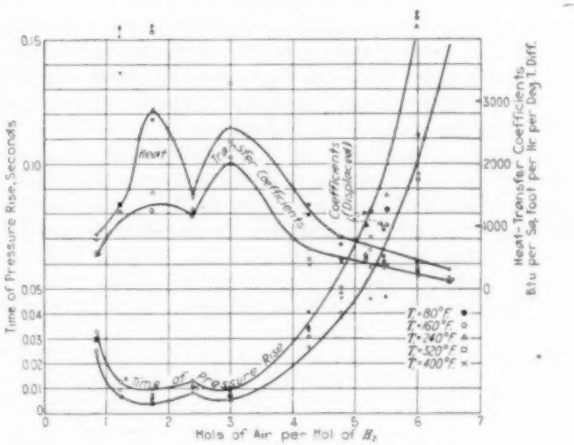

Fig. 10 Curves of Time of Pressure Rise

for higher initial temperatures (T_1) the ratio of pressures would be lower.

The curve of time-of-pressure rise (Fig. 10) shows two minimums, one on each side of the correct mixture. The experiments of R. W. Fenning[8] show the same effect on the rich side but not on the lean side.

The possible number of combinations of molecules of hydrogen with oxygen for lean mixtures and of oxygen molecules with hydrogen for the rich mixtures is greater than for the correct mixture. This would indicate the longest time of burning at the correct mixture and the shortest time at the explosive limits. This combination effect is offset by that of high mean temperature at the correct mixture and low mean temperature

[7] Bulletin No. 139, Eng. Exp. Station, University of Illinois.

[8] "Air-Hydrogen Explosions in Closed Vessels." Aeronautical Research Com. (England), 1923–24.

at the explosive limits. At the explosive limits the speed of the molecules is low compared with the speed at the correct mixture. The higher the molecular speed the greater the number of collisions per unit of time and the greater the possible number of combinations. For these experiments the above two factors apparently combined to give the time-mixture curve the two minimum points, one on each side of the correct mixture.

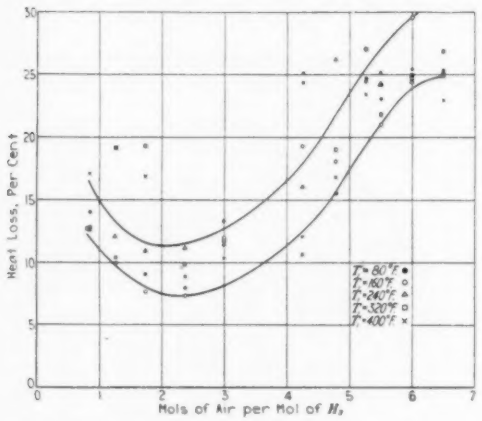

FIG. 11 HEAT LOSSES DURING PRESSURE RISE

HEAT LOSS

The heat loss during the pressure rise is indicated by the difference between the temperatures computed from the actual pressures and the theoretical maximum temperatures. Since differences of values based upon these temperatures approximately eliminate the deviation from perfect-gas laws, it is thought that the area between the curves (Fig. 11) indicates rather closely the range within which the heat losses for these experiments should lie. The heat loss ranges from 7.3 per cent at the correct mixture to 29.6 per cent at the 1 H_2 + 6 Air mixture.

In order to determine the heat-transfer coefficients it was assumed that the time rate of pressure rise was a straight line, making one-half of the temperature rise the mean temperature difference. With this assumption the heat-transfer coefficients shown in Fig. 10 were computed. The outlying points have been neglected, it being believed that enormous coefficients of heat transfer indicate leaky experiments. It is interesting to note that at the correct mixture the heat-transfer coefficients average above 1300 B.t.u. per sq. ft. of surface per hour, per degree difference in temperature. From the high rates of heat transfer determined it is quite evident that rapid combustion is accompanied by extraordinary movement of the mixture. A comparison of all the curves in Fig. 10 indicates that the heat-transfer coefficients during pressure rise vary inversely with the time of pressure rise.

Heat-transfer coefficients during the first part of the cooling process were also computed. In all cases in a very short time the coefficients of heat transfer dropped to values that would be considered normal. For example, in less than 0.2 sec. after maximum pressure the coefficients of heat transfer for the correct-mixture experiments had dropped to an average value of 115. At atmospheric pressure this would be equivalent to 1.6. For still air at atmospheric pressure the heat-transfer coefficient is about 1.4, indicating in this case only a small movement of the gas 0.2 sec. after maximum pressure.

The effect of radiation on heat loss during pressure rise is of considerable interest in that it was found to account for less than 1 per cent of heat loss for the experiment resulting in the highest temperature. This would indicate that in high-pressure combustion work conduction and convection account for practically all the heat loss.

FLAME PROPAGATION

There appeared to be no definite relationship between the rate of flame propagation and the initial temperature of the mixture. Values of rates of flame propagation given in Table 3 are the average values for all experiments with each mixture.

TABLE 3 AVERAGE RATES OF FLAME PROPAGATION

Mixture, mols of air per mol H_2	Avg. time of pressure rise, sec.	Rate of flame propagation, ft. per sec.
0.85	0.0281	10.8
1.25	0.0095	32.1
1.75	0.0066	46.2
2.39	0.0104	29.3
3.00	0.0068	44.8
4.25	0.0320	9.5
4.78	0.0447	6.8
5.25	0.0321	9.5
5.50	0.0747	4.1
6.00	0.1293	2.4
6.50	0.236	1.3

The maximum rate of flame propagation (82.3 ft. per sec.) was attained in an experiment with 1 H_2 + 1.75 Air at an initial temperature of 320 deg. fahr.

APM-51-5

Fatigue and Corrosion-Fatigue of Spring Material[1]

By D. J. McADAM, JR.,[2] ANNAPOLIS, MD.

BY NUMEROUS investigations of fatigue of metals certain facts and relationships have been well established. These will be briefly mentioned and defined.

Fatigue failure of metals is due to the repeated application of a range of stress that is insufficient to cause failure on single application. The range of stress may be between zero and a maximum, or between a maximum and minimum value, or there may be complete or incomplete reversal of stress per cycle. Fatigue depends more on the range of stress than on the extremes of the range. It has been definitely established that, below a limiting value of the stress range, fatigue failure does not occur even after many million applications of the stress range. This limiting range has been called the "endurance range."[3] A greater range causes failure after a number of cycles that decreases rapidly with increase in the range. When the endurance range involves complete reversal of stress per cycle, as in a rotating beam or cantilever, the half range is known as the "endurance limit" or "fatigue limit." The object of the great majority of endurance tests of metals has been to determine the "endurance limit."

The effect of varying the position of the endurance range with reference to the elastic range has been investigated for steel, but much further investigation is needed. Under many conditions of service, especially for springs, the stress range is between zero and a maximum or between a minimum and maximum. Under such conditions the endurance range may or may not be somewhat less than if it involved complete reversal of stress per cycle. Since information about this important subject is at present very incomplete, however, chief attention must here be given to the endurance properties of spring material under complete reversal of stress per cycle, with some tentative conclusions as to the endurance properties under actual service conditions.

In this paper the term "endurance limit" will be applied only to values obtained with specimens designed so as to avoid stress concentration due to abrupt change of section. With specimens so designed, carefully machined and polished, and tested under conditions as free as possible from corrosion, the endurance limit presumably represents an inherent property of the metal or alloy. The nominal values obtained with notched specimens, or with specimens subjected to simultaneous corrosion and fatigue, will be called "fatigue limits." In this paper attention will first be given to endurance limits. The influence of abrupt changes of section and the broad subject of corrosion-fatigue will be considered later.

Relation of the Endurance Limit to Other Physical Properties

The endurance limit seems to be more closely related to the tensile strength than to any other physical property except the Brinell number. The endurance limit seems to have very little relationship to elastic limit or to ductility. The ratio of the endurance limit (as obtained by rotating beam or cantilever) to the tensile strength, which has been called the endurance ratio,"[4] is for most normal metals between 0.4 and 0.55. For some non-ferrous metals the endurance ratio is lower, and may be as low as 0.25.

In the great majority of all fatigue tests the specimen has been tested as a rotating beam or cantilever. Some tests have been made under a range between direct tension and compression. The difficulty of avoiding eccentric loading in direct tension-compression tests has made many of the results of such tests of little value. The weight of evidence seems to indicate that if the loading is concentric the endurance limit as obtained by direct stress agrees closely with the limit obtained by rotating beam or cantilever, at least for metals and alloys whose endurance limit is below the elastic limit. The endurance limit in repeated shear or torsion is less than in tension-compression. The ratio of the endurance limit for torsion to the endurance limit for tension-compression varies from 0.38 to 0.84. These ratios for various kinds of material are given in Tables 5 and 6.

For commercial carbon steel of lowest carbon content the endurance ratio is about 0.5. For carbon steels of medium strength the endurance ratio is about 0.45. For high-carbon steels the endurance ratio may be somewhat less. For alloy steels the endurance ratio is usually about 0.5, unless the steel has been heat-treated to exceptionally high strength. For spring steels of highest strength the endurance ratio is usually less than 0.5 and may be little more than 0.4. If, however, a specimen of such steel is subjected to gradually increasing cyclic stress starting at a point well below the endurance limit, the endurance limit may be raised to about half the tensile strength. This seems to indicate that the lower endurance ratio obtained with the hardest material by ordinary endurance tests is due to internal stress.

Endurance Properties of Steels

In Figs. 1 and 2 are stress-cycle graphs illustrating the endurance properties of steels as determined by rotating-cantilever tests at the Naval Engineering Experiment Station. Ordinates represent the half range of stress and abscissas represent cycles on a logarithmic scale. Each set of graphs has its own scale of abscissas, which is indicated by numerals adjacent to the graph. Some of these graphs have been assembled from various papers[5,6,7,8] by the author. Others represent new data. For graphs that have been published elsewhere, the results of individual tests have been omitted and the stress-cycle relationship has been represented by lines only; for graphs representing new data, both individual results and the stress-cycle lines have been included. The solid lines represent results of rotating-cantilever tests of oiled specimens in air. The dotted and broken lines represent results of tests of notched specimens and results of tests of specimens under simultaneous corrosion and fatigue. These will be discussed later.

The unnotched specimen used in these experiments is shown in Fig. 6. The taper of this specimen is such that the maximum stress is in a plane $^3/_4$ in. out from the fillet, and the stress varies only about $1^1/_2$ per cent over a length of $1^1/_2$ in.

Beside each stress-cycle graph there are indicated some of the

[3] For this and the following references see list at end of paper.

Contributed by the Research Special Committee on Mechanical Springs and presented at the Annual Meeting, New York, N. Y., Dec. 3 to 7, 1928, of The American Society of Mechanical Engineers.

strength values as determined by tension test. These are represented by the following symbols: tensile strength, T. S.; Johnson's limit, J. L.; proof stress, P. S.; elastic limit, E. L.; proportional limit, P. L.

Each zigzag line in these figures represents the course of a fatigue or corrosion-fatigue test in which the stress was raised at intervals until the specimen failed or was removed. The lower end of the zig-zag line represents the original stress and the number of cycles endured at this stress. The course of the line represents the stress increases and the cycle intervals at which these increases were made.

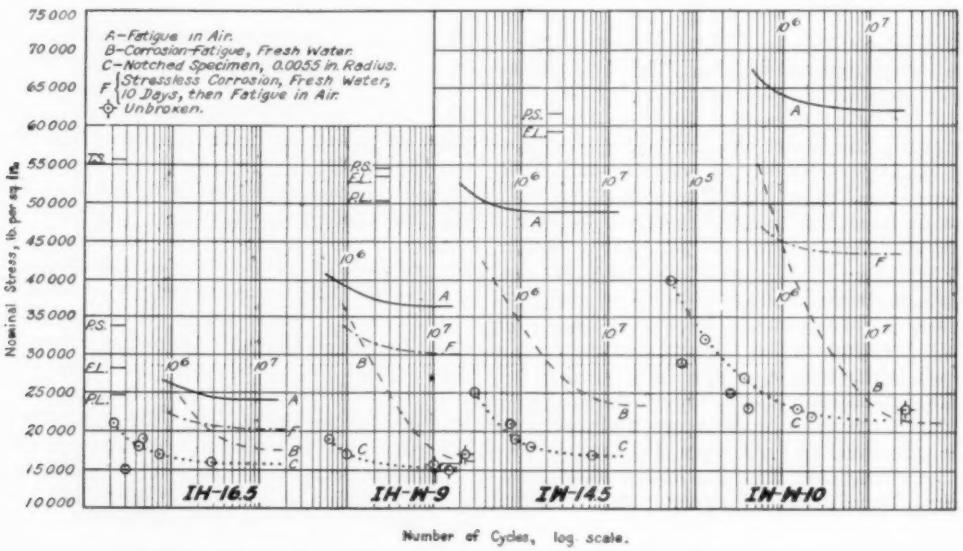

FIG. 1 FATIGUE AND CORROSION-FATIGUE OF CARBON AND NICKEL STEELS

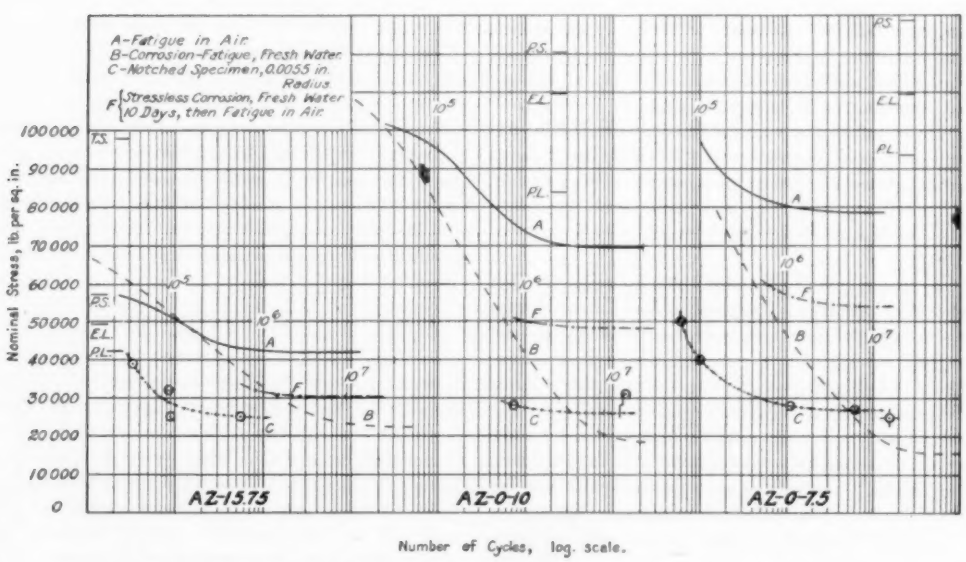

FIG. 2 FATIGUE AND CORROSION-FATIGUE OF CHROMIUM-VANADIUM STEEL

In Fig. 1 are shown two pairs of graphs representing results obtained with a 0.25 carbon steel and with a $3^1/_2$ per cent nickel steel, respectively. In each pair the graph on the left represents fully annealed material and the graph on the right represents quenched-and-tempered material. In Fig. 2 are shown three groups of graphs representing a chrome-vanadium steel in three different degrees of hardness as produced by heat treatment. The group on the left represents fully annealed material and the group on the right represents material of spring temper.

As illustrated by the solid lines in these figures, each stress-cycle graph is a curve approaching a horizontal asymptote, the ordinate of which is the endurance limit. A comparison of the endurance limits as obtained in this way with the corresponding tensile strengths will show that the endurance limit is roughly proportional to the tensile strength. With sufficient upward extension of the stress-cycle graph, there is usually reversal of curvature. As shown in a previous paper by the writer,[9] this reversal is due to rise of temperature of the specimen when tested at stresses above the endurance limit.

Endurance limits obtained in this way for various steels are listed in Table 5. Chemical composition is given in Tables 1 and 2 and details of heat treatment in Tables 3 and 4.

ENDURANCE PROPERTIES OF NICKEL-COPPER ALLOYS

Monel metal is the only nickel-copper alloy that is extensively

used for springs. As some other nickel-copper alloys, however, would be practically as suitable for springs it has seemed desirable to discuss briefly the endurance properties of the entire series of nickel-copper alloys as affected by chemical composition, cold working and annealing.

Heat treatment is the usual method of hardening steels. Some non-ferrous alloys such as duralumin can be hardened by heat treatment. Heat treatment can also be used to harden some characteristic of all fully annealed alloys made up of only one microconstituent (alpha solid solutions). During an endurance test, however, the elastic limit in the surface layers of a fully annealed specimen is undoubtedly raised by the cold working.

A comparison of all the graphs for fully annealed material shows that with increase in nickel content the endurance limit rises rapidly until the percentage of nickel is about 45 per cent,

[a] By difference

of the alloys of copper and of nickel. The most generally useful method for hardening non-ferrous alloys, however, is cold working. For this reason, in discussing the endurance properties of non-ferrous spring material, prominence must be given to the effect of cold working.

In Figs. 3 and 4 are shown stress-cycle graphs for a series of nickel-copper alloys ranging from pure copper to commercial nickel.[5,9,10] These graphs are in pairs. The graph on the left of each pair represents fully annealed material and the graph on the right represents material in a severely cold-worked condition. As illustrated by these pairs, cold working raises the endurance limit of nickel-copper alloys about in proportion to the increase in tensile strength.

It will be observed also that for fully annealed material the nominal endurance limit is above the elastic limit and even above the yield point as represented by proof stress. This seems to be which corresponds to the alloy constantan. With further increase in nickel content, the endurance limit changes relatively little. The endurance limit of monel metal (which has about 70 per cent nickel) is possibly a little higher than that of alloys having lower or higher nickel content. If monel metal is superior to constantan, however, the superiority is slight.

As shown in these graphs and in Table 6, it is possible to obtain cold-rolled nickel-copper alloys in rods 1 in. in diameter, with tensile strength of 135,000 to 140,000 and endurance limit of slightly over 50,000. To obtain an endurance limit of this amount, however, the cold-worked material must be given an annealing treatment (as indicated in the case of monel metal in Table 4) to relieve internal stress. In smaller rods or in wire, it should be possible to obtain even higher fatigue limit, if the severely drawn material is properly annealed so as to relieve internal stress with practically no loss in tensile strength.

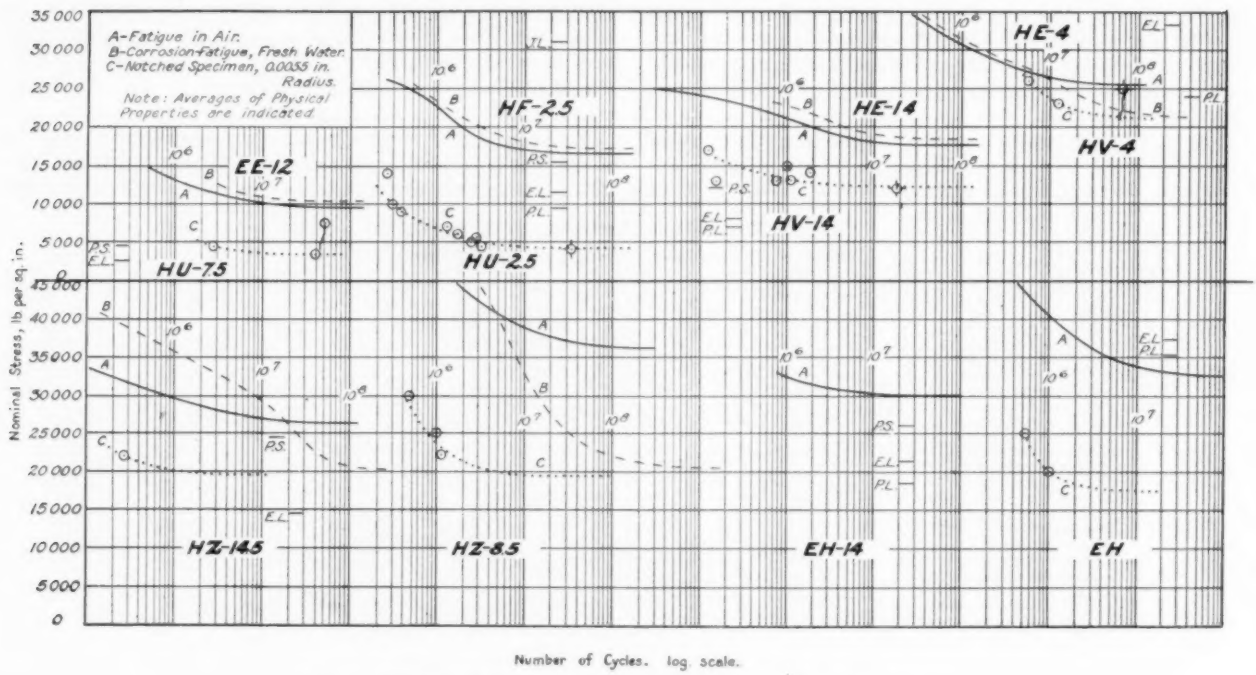

FIG. 3 FATIGUE AND CORROSION-FATIGUE OF NICKEL-COPPER ALLOYS

ENDURANCE PROPERTIES OF COPPER-TIN ALLOYS

In Fig. 5 are shown graphs illustrating endurance properties of three copper-tin alloys with tin content ranging from about 5 to 10 per cent. Each horizontal row of graphs represents one of these three alloys in three different degrees of hardness imparted by cold working. In each row the graph on the left represents fully annealed and the graph on the right represents most severely cold-worked material. As in previous figures, the solid-line graphs represent results of ordinary endurance tests.

As illustrated by the lower row of graphs, the endurance limit of the alloy containing 5 per cent tin is improved somewhat by moderate cold working. With increase in the severity of cold working, however, the endurance limit is raised little, if at all. As illustrated by the middle row of graphs, the endurance limit of the 8 per cent alloy is improved slightly by moderate cold working. With further increase in the severity of cold working, however, the endurance limit is lowered. As illustrated by the upper row in this figure, either severe or moderate cold working lowers the endurance limit of the alloy containing 10 per cent tin.

Comparison of the three kinds of fully annealed material seems to indicate that addition of tin beyond about 5 per cent causes little if any improvement in the endurance limit of a copper-tin alloy. Comparison with the endurance limit of annealed copper, as shown in Fig. 3, however, shows that the addition of tin up to about 5 per cent makes the endurance limit of the alloy more than double that of pure copper.

The results obtained with copper-tin alloys seem to indicate that cold working is less effective in raising the endurance

limit of these alloys than in raising the endurance limit of nickel-copper alloys. Even by moderate cold working, the endurance limit of copper-tin alloys is increased less than in proportion to the increase in tensile strength. This in spite of the fact that the cold-worked copper-tin alloys had been subjected to a low-temperature anneal (as indicated in Table 4) to relieve internal stress. As shown in previous papers[6,24] copper-zinc alloys in this respect behave like the copper-tin alloys.

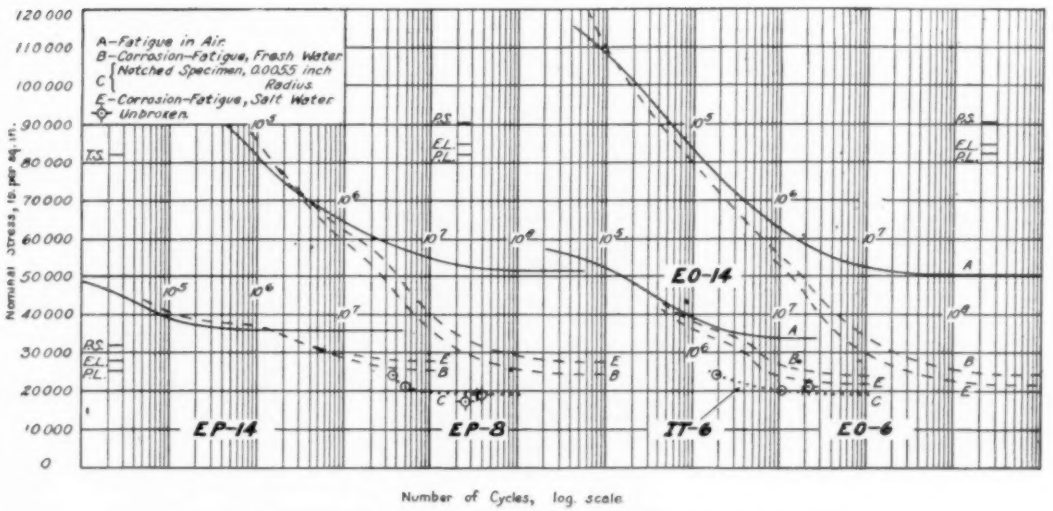

FIG. 4 FATIGUE AND CORROSION-FATIGUE OF MONEL METAL AND NICKEL

Possible reasons for the fact that the endurance limit of the copper-zinc alloys is apparently little improved by cold working were given in a previous paper.[5] It was there suggested that possibly the cold working has caused minute discontinuities in the metal. Such discontinuities might behave like notches and thus reduce the fatigue limit of the cold-worked material. Such internal notches would affect the fatigue limit more than they would affect the tensile properties. They would affect the fatigue limit of the severely cold-worked material more than they would affect the fatigue limit of material that had been subsequently annealed. It is possible, therefore, that the behavior of copper-tin and copper-zinc alloys toward cold working is due to the same cause, namely damage to the alloy in the cold-working process.

[a] Oil bath, instead of furnace, used in heat-treating this material.

As shown in a previous paper,[24] the endurance limit of cold-worked copper-zinc alloys is considerably affected by internal stress. The low-temperature annealing treatments given to the copper-tin alloys were for the purpose of removing, or at least diminishing, internal stress. In these annealing treatments, as determined by preliminary tests, the temperatures were the highest that could be used (for the times indicated) without decided decrease of the alloy's strength. It should be noted that the alloys that were heat-treated for three hours at 250, 350, and 375 deg. fahr. had practically the same tensile properties and endurance limits as the alloys that were heat-treated at 400 deg. fahr. It does not seem practicable, therefore, by heat treatment to cause any further reduction of internal stress. Any internal stress remaining in the bars, moreover, would be still further reduced by the machining of the specimens from the full-sized bars. For these reasons it seems probable that the low endurance limits of the severely cold-worked alloys containing 8 and 10 per cent tin are due chiefly to internal flaws in the hard material rather than to internal stress. As will be shown later, it would be possible for material with such internal flaws to show lower endurance limits in the cold-worked condition than when afterward annealed. It is possible also that the slight improvement of the fatigue limit of the copper-tin and copper-zinc alloys is due to some inherent property of these alloys. This subject needs further investigation. It is important to know definitely whether or not the endurance limit of these alloys in the form of spring wire is much or little greater than that of fully annealed material.

EFFECT OF VARYING THE POSITION OF THE ENDURANCE RANGE WITHIN THE ELASTIC RANGE

The results presented in Figs. 1 to 5 and in Tables 5 and 6 all are results of endurance tests with complete reversal of stress per cycle. Relatively few experiments have been made with other than complete reversal of stress per cycle. These cannot here be discussed in detail. Complete discussions of the relation between the endurance range and the mean stress of the cycle are given in a book by H. J. Gough[11] and in a book by H. F. Moore and J. B. Kommers.[12]

Moore and Jasper[13] investigated the effect of varying the mean

stress of the tension-compression range. Specimens were subjected to rotating-bend test and at the same time to additional tensile stresses throughout the entire cross-section. By this means the endurance range was investigated with various ratios between its superior and inferior limits. These authors conclude that, as the endurance range is moved away from the position involving complete reversal of stress, it decreases at an increasing rate. Other investigators have studied this subject and come to similar conclusions. Formulas, more or less elaborate, have been evolved to represent the change of the endurance range with change in the ratio between maximum and minimum stress of the range. These formulas have all been developed as a result of experiments with the tension-compression range.

The effect of varying the position of the torsional endurance range within the elastic range was discussed by the writer in a

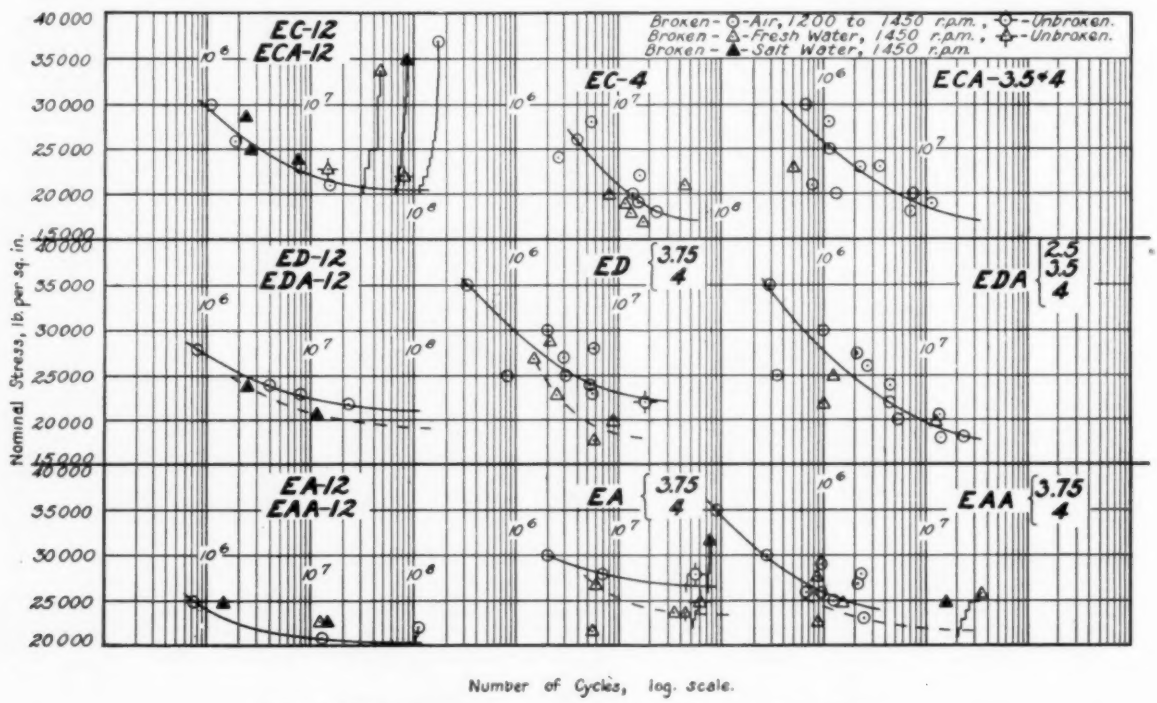

FIG. 5 FATIGUE AND CORROSION-FATIGUE OF COPPER-TIN ALLOYS

previous paper.[3] It was there shown that the torsional endurance range for steel decreases not more than about 5 per cent as the position of the stress range is moved from the middle to the tensile end of the elastic range. Even if the superior stress of the range is increased nearly to the yield point, the endurance range is only slightly less than for complete reversal of stress per cycle. These results indicate that a high elastic limit is of considerable value in spring steel. A high elastic limit makes it possible to vary considerably the position of the endurance range within the elastic range. As stated previously, however, the magnitude of the endurance range depends not on the elastic limit but on the tensile strength.

Almost simultaneous with this paper was a bulletin by H. F. Moore and T. M. Jasper[14] in which similar conclusions were reached as to the approximate constancy of the torsional endurance range within the limits, or even slightly beyond the limits, of the elastic range. More recently these conclusions have been confirmed in a paper by G. A. Hankins.[15] He says also: "In addition the present results show that the variations are small when the superior stress limits are well outside the original elastic or proportional ranges. In the case of mild steel and the normalized 0.6 per cent carbon steel, the safe ranges are less than 10 per cent below those for reversed stresses even when the superior limits of stress approach the ultimate stress of the material. In the case of hardened and tempered spring steels, there are marked decreases in the safe ranges at the high mean stresses." The conclusion seems to be well established, therefore, that the torsional endurance range for steel varies only slightly with variation in its position within the elastic range.

The constancy of the torsional endurance range for steel within the elastic range suggests the possibility that further experiments may show that there is a similar constancy of the tension-compression endurance range within the elastic range. The author in the before-mentioned paper[3] discussed the results obtained by Moore and Jasper[13] and suggested that these results seem to indicate an actual constancy of the tension-compression endurance range within the elastic range. It is worthy of note that nearly all who have investigated this subject have attempted to work out a formula that would apply whether or not the primitive elastic range is exceeded. While such formulas are useful, it appears to the writer that a knowledge of the effect of varying the position of the tension-compression endurance range within the elastic range is of more practical importance. Such knowledge is especially needed for application to spring design.

For steel springs subjected to a torsional range of stress, therefore, it is well established that the endurance range does not vary appreciably provided the elastic range is not exceeded. For steel springs subjected to a range of bending stress, it seems possible that the same law applies. Further investigation of this subject, however, is necessary.

For non-ferrous metals, the endurance range has been investigated only with complete reversal of stress per cycle. Investigation of the endurance range for non-ferrous metals with other ratios between the superior and inferior limits is much needed. For application to springs, a knowledge of the endurance range when the inferior limit is zero, or even when the range is between

a maximum and a minimum in the same direction, would be of great use in design.

Effect of Abrupt Changes of Section

The endurance properties discussed in the previous sections have been those obtained with specimens as free as possible from abrupt change of section. In springs, however, the surface is usually much less smooth than in the endurance test specimens. There are frequently also surface defects and internal flaws due to processes of manufacture of the metal and the forming of the spring. It is necessary, therefore, to consider the effect of abrupt changes of section on the nominal fatigue limit.

This subject has been investigated by Stanton and Bairstow,[16] Eden, Rose, and Cunningham,[17] R. R. Moore,[18,19] H. F. Moore and J. B. Kommers,[20] W. Norman Thomas,[21] and others. Theoretically, the stress concentration depends on the ratio between the notch depth and the radius of curvature at the bottom. In general, the conclusion reached by these investigators is that the reduction of fatigue strength of steel by notches is less than the theoretical reduction. The softer the material, the greater the difference between the observed and the theoretical reductions.

The writer has made fatigue tests on notched specimens of most of the materials that are represented in Figs. 1 to 4. All these tests were made with the same type of notch. The form and dimensions of this notch are shown in Fig. 6 in comparison with the unnotched tapered specimen. As shown in this figure, the notch has an angle of 60 degrees and the radius at the bottom is 0.0055 in. (0.14 mm.). To obtain the proper radius the tool was ground with frequent checking by microscopic measurement at a magnification of 50.

Results of these tests with notched specimens are shown in Figs. 1 to 4 in comparison with the previously described results of tests with unnotched specimens.

A comparison of the fatigue limits for the notched specimens of various steels in Figs. 1 and 2 shows that the nominal fatigue limit increases with increase in the strength of the steel. The percentage increase in the fatigue limit for the notched specimen, however, is much less than the percentage increase of the endurance limit of the metal (as obtained with unnotched specimens). The fatigue limit of the notched specimen ranges from 16,000 for annealed mild steel to 27,000 for chrome-vanadium steel of spring temper, whereas the corresponding endurance limit ranges from 23,500 to 78,000. The fatigue limit of the notched specimen, therefore, varies about 69 per cent, while the endurance limit varies 239 per cent.

Evidently, the greater the ratio of depth to radius of notch, the less influence does the strength of the material have on the fatigue limit of the notched steel specimen. The results would seem to indicate that with an even sharper notch the fatigue limit of the hardest steel would be no greater or even less than that of the mildest steel. This illustrates the great importance of avoiding abrupt changes of section and surface roughness in spring steel.

In Figs. 3 and 4 are shown results obtained with notched specimens of nickel-copper alloys in comparison with the previously described results obtained with unnotched specimens. The ductility of a metal as determined by tension test is not a reliable index of the damaging effect of notches. The fatigue limit of copper, for example, a metal with high ductility, is greatly affected by notches. This was pointed out by H. F. Moore and S. W. Lyon.[22] This fact is also illustrated in Fig. 3. The fatigue limits of both cold-rolled and fully annealed copper are reduced to about the same low value, although the ordinary endurance limit of the cold-worked metal is nearly twice that of the fully annealed metal.

With increase of nickel content to about 20 per cent, as illustrated by material *HE*-14, the fatigue limit of notched specimens is much greater than that of pure copper, although the endurance limit of the 20 per cent nickel alloy is only slightly greater than that of the cold-worked copper, *HF*-2.5. Comparison of the graphs for materials *HE*-14 and *HE*-4 shows that cold working improves the fatigue limit of notched specimens of the 20 per cent alloy. A comparison of the graph for material *HE*-4 with the graphs in the lower row of Fig. 3 and with the graphs in Fig. 4 indicates that the fatigue limit of specimens having this type of notch is practically unaffected by chemical composition or cold working, within a range of composition from 20 to 99 per cent nickel, although within this range the tensile strength and endurance limit vary greatly.

Evidently, therefore, for nickel-copper alloys as for steels, abrupt changes of section, surface defects, internal flaws, etc., tend to neutralize the effect of increased strength on the fatigue limit. If the notch is sharp enough, the effect of strength is neutralized for alloys having 20 to 99 per cent nickel. With even sharper notch, it is possible that this complete neutralization would prevail over an even wider range of composition.

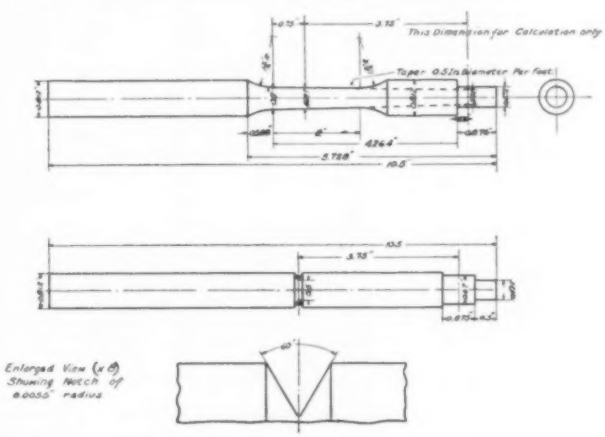

Fig. 6 Rotating-Cantilever Specimens Used in Fatigue Tests

The importance of surface condition for spring material, therefore, can hardly be overemphasized. On account of its hardness, spring material is especially susceptible to the effect of surface defects. Such material in service is never notched as deeply as were the specimens illustrated in Fig. 6. The shallower surface defects that occur in service, however, may be as damaging if the ratio of notch depth to radius is as great. That such defects often exist in springs is shown in a paper by F. C. Lea.[23] His fatigue tests on helical springs showed that the fatigue limit of the spring may be much lower than the endurance limit of the same material in the form of ordinary fatigue test specimens. He also showed that under such conditions the fatigue limit of a spring of high-strength steel may be little, if any, higher than that of a spring of mild steel. Lea's tests on springs, therefore, as well as the results of tests on notched specimens as shown in Figs. 1 to 4, show the importance of freedom from surface defects and internal flaws in spring material.

Corrosion-Fatigue of Spring Steels

In 1917 Haigh showed that the fatigue limit of brass in contact with ammonia is lower than that of brass tested in air. He also showed that the damage is greater if the fatigue and corrosion are simultaneous than if the corrosion is prior to the fatigue. In recent papers by the writer,[5,6,7,8,9,10] the combined influence of corrosion and fatigue has been discussed. It has been shown that even slight corrosion simultaneous with fatigue may cause

failure at nominal stresses far below the ordinary endurance limit. It was also shown that for most metals severe stressless corrosion prior to fatigue is much less damaging than even slight corrosion simultaneous with fatigue. The term "corrosion fatigue" has been used to designate the simultaneous action of corrosion and fatigue. The action of corrosion followed by fatigue has been called "prior-corrosion fatigue."

A stress-cycle graph representing corrosion fatigue is a curve approaching a horizontal asymptote, which may be called a "corrosion-fatigue limit." In Figs. 1 to 5 are shown corrosion-fatigue graphs for most of the alloys whose endurance properties in air have already been discussed.

As illustrated by the broken-line graphs in Fig. 1, the corrosion-fatigue limits for the two mild steels, and for the nickel steel in two degrees of hardness, differ very little. As illustrated by the three graphs in Fig. 2, the corrosion-fatigue limit for the steel of spring temper is actually lower than for the fully annealed steel. As shown in Fig. 3 of another paper,[6] for a steel of even greater strength the corrosion-fatigue limit is only 12,000, whereas for the same steel in the fully annealed condition the corrosion-fatigue limit is more than twice as great.

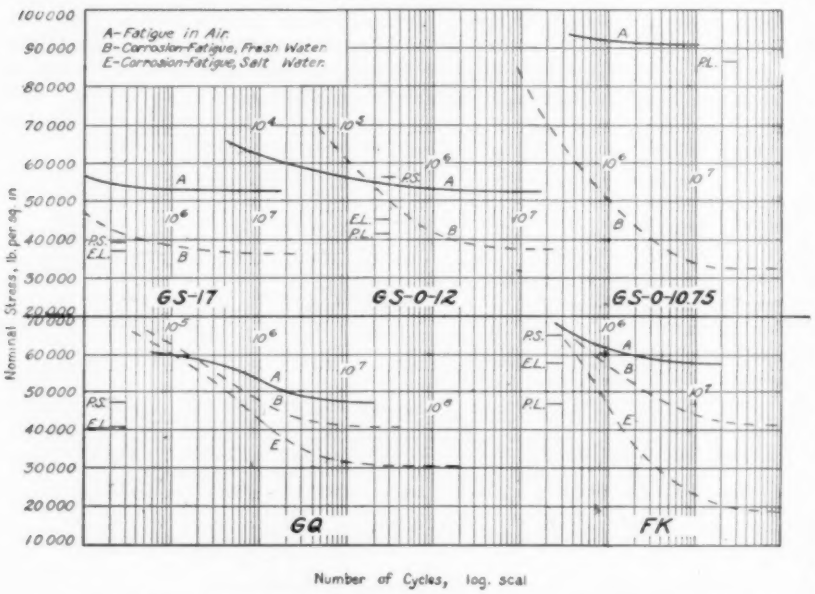

FIG. 7 FATIGUE AND CORROSION-FATIGUE OF CORROSION-RESISTANT STEELS

For steel of spring temper, as shown in Fig. 2 of the present paper and in Fig. 3 of a previous paper, the corrosion-fatigue limit in fresh water may be only one-fourth to one-ninth the endurance limit. In salt water, the corrosion-fatigue limit is still lower.

The rapidity with which corrosion fatigue manifests itself in these spring steels, moreover, is remarkable. As illustrated by the graph for *AZ*-O-7.5, in Fig. 2, in contact with water, failure would occur in 3 hours at a stress of 70,000, in 12 hours at a stress of 45,000, and in five days at a stress of about 20,000.

The fresh-water corrosion-fatigue limit for carbon and ordinary alloy steels ranging in tensile strength from 45,000 to 250,000 varies only from about 12,000 to 24,000. It is little affected by composition or heat-treatment unless such composition or heat-treatment affects the corrosion-resistance of the steel.

Results of prior-corrosion fatigue tests are also shown in Figs. 1 and 2. Graphs *F* represent results of fatigue tests of specimens that have been previously corroded for 10 days in fresh water. Comparison of these graphs with the corrosion-fatigue graphs shows that the effects of 10 days' stressless corrsioon followed by fatigue are much less than the effects of simultaneous corrosion and fatigue. It should be noted also that the prior-corrosion fatigue limit obtained under these conditions increases with increase in tensile strength, differing in this respect from the corrosion-fatigue limit. The phenomena of corrosion-fatigue and prior-corrosion fatigue as illustrated by the graphs in Figs. 1 and 2 suggest the idea that the effects are due to pits or notches in the surface, and that the notches produced by simultaneous corrosion and cyclic stress are usually sharper than the notches produced by stressless corrosion. This subject has been discussed in recent papers[7,8] and results have been presented showing the effect of stress, time, and number of cycles on the depth and sharpness of corrosion pitting. These results throw much light on the mutual effect of corrosion and cyclic stress. Much further investigation, however, is needed.

If sufficient chromium with or without other elements is added to increase the corrosion resistance of steel, the corrosion-fatigue limit is raised considerably above that for carbon or ordinary alloy steels. As shown in recent papers[5,6,7,8] the fresh-water corrosion-fatigue limit for corrosion-resistant steels is more than twice as great as for ordinary steels. It has been shown in recent papers,[7,8] however, that ordinary steels are severely pitted at a stress of only about 8000 lb. per sq. in. This stress, which has been called a "notching limit," is well below the corrosion-fatigue limit. It depends somewhat on time and number of cycles. It was also shown in these papers[7,8] that corrosion-resistant steels are not severely pitted at stresses below the corrosion-fatigue limit. For corrosion-resistant steels, therefore, the notching limit is about four times as great as for ordinary steels.

For many of the corrosion-resistant steels the elastic limit and proportional limit are low. This is a decided disadvantage for spring material. The steels represented in Fig. 7 have been selected from among those with highest elastic limit.

The upper row of this figure shows graphs for stainless steel in three degrees of hardness due to heat treatment. The group of graphs on the left represents fully annealed material. The group on the right represents material of spring temper. The elastic limit, proportional limit, and endurance limit are fairly high. As shown by the three broken-line graphs, the corrosion-fatigue limit of this material is little affected by heat-treatment. It is more than twice the corrosion-fatigue limit of ordinary steels.

The two groups of graphs in the lower row represent other corrosion-resistant steels with fairly good elastic limit. The graph on the right is a medium-chromium, high-nickel steel. This type has a higher elastic limit than does the high-chromium, low-nickel type, and hence would be more suitable for spring material. In view of the susceptibility of ordinary steels to corrosion fatigue, it is possible that the use of corrosion-resistant steels for this purpose may increase.

CORROSION-FATIGUE OF NICKEL-COPPER ALLOYS

Results of corrosion-fatigue tests of nickel-copper alloys in fresh water are shown in Figs. 3 and 4 in comparison with results obtained by endurance tests in air. As shown in Fig. 3, the corrosion-fatigue limit of copper and of the fully annealed alloy

HE-14 is not below the ordinary endurance limit. With increase in the endurance limit, due to cold working or to increase in the nickel content, the endurance limit rises above the corrosion-fatigue limit, as illustrated by the graph for alloy *HE*-4, by the groups of graphs in the lower row of Fig. 3, and by the graphs in Fig. 4. It should be noted also that the corrosion-fatigue limit of alloys having 20 to 99 per cent nickel is practically the same, although throughout this range of composition the endurance limit varies greatly. Under corrosion fatigue, therefore, most of the advantage of high strength due to cold working or chemical composition is lost.

As shown in recent papers,[7,8] for nickel-copper alloys the corrosion-fatigue limit corresponds to a fairly definite pitting limit. At lower stresses these alloys are not appreciably pitted. The superiority of nickel-copper alloys to ordinary steels under corrosion-fatigue, therefore, is somewhat greater than would be indicated by a comparison of their corrosion-fatigue limits as obtained under ordinary short-time tests. The salt-water corrosion-fatigue limit of nickel-copper alloys, moreover, is slightly higher (whereas the corresponding limit for steels is much lower) than the fresh-water corrosion-fatigue limit.

Corrosion-Fatigue of Copper-Tin Alloys

Corrosion-fatigue tests of copper-tin alloys, as illustrated in Fig. 5, gave somewhat erratic results, especially for the alloys of higher tin content. Results obtained with the 5 per cent alloy as shown in the lower row of the figure, however, seem to indicate that the intrinsic corrosion-fatigue limit of this material is about 21,000 or 22,000. The endurance limit of the fully annealed material is not quite high enough to reach this intrinsic corrosion-fatigue limit. The endurance limits of the cold-worked material, however, rise well above the corrosion-fatigue limit.

For the 8 per cent alloy, as shown in the middle row, the corrosion-fatigue limit seems to be slightly below 20,000. For the 10 per cent alloy, as shown in the upper row, the results are too erratic to permit definite conclusions. They seem to confirm the above-expressed tentative conclusions, however, that cold working has caused structural damage to this hard alloy.

On the basis of the results given in Fig. 5, therefore, the cold-worked 5 per cent alloy known as phosphor bronze seems to be the most suitable copper-tin alloy for spring material. Unless ways are found of avoiding damage due to cold working, the alloys containing 8 per cent and 10 per cent tin would be too erratic in behavior to be suitable as spring material. The corrosion-fatigue limit for the 5 per cent alloy is little, if any, lower than for the nickel-copper alloys. The salt-water corrosion-fatigue limit is practically the same as the fresh-water corrosion-fatigue limit.

Metallic Protective Coatings for Spring Material

In view of the results presented in Figs. 1 to 5, it appears evident that corrosion-fatigue is a frequent cause of failure of springs in service. Uncoated springs, therefore, exposed to even brief and intermittent contact with water, should be designed with the corrosion-fatigue limit in view. For such purposes corrosion-resistant steels may be more suitable than ordinary steels of higher physical properties. The possibility of raising the corrosion-fatigue limit of spring material by means of protective coatings, however, deserves careful consideration. An investigation of this subject has been started at the Naval Engineering Experiment Station.

Experiments have been made with a heat-treated chrome-vanadium steel, plated directly with chromium. Specimens so coated were subjected to corrosion-fatigue test in fresh water, and the results were compared with the results obtained with uncoated specimens of the same material. The results indicate that the corrosion-fatigue limit for coated specimens is little, if any, higher than for uncoated specimens. Experiments will be made to determine the effect of electroplating, first with copper or nickel, then with chromium.

Similar experiments were made with specimens electroplated with cadmium. The cadmium plating was done at the Washington Navy Yard. Two specimens were given a coating 0.0002 in. thick, and two other specimens were given a coating 0.0004 in. thick. The results are shown in Fig. 8 in comparison with the ordinary endurance and corrosion-fatigue graphs obtained with uncoated specimens.

As shown in the group of graphs on the left in Fig. 8, specimens coated 0.0002 in. thick have a corrosion-fatigue limit of about 35,000. This is more than twice the corrosion-fatigue limit of uncoated specimens. As shown in the group of graphs on the right, specimens given the thicker coating have a still higher corrosion-fatigue limit. Possibly if the corrosion-fatigue graphs for coated specimens were extended further by additional experiments for longer time, the difference between the corrosion-fatigue limits for the two thicknesses would grow less. Nevertheless, there seems to be an advantage in use of the thicker coating.

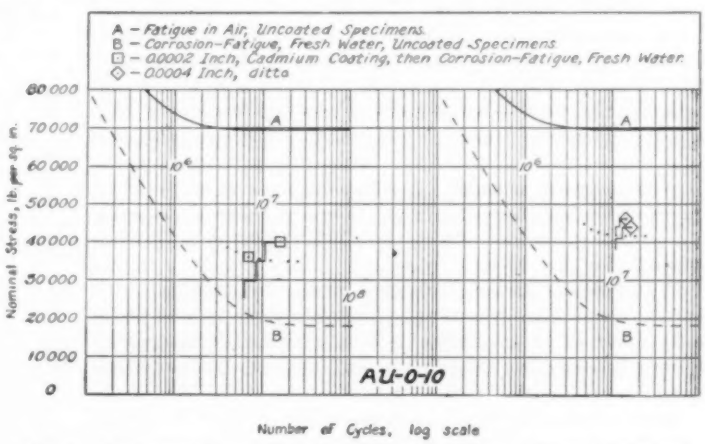

Fig. 8 Corrosion-Fatigue of Chromium-Vanadium Steel Specimens Plated With Cadmium

These preliminary experiments, therefore, indicate that cadmium plating, when properly applied, is of considerable value in raising the corrosion-fatigue limit of spring steel in contact with fresh water. This does not mean that steel springs, so coated, could be used for long periods under water. It does indicate, however, that cadmium plating would prevent damage due to corrosion-fatigue of springs subjected for short intermittent periods to the action of moisture. Investigation of the effect of metallic protective coatings of spring material is continuing.

Effect of Cycle Frequency on Fatigue and Corrosion Fatigue

The effect of cycle frequency on the endurance limit for a range of frequency between about 100 and 5000 cycles per minute is negligible. At much higher frequencies there is some evidence that the endurance limit is slightly higher. For cycle frequencies below 100 per minute, few determinations of the endurance limit have been made. It is possible that for frequencies below one per minute the endurance limit may be lower. At such low frequencies the time required for endurance tests to destruction is so long as to be almost prohibitive.

The effect of cycle frequency on corrosion-fatigue is of great importance. The interrelationship of the stress, time and number of cycles in causing penetration of metal under corrosion is still being investigated.

Summary

For spring steels the ratio of the endurance limit in tension-compression or repeated bend to the tensile strength is from 0.4 to 0.5. The ratio of the torsional endurance limit to the tensile strength is from about 0.2 to 0.3. The torsional endurance range is about twice the torsional endurance limit and is practically constant for any position within the elastic range. It seems possible, also, that in tension-compression or repeated bend the endurance range is practically constant within the primitive elastic range. Further investigation of this subject is needed.

Monel metal and other nickel-copper alloys can be obtained, by cold-working, with tension-compression endurance limit more than 50,000 lb. per sq. in., and with torsional endurance limit about 35,000 lb. per sq. in. No information is available as to the effect of varying the ratio between the superior and inferior stress of the endurance range. This subject needs investigation.

For copper-tin alloys the 5 per cent alloy, known as phosphor bronze, can be obtained with tension-compression endurance limit of about 27,000 lb. per sq. in. in the form of 1-in. round bars. In the form of smaller rod or wire, the endurance limit may be somewhat higher. Cold working, however, does not raise the endurance limit of this material in proportion to the increase in tensile strength. Nothing is known as to the effect on the endurance range of varying the ratio between the superior and inferior extremes of the range. This subject needs investigation.

The above-mentioned endurance limits are obtained with smooth specimens. The fatigue limit is greatly influenced by surface defects. Even shallow defects, if sufficiently sharp, may practically neutralize the effect of high strength on the fatigue limit.

Spring steels subjected to a range of stress while in contact with fresh water fail at a stress range only one-fourth to one-ninth the ordinary endurance limit. In contact with salt water the endurance range is even smaller. Under such conditions the advantage of high strength due to composition or heat-treatment is lost. The corrosion-fatigue limit depends more on electrochemical than on physical properties.

The corrosion-fatigue limit of corrosion-resistant steels is about twice that of ordinary steels. Corrosion-resistant steels are available with elastic limit high enough to be suitable for spring material. Electroplating ordinary steels with cadmium and probably with other metals more than doubles the corrosion-fatigue limit.

Nickel-copper and copper-tin alloys are subject to corrosion-fatigue, but are not appreciably pitted at stress ranges below the corrosion-fatigue limit. Under corrosion fatigue the advantage of high physical properties is neutralized.

The importance of protecting spring material against corrosion, especially when under a stress range, can hardly be overemphasized.

Acknowledgments

Acknowledgment is due to the following personnel of the Naval Engineering Experiment Station: To Captain H. C. Dinger, U. S. N., officer in charge, for encouragement received in this work; to Messrs. George F. Wohlgemuth and Lawrence Thompson, associate metallurgists; W. C. Stewart, assistant metallurgist; A. P. Vandermast, laboratorian; and John K. Amoss, leadingman-machinist, for assistance in the experiments.

Acknowledgment is also due to three manufacturers, The Firth-Sterling Steel Company, the International Nickel Company, and the American Brass Company, for generous cooperation by furnishing material.

Discussion

R. Eksergian.[25] The author has given us very valuable data as well as an interesting interpretation as to the properties of spring materials.

It appears from Tables 5 and 6 that the endurance limit for torsion averages somewhat less than 50 per cent of the endurance limit for tensile or bending stresses. That is, the torsion endurance limit is roughly from 20 to 25 per cent of the tensile strength of the materials. The remark that the endurance limit appears primarily dependent on the tensile strength and hardness alone and is quite independent of the ductility or elastic limit concurs with the works of Prof. H. F. Moore.

---

[25] Engineer, Baldwin Locomotive Works, Philadelphia, Pa. Mem. A.S.M.E.

A spring is subjected to a considerable variation in cycles of stress, and the stress range may take place between various minimum and maximum values. A very important question in the selection of a material is therefore the effect of unequal stress cycles on the endurance limit and the effect of alternations of stress about different mean values of stress on the endurance range.

The author's statement that the endurance range remains practically constant when the upper limit of stress does not exceed the elastic limit, particularly for torsion and very likely for direct stress, is of considerable importance in the selection of the proper working stress of a spring.

From observations made by the writer on oscillations of railway truck springs, it appears that a 35 per cent overload and 15 per cent underload is the maximum average stress range for an ordinary proportional spring. This means a stress range of 50 per cent of the work loading so that the endurance range should be equal to or greater than this value. That is, if f_w is the working stress and f_v the ultimate tensile stress, then, assuming the endurance range for torsion at $0.20\,f_v$, we have:

$$0.50\,f_w = 0.20\,f_v$$

therefore

$$f_w = \frac{0.20}{0.50} f_v = 0.40\,f_v$$

Thus the working stress would be about 40 per cent of the ultimate, and is also sufficiently below the elastic limit to prevent the average pack stress from passing into the plastic range and thus preventing a gradual settling of the springs. If the stress range is reduced, it would be desirable to increase the ratio of elastic limit to ultimate strength, so that surge loads will not greatly pass over the elastic limit.

Undoubtedly, in the selection of a satisfactory working stress the estimation of the concentration of stress is of importance, since the stress range should be based on the actual peak values.

The fact that the endurance limit is primarily dependent on the tensile strength alone, opens the question as to the importance of ductility. Since both plate and coiled springs are subject to occasional large overloads and deflections as well as considerable stress concentration, it appears to the writer that the ductile properties serve as a sort of safety valve for relieving the stress concentration and tending toward a better distribution of stress. Very often the major part of stress alternations for certain service is of relatively low amplitude, while occasionally the spring would be subjected to extreme amplitudes. In such a case the ductility of the material may become a factor of importance.

Thus we see the endurance strength of the spring demands a high ultimate strength, and for reducing peak loadings in the plastic range a high ratio of elastic to ultimate strength. This is consistent with a high-carbon steel. On the other hand, to allow for stress concentration, a lower carbon or plastic material is desirable. Finally, the flexibility of a spring is proportional to the square of the working stress, so that a high working stress is very desirable. This would indicate that a high ultimate strength and high elastic limit with maximum ductility are the primary qualifications of a good spring material.

J. M. Lessells.[26] This paper is further evidence of the continued interest being shown in the phenomenon of the fatigue of metals by a cyclic stress. In the present case we have a paper devoted entirely to spring material.

I shall restrict my remarks purely to the points dealing with the fatigue of metals and omit all reference to the corrosion fatigue data since I have had occasion in the past to discuss this entirely new field uncovered by Dr. McAdam.

I agree that the position of the endurance range with reference to the elastic range needs further investigation. This is a phase of fatigue of especial interest in spring applications since most of the stresses to which springs are subjected are never completely reversed. We are at present, in the Westinghouse Research Laboratory, investigating the condition where a steady stress has a variable one superimposed.

I agree that in tests between direct tension and compression it is necessary to take special precautions to avoid eccentric loading. This was done by P. L. Irwin[27] and is described fully elsewhere. In this connection it is well to point out that not only was good agreement found between the endurance limit by direct stress and by bending, for materials where the endurance limit was below the elastic limit, but this also obtained in the case of copper, nickel, and monel metal where the endurance limit was in excess of the elastic limit.

Material	Proportional limit, lb. per sq. in.	Endurance limit, lb. per sq. in. Direct stress	Bending
Annealed copper	1875	10000	11000
Annealed nickel	16000	38000	41000
Annealed monel metal	14000	40000	40000

Referring to the endurance limit as determined by bending and by torsion as given in Tables 5 and 6, columns 15 and 16, I note that the ratio of these values varies over quite a wide range, i.e., 0.84 to 0.38. On the basis of the maximum shear theory, this ratio should be 0.5. Mason,[28] using hollow specimens, found such to be true for low-carbon steel. I wonder if Dr. McAdam will comment on this point. This variation may be due to the use of solid specimens in torsion.

Dr. McAdam states that the endurance range has only been investigated for the complete reversal of stress for non-ferrous metals. It should be noted that Haigh[29] worked on the fatigue of brass for conditions of stressing other than complete reversal. I thoroughly agree, however, that more work is necessary.

Wheeler P. Davey.[30] Dr. McAdam mentions the remarkable rapidity with which corrosion fatigue manifests itself in spring steels. This corrosion fatigue is apparently tied up with the embrittling effect on steel of atomic hydrogen. This effect was described by T. S. Fuller of the Research Laboratory of the General Electric Co. in the Transactions of the American Electrochemical Society, vol. 32, p. 247 (1917) and his work has been confirmed by C. A. Edwards in the Journal of the Iron and Steel Institute, vol. 110, p. 9 (1924).

The crystal structure and inter-atomic spacings in iron and steel are such that at room temperature molecular hydrogen cannot pass through the crystals of the metal. However, it is possible for atomic hydrogen to pass through single crystals of iron or steel quite readily so that it is possible to measure on a manometer the pressure of molecular hydrogen formed by the recombination of the atoms of atomic hydrogen after they have passed through the crystals and have emerged from the surface. The presence of atomic hydrogen causes the iron or steel to become very brittle, and this brittleness apparently persists until the hydrogen has been driven out by heating the metal. Any source

[30] Professor of Physical Chemistry, The Pennsylvania State College, State College, Pa.

of atomic hydrogen is sufficient to produce the effect. The action of acids on the metal yields nascent (i.e., atomic) hydrogen. The corrosive effect of water or steam will also produce nascent hydrogen. It is inevitable that atomic hydrogen is produced at the surface of the steel during those electroplating processes which require the steel to be negatively charged in the electrolytic bath. I believe that T. S. Fuller took out a patent on a method of coating spring steel in such a way as to avoid the entrance of atomic hydrogen.

Of course, all of the foregoing has to do with the embrittling of the crystals themselves, and is in addition to such embrittling as may be caused by corrosion along inter-crystalline boundaries. The effect of inter-crystalline corrosion is to decrease the effective cross-section of the specimen. The effect of atomic hydrogen on spring steels is to cause brittleness of the crystals themselves.

H. W. Gillett.[31] Dr. McAdam's tentative conclusion that severely cold-worked copper-tin and copper-zinc alloys are damaged as to endurance through internal flaws rather than wholly through internal stress is most interesting, although since such flaws may doubtless be submicroscopic and still be effective, it will be difficult to establish their presence by other than indirect methods.

Internal stress in quenched spring steels, according to work reported by Mack and the writer in 1924,[32] appears to have considerable effect in lowering the endurance limit, since release of stress by prolonged tempering at such temperatures that the hardness and strength were either not at all affected or were actually slightly decreased resulted in marked improvement in endurance limit. The obvious conclusion was that for best endurance of heat-treated spring steels tempering times far in excess of those normally used would be of real advantage. It would be of interest to learn whether Dr. McAdam has had occasion to verify or disprove this conclusion.

The work reported to the American Society for Testing Materials and just referred to, very definitely corroborates Dr. McAdam's findings as to the effect of notches in hard spring steel. Un-necked bars tested in the Upton Lewis endurance machine, and so gripped that there was stress concentration at the grip analogous to that at a notch, gave fatigue limits (using the nomenclature Dr. McAdams suggests, to differentiate between "endurance limit" of a specimen without stress concentration and "fatigue limit" of one with stress concentration) of about 30,000 lb. per sq. in., no matter whether the tensile strength was 100,000 or 200,000 lb. per sq. in. Only the very hardest steels tested fell materially above this figure, and only the very softest one (of the heat-treated steels tested, materially below it. The true endurance limits on properly necked bars were of course about 50 per cent of the tensile strength. The 30,000 lb. per sq. in. figure agrees closely with Dr. McAdam's maximum of 27,000 lb. per sq. in.

Still earlier, Stribeck (*Z.V.D.I.*, vol. 67, 1923, p. 631) gave fatigue limits of 27,000 to 34,000 lb. per sq. in. for specimens gripped so as to set up local stress concentration for steels varying from 78,000 to 140,000 lb. per sq. in. in tensile strength. There seems to be no question that notches are more evil in very hard steel than in very soft steel. This fact leads to the further conclusion that spring steel ought to be as clean as it can be procured, since inclusions act as internal notches.

In regard to the behavior of cadmium coatings, it would be of interest if Dr. McAdam would state whether the coatings at a stress of 35,000 lb. per sq. in. are not above their own endurance limit, and what the tested surfaces look like.

In some analogous work at the Bureau of Standards with duplex metals, the softer metal being on the surface, there is indication that a crack or scratch in the soft surface is not readily propagated through the harder base, even though the coating is in good metallic contact with the metal underneath.

The effect of varying the position of the endurance range is something that must be settled before ordinary rotating-beam endurance tests can be applied to springs with complete certainty. Indeed, before that point can be effectively studied it is necessary to know more about the relation between rotary-beam tests and axial-loading tests with completely reversed stress. There is lack of agreement between some American and some English investigators on this point, and the subject is being studied at the Bureau of Standards. Our experience on that probelm to date leads us to feel that there is a very little amount of data on axial-loading tests in existence which have been carried out on apparatus in which sufficiently true axial loading was obtained to give data on which much reliance can be placed. The variation in endurance range with change in position of the range is generally found to be within 10 per cent, and deviation from axiality of loading that would not make errors of 10 per cent quite probably is more likely to be the rule rather than the exception. Hence we feel that Dr. McAdams torsional-endurance data are practically the only data on change of position of the range that are reliable enough to justify drawing conclusions therefrom.

Author's Closure

Replying to Dr. Wheeler P. Davey, I would say that the suggestion that the phenomena of corrosion fatigue may be due to influence of nascent hydrogen has been made by Dr. Speller and by Mr. Fuller in discussing previous papers[5,7] by the writer. It appears probable, however, that nascent hydrogen is not responsible for the effect of water in lowering the fatigue limit of steel. In the two-stage tests described by the author in previous papers,[7,8] the interval between the corrosion stage and the fatigue stage varies from a few hours to several days. This variation has no effect on the resultant fatigue limit. Damage persists, therefore, after the nascent hydrogen has had opportunity to escape.

A recent paper by T. S. Fuller[33] confirms the conclusion that corrosion fatigue of steel in water is not due to nascent hydrogen.

Corrosion fatigue affects practically all metals. The phenomena, therefore, must be explained by hypotheses that are applicable to all metals. As shown by the author in recent papers[7,8,34] the phenomena of corrosion fatigue may be attributed to the fact that cyclic stress accelerates the penetration of metal due to corrosion.

Dr. Gillett's conclusion that internal stress in quenched spring steels has considerable effect in lowering the endurance limit is in accord with results obtained at the Naval Experiment Station.

An investigation of the effect of cadmium coatings on spring steel is being continued. We have not yet determined whether a coating on steel that is stressed to 35,000 lb. per sq. in. is above the endurance limit of the cadmium. On account of the lower modulus of elasticity of the cadmium, however, the stress in the coating is much less than in the steel.

APM-51-6

Combined Stresses in Thick-Walled Cylinders[1]

By EARLE B. NORRIS,[2] BLACKSBURG, VA.

The paper describes some tests which were made on 11 thick-walled cylinders of high-quality gun steel, ranging in bore from 3 in. to 9.5 in., and with ratios of outside to inside diameters of 1.5, 2, and 3. To the author the evidence seems to warrant the conclusion that the maximum-strain theory of St. Venant is correct for cases of tension and compression in mutually perpendicular planes where the tension stress is the greater of the two.

FOR SEVERAL years past the Army Ordnance Department has been conducting an extensive research program at Watertown Arsenal upon thick-walled cylinders subjected to internal pressure, both within and beyond the elastic limit of the material. In addition to the information sought by the Ordnance Department, the data accumulated afford an opportunity to study the effects of combinations of tension and compression upon mutually normal planes and to test the various theories relative to the elastic strength of material subject to such a combination of stresses.

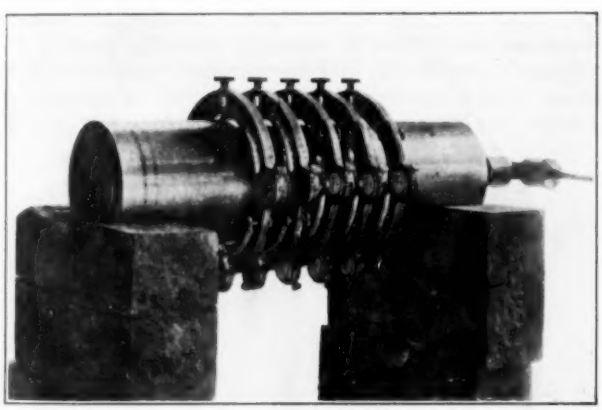

FIG. 1 TEST CYLINDER WITH GAGE RINGS SET UP FOR TEST

Many contributions have been made to the technical literature on this subject, some of them philosophical discussions and others based upon experimental data. We are still, however, in the dark on many phases of this subject of combined stresses. This paper is offered merely as one more contribution to the mass of literature in this complex field. It relates only to the case of tension upon one plane in combination with compression upon a plane normal thereto. In view of the apparent conflict of theories and of many of the experimental studies, any conclusions to be derived from this paper should be considered as being applicable only to conditions similar to those used in these tests.

DATA ON CYLINDERS TESTED

The particular series of tests with which this paper is concerned was made upon a series of 11 steel cylinders of high-quality gun steel, ranging in bore from 3 in. to 9.5 in. and with ratios of outside to inside diameters of 1.5, 2, and 3. The serial numbers of the cylinders, their dimensions, and the elastic limits of the steel in tension, as determined from tangential specimens, are as given in Table 1.

METHOD OF TESTING

A photograph of one of the cylinders set up for test is shown in Fig. 1. This cylinder is shown with five gage rings, each carrying three Ames dial gages. One of the gage rings with the dial gages is shown separately in Fig. 2. The sum of the readings of the two gages in the horizontal plane gave the diametral change in that plane. The change in the vertical plane was given directly

2	3	× 6	19	12	75,000
3	3	× 9	19	12	75,000
4	6	× 9	31	24	75,000
5	6	× 12	31	24	75,000
6	6	× 18	31	24	60,500 to 68,650 65,000 mean
7	8	× 12	40.5	32	67,000 to 91,000 77,125 mean
8	8	× 16	40.5	32	66,000 to 85,000 73,750 mean
9	8	× 24	40.5	32	64,750 to 76,350 70,750 mean
10	9.5	× 14.25	48	38	69,750 to 73,750 71,100 mean
11	9.5	× 19	48	38	64,700

by the single gage at the bottom of the ring, the adjustable screw at the top being necessary to carry the weight of the ring and to provide a vertical adjustment. In certain of the tests only three gage rings were used, all measuring dilations of the outside of the cylinders. In other tests each gage ring was used to determine the dilation of the cylinder at a particular annulus, the gage pins being inserted into radial holes drilled into the cylinder to the desired depth. These dial gages read directly to 0.0001 in. The observers on the tests were able to record readings to ap-

Presented at the Knoxville Meeting, Knoxville, Tenn., March 21 to 23, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

BY-LAW: The Society shall not be responsible for statements or opinions advanced in papers or...printed in its publications (B2, Par. 3).

proximately one-fourth of a division, or to 0.000025 in. On a diameter of 10 in. there would therefore be indications of unit deformations read to approximately 0.0000025 in. per in.

The cylinders were closed by steel spools having a slight mechanical clearance in the bore and fitted with self-sealing rubber packings bearing against the bore and held out by the pressure of the water. In the first tests an annular rubber sack was used between the spool and the bore of the cylinder, but this was later replaced by the use of C-ring packings. Fig. 3 shows one of the spools assembled, while Fig. 4 shows it disassembled.

FIG. 3 ASSEMBLY OF STEEL SPOOL USED FOR SEALING TEST CYLINDERS

Pressures were established by means of a Watson-Stillman high-pressure pump supplying water to an intensifier of 18:1 ratio. Pressures were determined by a Crosby test gage in the low-pressure line to the intensifier. The intensifier ratio was corrected for the mass and friction of the ram. The pressure readings thus obtained were checked at regular intervals against the pressures as shown by a coil of manganin wire in the high-pressure line to the cylinders. The electrical resistance of this manganin wire varies directly with the pressure to which it is subjected. In addition, the Crosby test gage was calibrated at regular intervals by the manufacturers.

STRESSES PRODUCED

Since the axial forces are carried by the spools rather than by the cylinders, it is evident that there are no direct axial stresses produced in the cylinders. There are two principal stresses produced in the metal, a radial pressure produced by the internal pressure and a tangential tension.

Referring to Fig. 5, in which

P_0 = unit internal pressure
R_0 = internal radius
R_1 = external radius
r = any radius at which the stress is desired
t = tangential tensile stress produced, and
p = radial compressive stress produced,

$$t = \frac{P_0 R_0^2}{R_1^2 - R_0^2}\left(\frac{R_1^2}{r^2} + 1\right) \quad \ldots\ldots [1]$$

$$p = \frac{P_0 R_0^2}{R_1^2 - R_0^2}\left(\frac{R_1^2}{r^2} - 1\right) \quad \ldots\ldots [2]$$

The derivation of these equations, which are generally credited to Lamé, will not be repeated here, but may be found in any standard text on mechanics of materials, or in Tschappat's "Ordnance and Gunnery," pp. 228–231. Being based upon theories of elasticity, they are applicable only within the elastic limits of the metal and assume that the cylinders are free from initial stress. These two stresses are the ones which are concerned in this study, and it is the purpose of this paper to show the relation of these two stresses to the elastic strength of the cylinders tested.

Since the cylinders were longer than the length subjected to internal pressure, it is well to examine the effect of this "overhang." It is clear that the ends of the cylinders projecting beyond the packing rings were not directly stressed, and that these ends would exert a restraining effect upon the expansion of the cylinders for a certain distance inside of the packing rings.

The deformation of these ends is shown on a grossly exaggerated scale in Fig. 6. The line A-B represents the original position of an element of the bore before application of pressure. The line A'-B' represents its approximate position under pressure. The deviations of A'-B' from the original position A-B can be taken as representing the radial forces exerted by the cylinder in resisting the hydraulic pressure. Obviously, if the cylinder is long enough, there will be a length from some point p at the right of the packing to a corresponding point at the other end in which the cylinder will expand freely and will exert a radial resistance in full equilibrium with the internal pressure. To the left of p, as we approach the packing, the overhang exerts a restraining influence and the radial resistance of the cylinder is not adequate to balance the internal pressure. This deficiency is transferred (by shear) to the overhang. At the extreme end we find that the cylinder has actually contracted from its original diameter, thus exerting an outward force. There is, evidently, a bending stress in this overhang, due to the fact that the reactions or radial resistances are not directly opposite the applied pressures. It remains only to find by test the extent of this end effect and to be sure that, for the purposes of these tests, the measurements of expansions of the cylinders are taken well within the straight sections of the cylinders.

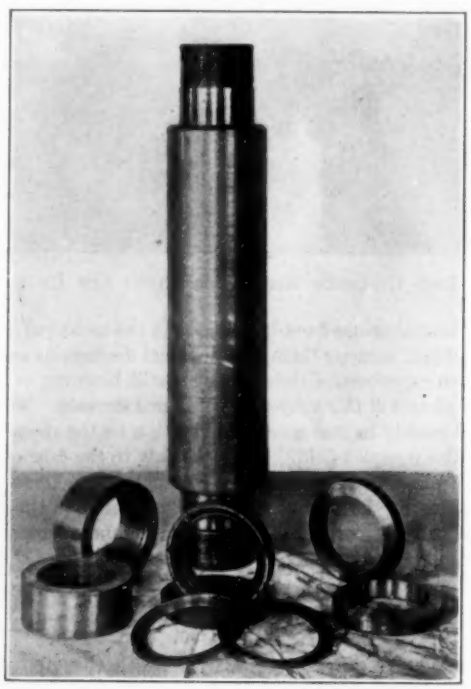

FIG. 4 STEEL SPOOL TAKEN APART TO SHOW PACKING

That length of the cylinder in which the elements remain straight under pressure must be free from bending stress, since there could be bending only where there was a resultant curvature of the elements.

Experimental Verification of Lamé's Laws

Lamé's Equations [1] and [2] should give the tangential tension and the radial compression at any radius r of a cylinder under a given pressure P_0. (As these equations are presented they both give positive values, although one is tension and the other compression.) The equations show that the tangential stress is the greater, but that both produce a shortening of a radial element and a lengthening in the tangential direction. Using the customary E to represent the modulus of elasticity and $1/m$ for Poisson's ratio, the tangential unit deformation e_t produced by the stresses of Equations [1] and [2] will be

$$e_t = \frac{t}{E} + \frac{p}{mE} \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

By the use of the arrangement of gages shown in Figs. 1 and 2, it is possible to measure the diametral enlargement of any annulus of a cylinder and to compare it with the theoretical enlargement given by Equation [3], provided the stresses are within the elastic limits, since these equations are based on the theory of elasticity. In the set-up of Fig. 1 each gage ring has its gage pins inserted into holes drilled to a given depth in the cylinder walls. Thus with five gage rings it is possible to observe the changes of diameter at five different annuli. This study was made of a number of cylinders at various pressures within the elastic limits of the metal, but the calculations and observations for a single case will serve to show the agreement between the observations and Equation [3]. Table 2 gives this comparison for cylinder

$1/m$ is taken as 1/3.

Table 2, which is typical of the results obtained from all the cylinders, shows a maximum deviation of the observations from Lamé's laws of 5 per cent and may be taken as a substantiation of his theories, if any such experimental proof were needed.

There are, however, several conflicting or varying theories as to how these two "true" stresses should be used to determine the limit of elastic resistance. There is tension in a tangential direction with compression exerted simultaneously normal thereto, or in a radial direction. Both produce a shortening of radial elements and a lengthening of tangential dimensions.

Theories of Combined Stresses

Rankine's Theory. Rankine, Lamé, and Clapeyron advanced the maximum-stress theory that, regardless of what the stresses acting in mutually perpendicular planes might be, elastic failure would occur only when one of the stresses reached the elastic

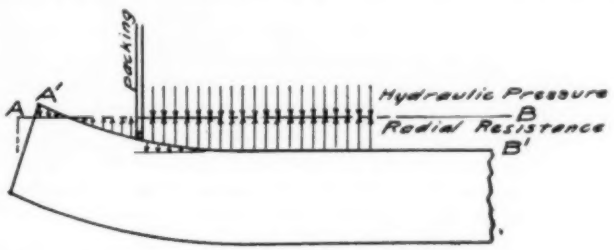

Fig. 6 Deformation at Ends of Test Cylinders Due to Unstressed Portion Beyond Packing Rings

limit of the material. This Rankine theory, so-called, has no following at the present time.

St. Venant's Theory. St. Venant advanced the maximum-strain theory that the material would remain elastic as long as the strain, or unit deformation, in any direction did not exceed the permissible strain as determined by the elastic limit of the material under simple stress. In the cylinders under consideration t is the greater of the two stresses, and the greater strain would be produced in the direction of t, i.e., tangentially. The combined strain thus produced by t and p is given by Equation [3]. According to St. Venant's theory this combined strain must be within the strain shown by a simple tensile test at the elastic limit, and, when that strain has been exceeded, the material is permanently deformed. Then if θ represents the elastic limit of the material in tension, the elastic resistance of these cylinders is reached when at any annulus

$$\frac{t}{E} + \frac{p}{mE} = \frac{\theta}{E}$$

or when

$$t + \frac{p}{m} = \theta \quad \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

Equations [1] and [2] are so written as to give positive values, although the one is tension and the other compression. Equation [4] is written with this in mind. Those who prefer to consider compression as negative in value may change the factor in the parenthesis in [2] to read $\left(1 - \frac{R_1^2}{r^2}\right)$, thus securing a negative value for this stress. This must be accompanied by a change of Equation [4] to read $t - \frac{p}{m} = \theta$.

Guest's Theory. Coulomb, Hartmann, and Guest, and more recently Duguet and Mohr, have held that elastic failure is in the nature of a shear or sliding, and that inelastic deformation will occur under a combination of stresses when the resultant shearing stress becomes equal to the shear produced by a simple stress at the elastic limit of the material. In a simple tension or compression test the maximum shear is in a plane making an angle of 45 deg. with the axis of loading, and its unit value at the elastic limit is

$$S_s = \frac{\theta}{2}$$

By the same analysis, the maximum shearing stress produced by tension and compression at right angles, as in the case under consideration, is

$$S_s = \frac{t + p}{2}$$

Hence, if the maximum-shear theory of Guest is applicable to this case, the elastic limit of the material would be reached when

$$t + p = \theta \quad \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

Some variations of this theory have been proposed. Coulomb attempted to consider the effect of internal friction upon the angle and value of the maximum shearing stress. Mohr's modification takes into account the fact that limiting stresses (elastic limits) in tension and compression are quite different for some materials. When these elastic limits are the same, Mohr's theory becomes the same as Guest's. This may be assumed to be the case with the material of these cylinders with which we are dealing.

Comparison of Test Data With Shear Theories

The experimental work done at Watertown Arsenal upon these eleven cylinders affords an opportunity to check these three principal theories with the data secured. Without reproducing all the observations and data taken, which would require many pages, an explanation of the methods used and the general results will be given.

As a preliminary step, the permissible pressures within the elastic limits of the cylinders were calculated by St. Venant's maximum-strain theory, which is the theory followed in American ordnance practice. These permissible pressures were then applied to the cylinders eight successive times, while readings of the external dilations were taken at pressure increments of 5000 lb. per sq. in. and at similar decrements as the pressures were removed.

Under this program, cylinders Nos. 1, 7, 8, and 10 showed a slight flow or permanent deformation at the pressures to which they were subjected. The other cylinders showed complete recovery, and plans were made to carry them to higher pressures. Cylinders 4 and 5, however, were then annealed for purposes which have no relation to this paper. They were therefore lost as far as any more definite location of their pressure limits is concerned. It is known that they supported elastically the pressures given in column 5 of Table 3.

Cylinders 2, 3, 6, and 9 were carried to higher pressures by increments of 2000 lb. On cylinder 11, unfortunately, there are no readings between pressures of 35,000 and 40,000, between which the elastic limit of pressure was reached. In carrying cylinders 2, 3, 6, 9, and 11 to higher pressures, holes were drilled into the walls and readings taken of the expansions at different annuli, as was explained in connection with Table 2.

Table 3 gives in column 5 the pressures at which the elastic limit of the metal was reached, as nearly as they can be located. Columns 2, 3, and 4 give in comparison the pressures at which the elastic limits would be reached according to the three general theories of combined stresses.

In calculating these, it will be noted from Equations [1] and [2] that tension and compression are greatest at the bore, i.e., when $r = R_0$. By substituting R_0 for r, expressions are obtained for the true tension and compression at the bore. According to Rankine's theory, permanent deformation will impend when t reaches the elastic limit θ of the material. Solving for P_0, according to this theory,

$$P_0 = \theta \frac{R_1^2 - R_0^2}{R_1^2 + R_0^2} \quad \ldots\ldots\ldots\ldots\ldots [6]$$

Under St. Venant's theory the stresses in tension and compressions at the bore must be combined by Equation [4]. Using a value of $^1/_3$ for $1/m$, this gives for the permissible pressure:

$$P_0 = \frac{3}{2} \theta \frac{R_1^2 - R_0^2}{2 R_1^2 + R_0^2} \quad \ldots\ldots\ldots\ldots\ldots [7]$$

By Guest's theory Equations [1] and [2] must be combined by means of Equation [5], which gives

$$P_0 = \theta \frac{R_1^2 - R_0^2}{2 R_1^2} \quad \ldots\ldots\ldots\ldots\ldots [8]$$

In applying these equations, the mean elastic limits of the cylinders were used. Reference to Table 1 reveals that for some of the larger cylinders there was a considerable variation in elastic limits as shown by different specimens. This is especially noticeable in cylinders 7, 8, and 9. There may be some question as to the wisdom of using the mean value instead of the minimum. However a cylinder could not deform permanently at one point without its being evident also at other points in the circumference. The higher elastic limit at one point will certainly exert some restraining influence upon sections of lower elastic limits. This question may be considered in interpreting the results of the tests on those cylinders.

Discussion of Table 3

A casual comparison of column 5 with the calculated values in columns 2, 3, and 4 will convince the reader that the St. Venant theory, as represented by column 3, comes nearest to the actual pressures sustained by the cylinders without inelastic flow. In

TABLE 3 THICK-WALLED STEEL CYLINDERS UNDER INTERNAL PRESSURE; PRESSURES AT ELASTIC LIMIT OF MATERIAL

(For dimensions of cylinders and elastic limits of material, see Table 1)

				40,000 −	

five of the cylinders (Nos. 1, 7, 8, 9, and 10) there was evidence of a slight inelastic flow at pressures somewhat below those indicated by St. Venant's theory. In the cases of cylinders 7, 8, 9, and 10 it will be noted from Table 1 that the physical tests showed a lack of uniformity in the metal. Since mean values of elastic limits have been used, it is possible that soft streaks as shown by the physical tests may account for the flow of these cylinders at lower pressures. Not only these cylinders but some of the others showed decided departures from circular sections when stressed considerably beyond their elastic limits. In cylinders 4 and 5 the elastic pressure limit may be above that indicated by St. Venant's theory but cannot be much, if any, below. These two cylinders were not tested to higher pressures than those given in column 5. Cylinder 2 is in agreement as closely as can be determined. Cylinders 3, 6, and 11 supported higher pressures than would be indicated by St. Venant's theory.

Altogether five cylinders failed to support without permanent flow the pressures indicated by St. Venant's theory; three supported higher pressures; and three were uncertain, but with the probabilities that two were higher and one lower. Thus the probabilities are six below and five above St. Venant's theory.

As another method of comparison, the sum total of the pressure limits for the eleven cylinders according to Rankine's theory is 456,380. For St. Venant's theory it is 379,000. For Guest's it is 291,900. In attempting to sum up column 5, the author has deducted 1000 from the values given for cylinders 1, 7, 8, 9, and 10. He has similarly added 1000 to the values for No. 4 and 5 and has used the means of the two limiting pressures given for Nos. 3, 6, and 11. This gives a total for column 5 of 373,700. This differs from the total for the St. Venant theory by only 1.4 per cent.

Summary

To the author this evidence seems to warrant the conclusion that the maximum-strain theory of St. Venant is correct for cases of tension and compression in mutually perpendicular planes where the tensile stress is the greater of the two. Certainly the evidence shows the theories of Rankine and Guest to be beyond possible consideration for stress combinations of this type.

Other studies indicate that the shear theory, as developed by Guest and Mohr, may be the most reliable for certain cases, namely, those where fracture can be definitely shown to be due to shear or sliding. In this connection, Fig. 7 will be of interest in showing the type of fracture in one of these cylinders which was carried to incipient rupture. These evidences of fracture show no relation whatever to shear. They rather show actual separation by a tangential movement or strain, the planes of fracture being generally normal to the direction of the tangential stresses. These fractures give supporting evidence to the probability of the correctness of the St. Venant theory in this case.

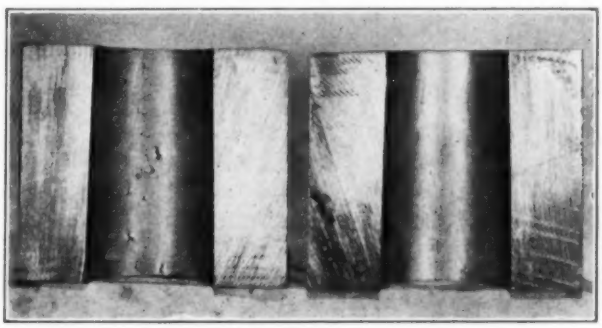

Fig. 7 Type of Fracture in One of the Test Cylinders

APM-51-7

Short Flanged-Tube Cantilevers Under Concentrated Radial Load

By WENDELL P. ROOP,[1] WASHINGTON, D. C.

The author gives results of tests of a short thin-walled tube fixed at one end and reinforced at the free end by a flange, which was loaded radially at the free end. The elastic deflections and ultimate strength were observed, and the author devises formulas for their expression. The strength and stiffness of an elastic ring are discussed mathematically in an appendix.

THE usual formulas for strength and stiffness of a cantilever become inapplicable when the length of the cantilever is not great compared with its depth, and when the external load is not distributed over the end section in accordance with the assumptions of simple beam theory.

Tests have been made on a simple type of cantilever structure consisting of two elements: namely, a thin-walled tube of a length eight-tenths its diameter, reinforced at its free end by a flange. This structure was loaded radially by means of a hook, and elastic deflections and ultimate strength were observed.

As a first approximation these two elements may be considered separately. The flange (or ring) may be supposed to be supported only at the ends of a diameter transverse to the load. Theoretical analysis of the action of a ring so loaded is given in an appendix. The tube may be regarded as a simple cantilever whose load is applied to its free end by the ring, supposed to be stiff enough to realize the distribution assumed by the simple theory. The first approximations thus obtained have been used to obtain nominal values with which to compare the experimental data.

Ring Stiffness. It is found that the ring and tube are not independent of each other. The ring receives support from the tube which is relatively greater as the ring is smaller. The change in transverse diameter under load P is

$$\delta = \frac{P}{ER} \frac{1}{[17\ (I/R^4) + 0.02\ (t/R)]}$$

R being the radius, assumed equal in tube and flange, I the sectional moment of inertia of the ring, and t the thickness of the tube wall.

Strength of the Tube. On the other hand, the ultimate strength of the tube is strongly affected by the stiffness of the ring, being

$$Q = 14{,}500 \left[1 - \frac{21}{[(P/10^3\delta) + 5]^2}\right] \text{lb. per sq. in.}$$

Q is the average shear in the tube section, obtained by dividing the load by the sectional area. The nominal shear, approximating the actual maximum shear stress, is twice as great.

These two formulas summarize the quantitative results of the tests. They evaluate the stiffness of the ring and the strength of the tube.

Strength of the Ring. As to the strength of the ring, no complete failure was obtainable, but departures from proportionate deflections began at loads that were small compared with the strength of the tube. The strength of the ring (in terms of nominal value of maximum stress) is of no special significance, as overstressing locally leads simply to local yield and consequent increase of area within which stresses moderately exceed the elastic limit.

Upon removal of a load thus locally exceeding elastic limits, stresses in the region overstressed are reversed, so that when reapplication of loads begins a complex pattern of initial stress already exists. The characteristic behavior is this: Up to loads not exceeding the previous maximum the structure gives deflections proportional to loads (aside from moderate hysteresis), and repeats this performance with little or no cumulative deflection, provided the maximum has not exceeded a certain value. If the load is increased beyond the previous maximum, the course of the first deflection curve is resumed and a new maximum established. The systematic determination of the critical loads, beyond which repeated application might lead to cumulative deflection, has not been undertaken, but it is clear that the ring is able to resist without cumulative deflections repeated loads leading to nominal bending stresses considerably exceeding elastic limits as determined in a tensile test specimen.

Cantilever Deflections. The cantilever deflections of the tube are found to vary considerably and unsystematically. Whether this is due to errors of observation or to irregularities in the action of the structure is not clearly established. An approximate or nominal deflection is found by adding the nominal bending deflection to *twice* the deflection in shear, obtained by taking the shear stress equal to its average value, or total load divided by sectional area of tube. The factor 2 may be roughly justified by the fact that in a tubular section in combined bending and shear the maximum shear stress is twice the average. Observed cantilever deflections are referred to such nominal values simply for purposes of comparison. It is found that observed values exceed the nominal values by as much as fourfold, though in many cases by less than this, and in one case the observed value is even less than the nominal.

There appears to be no reason why the results of these tests with models should not be applicable to large structures approximating the form and proportions of the models, similarly loaded, except in so far as continuity of structure is broken by riveted joints.

As to structures departing from the proportions of the models, it is naturally not possible to speak with like assurance. The governing action appears to be the stiffening effect of the ring in preventing wrinkling. At the ratio of length to depth adopted in the models, viz., $^8/_{10}$, the support received by the tube from the ring depends on the stiffness of the ring; if this is sufficient the tube develops a resistance to maximum shear approximating 30,000 lb. per sq. in. It is unlikely that this figure could be increased by a closer spacing of ring stiffeners.

Thus in a shorter cantilever the shear would be unchanged, and unless the shorter length of tube between ring stiffeners did have an influence, we should expect the equation as given for ultimate strength of tube to remain valid. On the other hand, as the lengths considered become greater, a proportion is undoubtedly soon reached at which bending is the predominant action, and buckling leads immediately to collapse. It is clear that longer cantilevers are unable to make effective resistance to bending beyond the buckling point, though that is exactly what is observed in shorter ones. Thinking always of the mode of ultimate failure, we see that there is presumably a critical length beyond which tubular cantilevers of a given diameter will begin to fail in bending. It is impossible to infer

[1] Lieutenant, Construction Corps, U. S. N., U. S. Experimental Model Basin, Navy Yard, Washington, D. C. Mem. A.S.M.E.

from the data what that critical length may be or how it would depend on the diameter. The choice between failure in shear and failure in bending is not simply a matter of comparing the nominal shear stresses and compressive stresses with the values at which they would cause failure in flat plates of similar proportions of length and thickness. More extensive tests are required on the point, but it is certain that within the rather wide

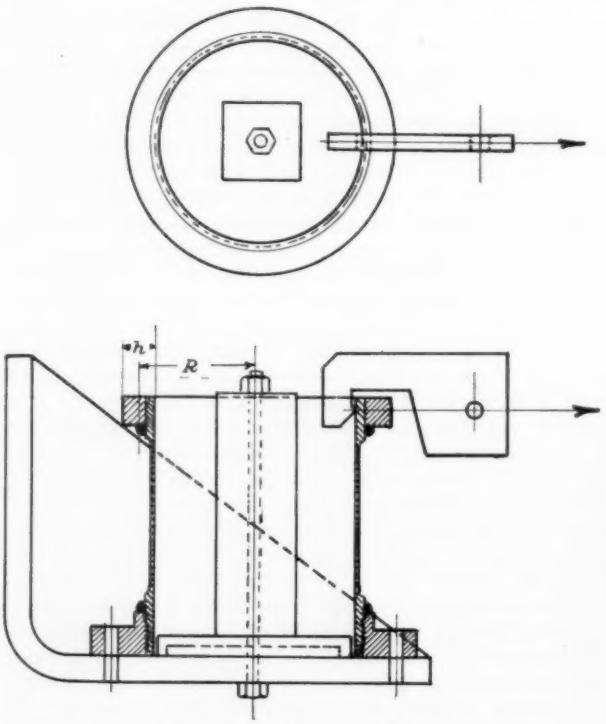

FIG. 1 LAYOUT AND LOADING OF FLANGED TUBE

range of wall thicknesses and ring strengths tested, tubular cantilevers of a length eight-tenths the diameter fail by wrinkling in the region of maximum shear. The shear intensity at which failure occurs depends on the ring stiffness as shown in the formula. Until better information is available, this formula may be used up to the limits, wherever they are, within which failure occurs in shear.

DETAILS OF THE TESTS

The chief results will now be taken up and justified in detail by reference to the data and the methods used.

In all, twelve models of varying ring stiffness and wall thickness have been tested. The deflections directly observed were simply those of four radii of the ring, taken from a post supported at the axis of the tube by rigid connections with the base, as indicated in Fig. 1. Two of these observed radii were transverse to the load; the sum of their increments gives the diametral deflection. That these two radii were not always exactly equal shows that the post did not function perfectly as a point of reference. But this does not affect the observations of diametral deflection.

These radial deflections were observed with calibrated "Last Word" dials, and the results plotted as a function of load.

The Diametral Deflection showed quite consistent values, with relatively little hysteresis or other departure from linear variation with load, up to certain elastic limits. In spite of the relative certainty with which each value of ring stiffness was determined, the spots in Fig. 3 are rather scattered, and obscure any moderate variation with h/R which might exist. It would be expected that ring stiffness would fall somewhat under the values calculated for the case of pure bending on account of the additional deflection in shear; this would be relatively greater at greater values of h/R.

The theoretical value of ring stiffness, or load per unit diametral deflection, is

$$\frac{P}{\delta} = 19.7\, E\, \frac{I}{R^3}$$

if the ring is thin in proportion to its radius, and if the load and supporting forces are concentrated at points. As soon as we have to deal with a ring attached to a tube, there is uncertainty as to where ring stops and tube begins, reflected in uncertainty as to the value of I. It is here assumed that the tube extends through the ring. In calculating I, no material enclosed between the two cylinders bounding the tube was included. The support afforded to the ring by the tube is accounted for by the term $0.02\, Et$, which is dimensionally correct but empirically determined. In case of a jointed connection between ring and tube the joint would form the boundary.

The addition of the term in tube-wall thickness gives us calcu-

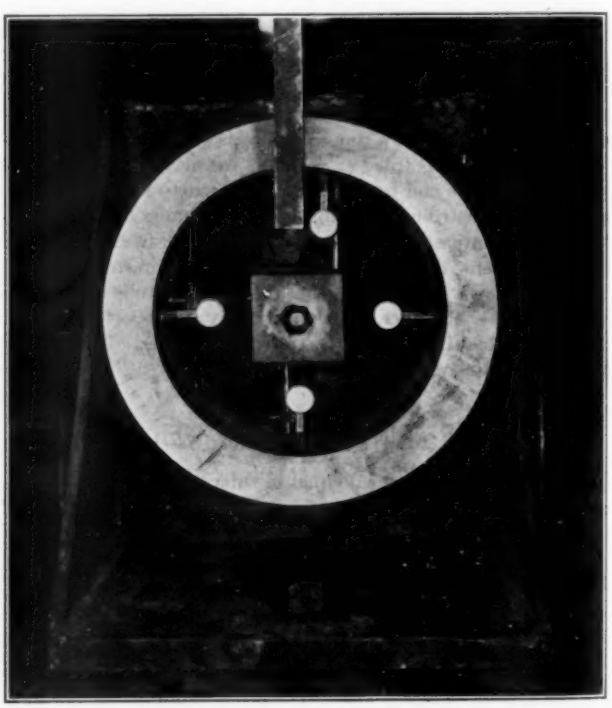

FIG. 2 TOP VIEW OF LAYOUT

lated values of ring stiffness which agree fairly well with those observed. The formula which represents the observed data best is

$$\frac{P}{\delta} = E\left[17\,\frac{I}{R^3} + 0.02\, t\right]$$

In Fig. 3 is plotted the ratio of observed ring stiffness to that found from this formula.

In order to make this formula applicable to similar structures of different size, it may be written

$$\frac{P}{\delta} = ER\left[17\,\frac{I}{R^4} + 0.02\,\frac{t}{R}\right]$$

Since the quantity in brackets is of zero dimensions, no confusion in units can arise. The above comment is all directed to the diametral deflection taken transverse to the load. The relative precision with which these deflections were observed extends only to certain limits of load, beyond which deflections exceed values proportionate to the load. In models 9 to 12 closely spaced load increments made it possible to follow the deflections rather closely as they varied with load, and it was found that diametral deflections are affected to a certain extent by whatever affects radial deflections parallel to the load, especially with respect to the proportionality limits. These limits, in the case of diametral deflections, need not indicate that bending stresses at the side points have become excessive, but may only show that deflections have occurred elsewhere in the ring or in the tube which have altered the stress distribution. This matter will be discussed further in connection with ring strength and cantilever deflections.

The rather close agreement of the empirical formula with that obtained analytically for the case of pure bending under concentrated external forces, indicates that the conditions under which the ring worked in the tests did not depart greatly from those assumed in the mathematical study. This agreement may be accepted as also affording partial confirmation of the theoretical results for load divided between front and rear points, although such divided loads were not applied to the steel models. It is

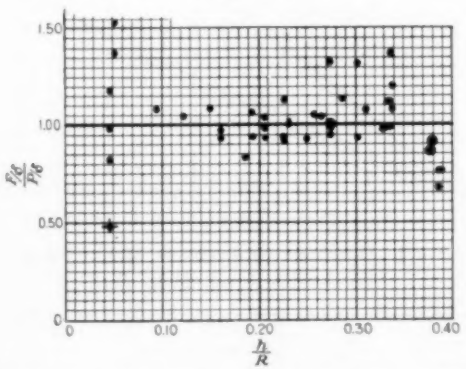

FIG. 3 RING STIFFNESS. LOAD PER UNIT TRANSVERSE DIAMETRAL DEFLECTION

$$\text{Ring stiffness } \frac{P}{\delta} = E\left[17\,\frac{I}{R^3} + 0.02l\right]$$

$\frac{F/\delta}{P/\delta}$ = ratio of observed to calculated ring stiffness

h/R = ratio of width of ring to radius

worth noting that the stiffness of the ring under divided load is much greater than under undivided load.

Ultimate Tube Strength. Each model was ultimately loaded to the maximum it would carry. The normal ultimate failure was caused by wrinkling in the sides of the tube wall and so gave a value of ultimate tube strength. In various cases high values of load were reached which fell short of the ultimate wrinkling load. All the data are plotted in Fig. 4. Large and permanent deflections of the ring occurred in all cases before the wrinkling load was reached. On the other hand, the failure in wrinkling was essentially of unstable mode, and up to the moment at which wrinkling occurred no distress in the tube was apparent. The wrinkling loads were very definite. The ordinate in Fig. 4 is the wrinkling load divided by the sectional area of the tube; to obtain the nominal maximum value of shear stress in the tube section, this should be doubled. In a purely empirical way it is noted that this shear intensity at the wrinkling load depends on ring stiffness. The evidence as to the functional relation is contained in Fig. 4. The values of ring stiffness, in load per unit diametral deflection, are observed values; calculated values might have been used on models 1 to 8, but in models 9 to 12 the rings were so slender that the wrinkling load could hardly be approached unless the ring were somehow supported. The support used consisted of a transverse brace like the stud in a link of anchor chain. This reduced the diametral deflections to about one-third or less what they would have been without

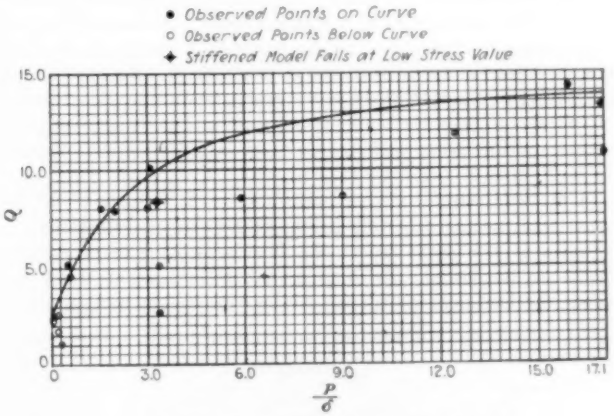

FIG. 4 ULTIMATE STRENGTH OF TUBE

$$Q = 14{,}500\left(1 - \frac{21}{[(P/\delta) + 5]^3}\right)$$

P/δ = ring stiffness, load per unit diametral deflection in 100,000-lb. units

Q = wrinkling load ÷ tube-section area in 1000-lb. units

it; this mode of stiffening the ring operates to increase the effectiveness of the resistance of the tube to shear just as well as a heavier ring section. As an example of this take model 10. With the ring bare it could not be loaded beyond an average shear stress of 2600 lb. per sq. in. without excessive ring deflections, and, according to Fig. 4, near approach to wrinkling. When a heavy cast-iron ring was slipped over the flange ring and wedged tight, the average shear stress was run up to 10,700 lb. per sq. in. with no distress anywhere; the diametral deflection was substantially zero. With a light transverse brace, diametral deflections were about one-sixth those of the bare ring and the tube wrinkled at 8000 lb. per sq. in.

In Fig. 4 ultimate strengths are plotted on ring stiffness. Since in a general way those models with the heaviest rings also had the thickest walls, it might be supposed that the variation with ring stiffness is spurious, and that it is the wall thickness that really determines the ultimate value of shear stress. The case of model 10 already cited, and other similar cases, offer convincing proof that the ring stiffness is actually the controlling factor.

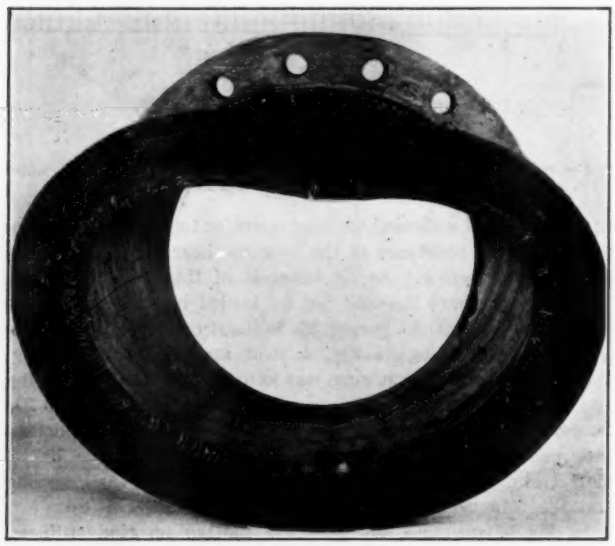
Ring Strength. Rupture of the ring was in no case obtainable, but departures from proportionality of deflections began at very small load. Radial deflections in line with the load were subject to error due to motion of the datum post, but again this did not affect diametral deflections. The diametral deflection parallel to the load was compared with that transverse to the load. The calculated values of the first is about 10 per cent greater than that of the second, and this figure is verified on the average, but shows larger values in thick rings, probably due to deflections in shear, which would be especially great in way of the point of application of the load. It is at this point that the ring is most heavily stressed and that the strength limit will first be manifest.

The load at the strength limit of the ring cannot be as accurately defined as the two quantities already dealt with. Long before there is any question of rupture, we run into ring distortions which completely alter the form and hence the stress

distribution in both ring and tube. This is true even of the heaviest ring sections used in the tests, so that rupture of the ring was not obtainable except in one case in which small cracks opened in a weld, and set a limit to the load that could be carried. (See Fig. 5.) However, the rings tested were all of solid rectangular section; doubtless sections stiffened by coring would act differently.

The conditions of loading of the ring are believed not to depart greatly from those of a straight beam, so far as failure at the section of maximum bending moment is concerned, so that study of rings of special sections is unnecessary. Sections which would fail in a stable mode in a straight beam may be expected to fail also in a stable mode in the ring, and with rings of such sections ultimate strength has no exact significance with respect to structures of the type studied.

A strength limit based on appearance of permanent deflections also meets with difficulties, as permanent deflections, especially at the point where the load acts, appear practically from the beginning. Data on radial deflections at the point where the load acts are subject to error due to the motion of the



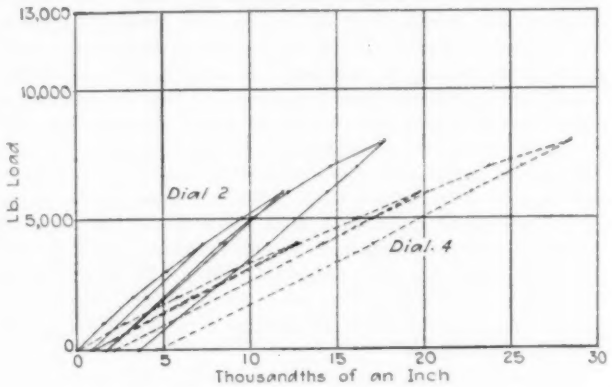


FIG. 5 RUPTURE OF RING DUE TO SMALL CRACKS OPENING IN WELD

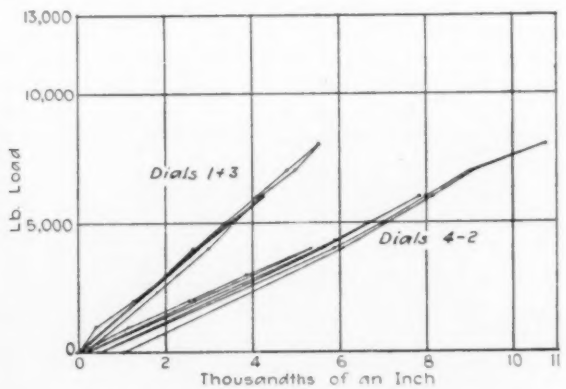
datum post. No measurements of a single radius have been used in reducing data for quantitative results. In a qualitative way, however, radial deflections can tell us something about what is happening, especially as the deflections at the load point are large compared with the probable motion of the datum post.

The general nature of the behavior of all models may be illustrated by No. 6; the data for this model were especially clear and consistent, yet the features indicated were typical of all models. Deflections on the initial loading are shown in Fig. 6. The transverse diametral deflections are consistent and proportional throughout; the parallel diametral deflections are almost equally so, but show a value almost twice the transverse one instead of 10 per cent greater as calculated.

The radial deflections at the point of load and opposite (marked stations 4 and 2) are plotted separately. They show that both points moved in the direction of the load at rates that increased with increasing load. Removal and reapplication of the load gives the characteristic behavior already described.

The flange in this first run was 2.42 in. wide by 0.95 in. thick, and the wall thickness 0.05 in. After the first run the flange was reduced in width. The removal of this material had the effect of partially restoring the original unstressed condition, so that subsequent first runs after machining showed similar



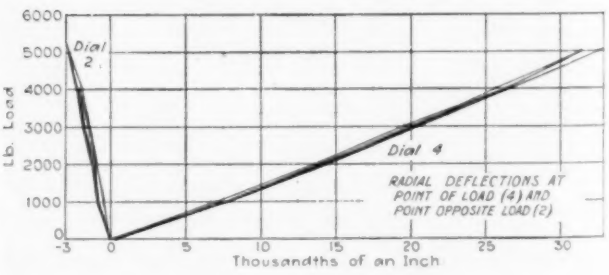


FIG. 6 OBSERVED DEFLECTIONS, MODEL NO. 6
(Initial loading; flange width, 2.42 in.)

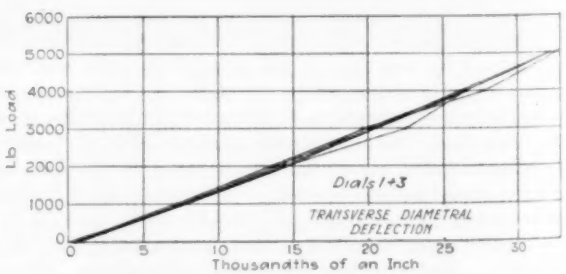

FIG. 7 OBSERVED DEFLECTIONS, MODEL NO. 6
(Flange width, 0.90 in.; deflections within proportional limits on enlarged scale)

effects, but with departures from a straight line not quite so pronounced. A test in compression instead of tension showed loops that were much wider, and even the transverse diametral deflec-

tions were to some extent affected. Test with a wide hook showed rather irregular results.

After these special loadings, the model was retested in tension as in the initial run, but with flange width of 0.90 in. Efforts were made to improve the fixity of the datum post, but without affecting it much. Its motion is believed not to have amounted to more than about 10 per cent of the radial deflections at sta-

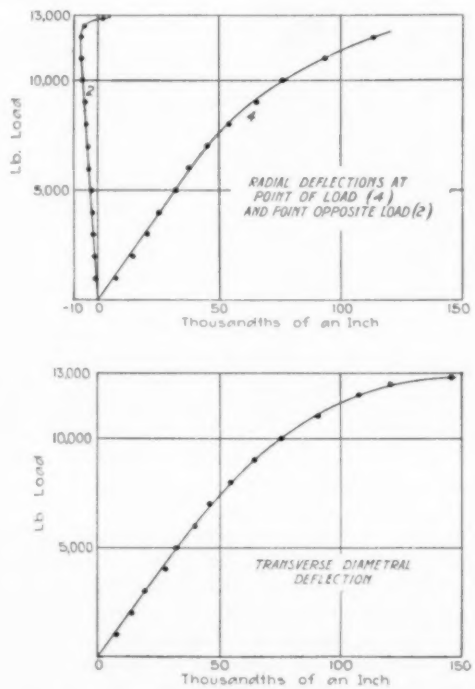

FIG. 8 OBSERVED DEFLECTIONS, MODEL NO. 6
(Failed at 13,930 lb.; flange width, 0.90 in.)

tion 4. Up to the previous maximum all deflections were consistent and linear, as shown in Fig. 7. Ring stiffness now being greatly reduced as compared with that in initial test, the motion at station 2 is opposite to the load in direction. The point of yield of the cantilever is clearly marked in Fig. 8 by the reversal of the deflection at station 2 (see below). But no such clear indication of ring-strength limit is to be found.

Up to the limit to which the load was carried in removal and reapplication, it was found that after the initial loading the deflections were substantially linear. Doubtless there is a critical load beyond which each successive reapplication of the same load would result in increased deflection. Such a point, however, has not been found, and for the immediate purpose it is unnecessary to find it. If ring stiffness is in itself of no great significance, the ring can be depended on to withstand any load that the tube will withstand, and the limiting action would be that of local stress in way of the load. In the commoner case in which ring stiffness is the controlling feature, the formula for ring stiffness given above will serve as a guide.

The only case not covered by these observations is that of a lightened ring section of great stiffness and small strength, which, by failure through instability, might establish a definite limit to ring strength. Such a section would be handled in design as in a straight beam, and the maximum bending moment is calculated to be

$$M = \frac{FR}{4}$$

which is just what it would be in a straight beam of length $2R$ with fixed ends.

In order to obtain further confirmation of the ring formula, and to obtain data on the stress distribution in the ring, especially under divided load, a photoelastic study was made of two rings 4 in. in diameter; they were supported at the two ends of the horizontal diameter, and loaded with equal weights at top and bottom. Under these circumstances analysis shows the bending moments to be zero at the points of support, and this is verified experimentally; the maximum bending moments and stresses appear to occur at the two load points, but the maximum is rather sharp, and the highly stressed area adjoining is not extensive. Under these circumstances it is not surprising to find that observed maximum moments and stresses are only about half the calculated values. A feature not studied analytically is the distribution of moment and stress around the ring. An extended region around the quarter-points is seen to be rather highly stressed, though the maxima at the load points are definitely higher. The isochromatics, lines of stress, and curves of tangential stress are shown in Figs. 10, 11, and 12. They serve to emphasize the difference between the loading used and loading in ordinary tension at opposite points, as in a chain. The latter case is much simpler and has been studied repeatedly. In one feature, however, the two cases are similar, viz., both show actual strength limits which are higher than stresses calculated from bending loads would indicate. A rather broad analogy with the action of a gun which has been subjected to auto-frettage exists.

FIG. 9 AXIAL SECTION OF MODEL NO. 6

The photoelastic study was made by the Heat and Light Division of the Naval Research Laboratory, Belleview, D. C.

In connection with ring strength we may finally note again the interdependence of deflections in different parts of the ring as soon as elastic limits are exceeded locally. Radial deflections at the load point and point opposite show a marked tendency to pass proportional limits at the same load, although the calculated stress at the first point is about four times that at the second. The photoelastic study, although it dealt with a loading different from that used in the steel models, nevertheless indicated in general that the stress in way of point of load reaches a rather sharp maximum, but also has high intensity over extended regions elsewhere. The departure of deflections from proportionality does not become appreciable until local stresses about the point of maximum stress have exceeded the elastic limits of the material over a moderately extended region. But when the stresses about the quarter-point reach excessive values, the non-elastic yield tends to become general throughout the structure, because the maxima there are flatter. Undoubtedly the tube enters into this matter also, so that the photoelastic results have only a general bearing on this point. It is mentioned in detail in order to give an example of the inapplicability of analysis based on elastic action in a complex structure to questions of strength involving stresses exceeding elastic limits.

Cantilever Stiffness is indicated by the data obtained with less certainty than any other quantity investigated. Cantilever

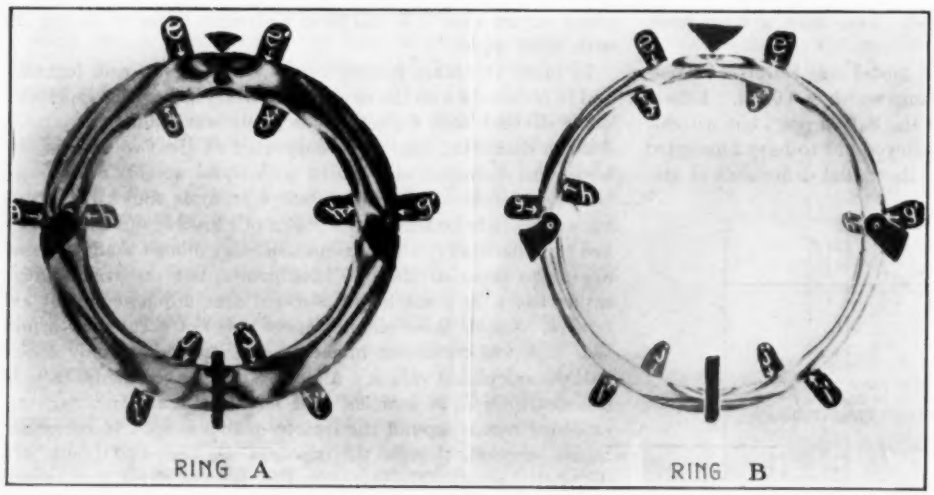

FIG. 10 ISOCHROMATICS UNDER DIVIDED LOAD

is about 15 per cent. The motion of the datum post is more difficult to estimate, but changes were made in the hope of reducing this motion. The first of these changes effected a great improvement; it consisted in inserting a plate under the post as shown in Fig. 1, recessed so as to bear only around the circumference. This eliminated warping of the back plate as a source of error. Later all connection with the back plate was dispensed with and the post supported by a diaphragm plate welded to the inside of the base of the tube. This eliminated the threaded connection of tube to flange and the bolted connection of flange to back plate, but no improvement in data appeared to result. The motion of the post is believed to be small because after these changes the connection of the post with the base of the tube is as direct as it is possible to make it, because the stress on the post and diaphragm on which it rests is practically nil, and because the transverse radial deflections were observed to be very nearly equal.

Nevertheless, the cantilever deflections obtained were very erratic, and no generalizations about them are permissible. It is worth noting, however, that they are not inconsistent with the assumption of a rather heavy shear concentration, such as would cause deflections greater than nominal without altering the general nature of the action of the structure as failure is approached. Such a shear concentration may be supposed to depend on wall thickness and on accidental non-uniformities

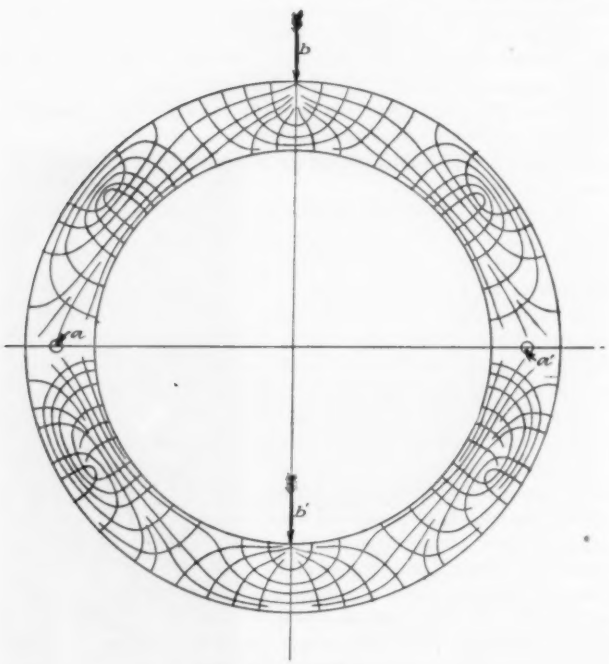

FIG. 11 STRESS LINES
(Ring loaded at b and b'; supported at a and a'.)

deflections were not observed directly at the ends of the transverse diameter, but were inferred from the radial deflections at station 2, the point opposite to the load. Under tensile load this point, of course, moves outward with respect to the center of the ring. Since the center of the ring moves in the direction of the load, station 2 may move either with or against the load, depending on whether the cantilever deflection is greater or less than the ring deflection.

The ring deflection at station 2 is calculated to be 0.384 times the transverse diametral deflection. This ratio is applied to the observed diametral deflection, and the result combined with the observed radial deflection at station 2. Errors in the cantilever deflection so found may arise in motion of the datum post, and in departure of the actual ratio from its calculated value. The error in the ratio is probably less than the departure of actual from calculated transverse diametral deflections, which

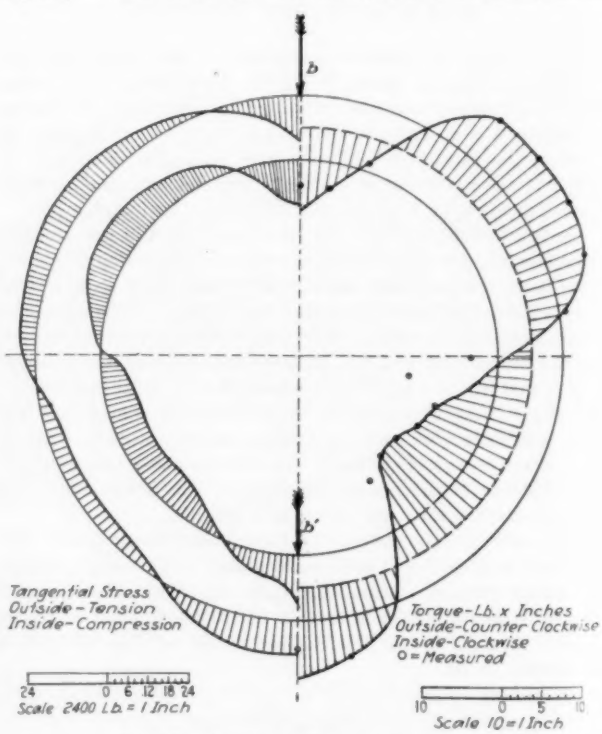

FIG. 12 CURVES OF TANGENTIAL STRESS

of various sorts such as would determine the pattern in which wrinkling will occur on failure. A feature of importance is the buckling at the point of maximum compressive stress in bending. The formula given above for ultimate strength of the cantilever takes no account of the bending load; the justification for this lies in the facts about buckling. Failure of the cantilever was due to wrinkling in the sides and was unstable

FIG. 13 MODEL NO. 6, SIDE VIEW

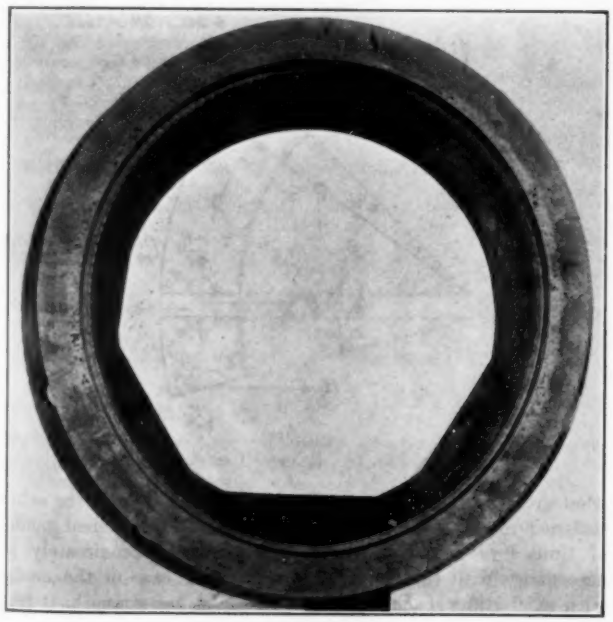

FIG. 14 MODEL NO. 6, END VIEW

in mode. Ultimate loads actually carried were many times those which consideration only of the compressive stresses at the buckling point would indicate to be possible. The slenderness ratio of an axial section of one side of the tube is very high, as may be appreciated by looking at Fig. 9. The curvature of the tube wall undoubtedly assists it to withstand buckling, but the loads at which buckling actually became noticeable were still less than the ultimate wrinkling load. In addition, buckling was not marked by any distinct discontinuity in the cantilever stiffness. Taking all these facts into consideration, it is clear that at loads approaching the limit of cantilever strength the action in buckling is of little or no direct influence.

Indirectly, buckling probably does have some effect on ultimate strength by initiating departure from the cylindrical form, and furnishing a starting point for the wrinkles. The tube falls into a series of folds which spread from the center where buckling occurs. When cantilever stiffness is plotted as a function of load, a roughly periodic variation occurs which suggests that the stiffness drops away when a new fold begins to form, and recovers as the stress is redistributed in consequence, until the wrinkling point is reached. Effects of this sort are probably quite sufficient to explain the erratic character of the data on cantilever stiffness.

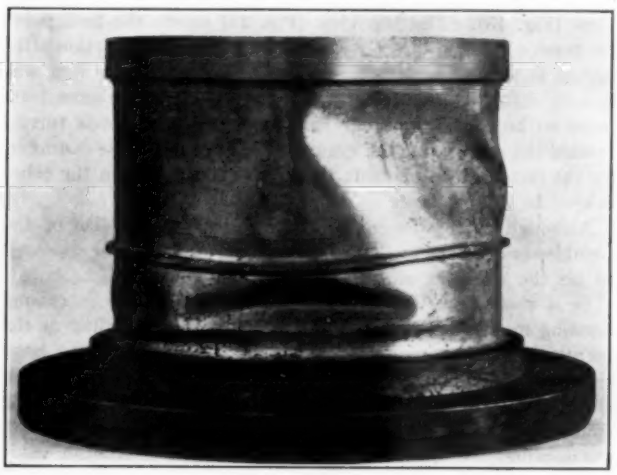

FIG. 15 MODEL NO. 10, SIDE VIEW

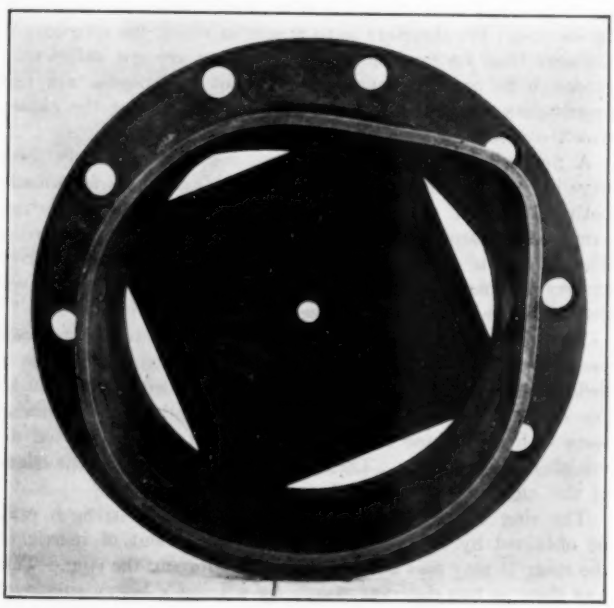

FIG. 16 MODEL NO. 10, END VIEW

The tests show, however, that these effects are unrelated in a large way to the ultimate loads, which depend consistently on values of average shear in the tube section, regardless of the buckling loads.

Figs. 13 to 16 have been chosen from the photographs which were taken of all models after failure, to illustrate typical patterns. In each of these cases the deflections have been carried considerably beyond the point at which the load passed its maximum

value, in order that the nature of the folds might be made more apparent. This partly obscures the facts as they develop under increasing load, which are as follows: The first sign of distress in the tube is a slight bulge at the base, in way of point of loading if in tension. This does not disturb the deflection curves in any unmistakable way, and the buckling does not immediately increase much. As the load goes on increasing, however, yield begins to be apparent in the deflections, the buckling increases strongly, and shortly wrinkles appear suddenly, after which the maximum load will not again be accepted.

In No. 6 the buckle appears at the center of a symmetrical series of wrinkles, turned about 30 deg. to the left in the side view (Fig. 13). The top view (Fig. 14) shows the load point (in tension) turned directly downward; the ring distortion after failure is seen to be small. In No. 10 (Fig. 15) the ring was greatly distorted by the ultimate load, and would have been more so but for the transverse brace. The buckle is turned toward the reader, but the symmetry of the wrinkles is disturbed by the fact that on one side they come above and on the other below the ring stiffener.

Although there was considerable variety in the size of the wrinkles in different models, the essentials of the action appeared to be the same in all.

It is clear that the tube continues to resist the increasing bending moment after buckling has occurred. Buckling at the point of greatest nominal compression must somehow have the effect of shifting the compressive load to material better adapted to carry it; it cannot, of course, eliminate bending effects, which are inherent in the manner of loading. In fact, the compressive stresses must have a greater maximum value after buckling has shifted the load to fibers nearer the neutral axis. Nevertheless the fact is that the structure withstands loads up to several times that at which buckling becomes apparent to the eye. We therefore have a case in which the structure is stronger than its weakest part. The data are not sufficiently extensive to permit generalization about such cases, nor has opportunity occurred for a detailed investigation of the causes which control the form of the wrinkle pattern.

A number of incidental variations were tried. Early tests were in compression, later ones in tension. Six tests were made both in tension and compression. The diametral deflection averaged the same in both within limits of observational error. The cantilever deflection appeared to be about one-quarter greater in tension, but in view of the variability of cantilever deflections, no great significance is attached to this result.

In three tests a wide hook was used, which spread the load over a sector of about 60 deg. This did not alter the cantilever deflections, but diminished the diametral deflections about 15 per cent on the average. In the photoelastic studies similar tests with distributed load were made, and those indicated diminished stress values. The maximum stress came at the edges of the surface through which the load was applied.

The ring stiffness necessary to develop tube strength may be obtained by increasing the sectional moment of inertia of the ring; it may also be obtained by reinforcing the ring. This was done in two different ways: by placing a heavy ring over the ring flange and wedging the two into intimate contact; and by inserting a cross-piece transverse to the load, like the stud in an anchor-chain link.

All the models were turned from seamless drawn tubing. The heavier ring flanges were welded on, but otherwise the models were all of unbroken metal, with one exception. In all but three the tubes were simple cylinders; in those, three types of tube reinforcement were introduced. In one, the tube-wall thickness was increased for two-fifths the height above the base. In one, a circular stiffener was placed at two-fifths height. In one, axial stiffeners were riveted to the uniform tube wall, and this was the only case in which the continuity of the tube wall was interrupted by rivet holes or joints.

With respect to cantilever strength, the increased thickness at the base and the circular stiffener gave results not different from those with the unstiffened tubes; the riveted model, however, showed diminished rather than increased strength. Cantilever stiffness, though more variable, was on the whole somewhat greater in the case of the axial stiffeners than in the other stiffened models, but greatest of all in the unstiffened model of similar proportions. Ring stiffness was approximately in accordance with the formula, except in the case of the model with axial stiffeners, in which, as in cantilever strength, it had a low value rather than a high one.

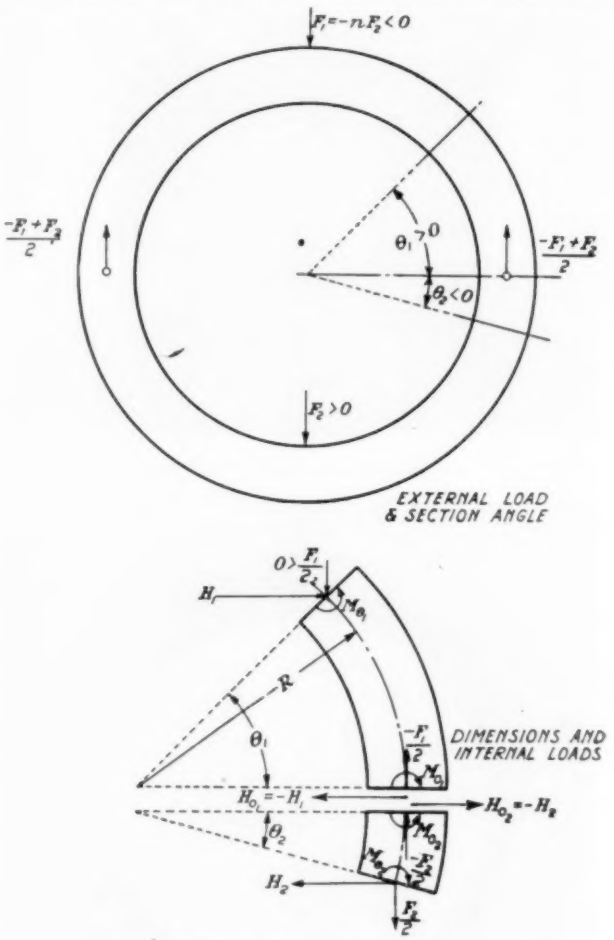

FIG. 17 ELASTIC RING

ACKNOWLEDGMENT

The models described were made at the U. S. Experimental Model Basin, and tested with the assistance of Dr. A. H. Stang at the Bureau of Standards.

Appendix

STRENGTH AND STIFFNESS OF AN ELASTIC RING

THE procedure will be to calculate bending moment M and deflection δ in a ring (Fig. 17) of sectional moment of inertia I loaded with a force F_1 at the front point, and $F_2 = -F_1/n$, at the rear point, so that the total load is $F = F_2 - F_1 = F_2 (1 + n)$, the support being equally divided between the two side points. The load

F_1 is considered negative because it acts radially inward and F_2 positive because outward. The calculations will be made on the curved-beam theory, and separately for the front half of the ring (subscript 1) and the rear half (subscript 2). Points on the ring are referred to the angle θ, measured positively counterclockwise from the right side point (3 o'clock) looking down on the ring. Deflections are measured radially, positive outward; angular deflections α of elastic lines are positive when increase in θ accompanies increase in δ. Bending moments acting across a radial section at angle θ are reckoned positive clockwise; at each such section there is an action and a reaction of opposite sign. M_θ denotes the moment at section θ acting on the sector between zero and θ, and M_0 the moment at section zero acting on the same segment. At the radial section at angle θ there is also a force whose components will be called V, parallel, and H, perpendicular, to the line of action of the applied forces F. Following the same convention as for the moments, V_θ and H_θ denote the components of force applied to the sector between zero and θ, and V_0 and H_0 those applied to the same sector at θ = zero. In the case of the forces we have immediately

$$V_\theta = -V_0$$

and

$$H_\theta = -H_0$$

On account of symmetry it is clear that

$$V_0 = -\frac{F}{2}$$

By reason of symmetry, $\alpha = 0$ when $\theta = \pi/2$ and when $\theta = -\pi/2$.

Upper Half, Subscript 1

$$F_1 < 0,\ H_{01} < 0,\ \theta_1 > 0$$

Considering equilibrium of the sector between $\theta = 0$ and $\theta = \theta_1$,

$$M_{01} + M_{\theta 1} - H_{01} R \sin\theta_1 + F_{1/2} R (1 - \cos\theta_1) = 0 \ldots [1]$$

H_{01} being the transverse (radial) force exerted on the surface at $\theta = 0$, reckoned positive outward.

Since $\alpha_{\pi/2} = 0$,

$$\alpha_\theta = \frac{R}{EI}\int_{\pi/2}^{\theta} M_\theta \, d\theta$$

Solving Equation [1] for $M_{\theta 1}$, substituting and integrating,

$$\alpha_{\theta 1} = \frac{R}{EI}\left[\frac{F_1 R}{2}\left(\sin\theta_1 - \theta_1 + \frac{\pi}{2} - 1\right) + M_{01}\left(\frac{\pi}{2} - \theta_1\right) - H_1 R \cos\theta_1\right] \ldots [2]$$

Now in general $\delta_\theta - \delta_0 = R\int_0^\theta \alpha_\theta \, d\theta$

and by substituting the value of α and integrating

$$\delta_{\pi/2} - \delta_0 = \frac{R^2}{EI}\left[\frac{F_1 R}{2}\left(1 - \frac{\pi}{2} + \frac{\pi^2}{8}\right) + M_{01}\frac{\pi^2}{8} - H_1 R\right] \ldots [3]$$

The condition that the length of the sector from 0 to $\pi/2$ is invariable is now introduced; this amounts to neglecting the effects of tension in the ring as compared with bending. This gives us the condition

$$\int_0^{\pi/2} (\delta_\theta - \delta_0)\, d\theta = -\frac{\pi\delta_{01}}{2}$$

Evaluating the integral,

$$\frac{\pi\delta_{01}}{2} = -\frac{R^2}{EI}\left[\frac{F_1 R}{2}\left(-1 + \frac{\pi}{2} - \frac{\pi^2}{8} + \frac{\pi^2}{24}\right) + M_{01}\frac{\pi^2}{24} - H_1 R\right] \ldots [4]$$

Lower Half, Subscript 2

$$F_2 > 0,\ H_2 > 0,\ \theta_2 < g$$

The equations corresponding to those given above are

$$M_{02} + M_{\theta 2} - H_2 R \sin\theta_2 - \frac{F_2 R}{2}(1 - \cos\theta_2) = 0 \ldots [1]$$

$$\alpha_{\theta 2} = -\frac{R}{EI}\left[\frac{F_2 R}{2}\left(-\sin\theta_2 + \theta_2 + \frac{\pi}{2} - 1\right) - M_{02}\left(\frac{\pi}{2} + \theta_2\right) - H_2 R \cos\theta_2\right] \ldots [2]$$

$$\delta_{-\pi/2} - \delta_0 = \frac{R^2}{EI}\left[\frac{F_2 R}{2}\left(1 - \frac{\pi}{2} + \frac{\pi^2}{8}\right) - M_{02}\frac{\pi^2}{8} - H_2 R\right] \ldots [3]$$

$$\frac{\pi\delta_{02}}{2} = \frac{R^2}{EI}\left[\frac{F_2 R}{2}\left(1 - \frac{\pi}{2} + \frac{\pi^2}{8} - \frac{\pi^3}{24}\right) + M_{02}\frac{\pi^3}{24} + H_2 R\right] \ldots [4]$$

Combined Halves

Equating δ_{01} and δ_{02} and noting that $H_1 = -H_2$ and $F_1 = -nF_2$,

$$H_2 = F_2\frac{n+1}{4}\left(\frac{\pi^3}{24} - \frac{\pi^2}{8} + \frac{\pi}{2} - 1\right) = F_2(n+1) \times 0.157256. \ [5]$$

Equating δ_{01} and α_{02}, and noting in addition that $M_{01} = -M_{02}$,

$$M_{02} = F_2 R\frac{1-n}{4}\left(1 - \frac{2}{\pi}\right) = F_2 R(1-n) \times 0.0908450 \ldots [6]$$

The radial deflections at the three stations are as follows:

$$\delta_1 = \delta_3 = \delta_0 = F_2\frac{R^3}{EI}(1-n)\left(\frac{1}{2\pi} - \frac{1}{4} + \frac{\pi}{48}\right)$$

$$\frac{1}{2\pi} - \frac{1}{4} + \frac{\pi}{48} = 0.025395$$

$$\delta_4 = \delta_{-\pi/2} = F_2\frac{R^3}{EI}\left[\frac{1}{\pi} - \frac{\pi}{12} + (1+n)\left(-\frac{1}{2\pi} + \frac{1}{2} - \frac{5}{24}\pi + \frac{\pi^2}{16} - \frac{\pi^3}{96}\right)\right]$$

$$\frac{1}{\pi} - \frac{\pi}{12} = 0.056510;\quad -\frac{1}{2\pi} + \frac{1}{2} - \frac{5}{24}\pi + \frac{\pi^2}{16} - \frac{\pi^3}{96} = -0.019789$$

$$\delta_2 = \delta_{\pi/2} = F_2\frac{R^3}{EI}\left[\frac{1}{\pi} - \frac{\pi}{12} + (1+n)\left(-\frac{1}{2\pi} - \frac{1}{2} + \frac{7}{24}\pi - \frac{\pi^2}{16} + \frac{\pi^3}{96}\right)\right]$$

$$-\frac{1}{2\pi} - \frac{1}{2} + \frac{7}{24}\pi - \frac{\pi^2}{16} + \frac{\pi^3}{96} = -0.036721$$

The moments at the same three stations are:

$$M_1 = M_3 = M_0 = F_2 R(1-n)\frac{1}{4}\left(1 - \frac{2}{\pi}\right)$$

$$\frac{1}{4}\left(1 - \frac{2}{\pi}\right) = 0.090845$$

$$M_4 = M_{-\pi/2} = F_2 R\left[\frac{1}{\pi} + (1+n)\left(-\frac{1}{2\pi} + \frac{1}{2} - \frac{\pi}{8} + \frac{\pi^2}{32} - \frac{\pi^3}{96}\right)\right]$$

$$\frac{1}{\pi} = 0.318310;\quad -\frac{1}{2\pi} + \frac{1}{2} - \frac{\pi}{8} + \frac{\pi^2}{32} - \frac{\pi^3}{96} = -0.066412$$

$$M_2 = M_{\pi/2} = F_2 R\left[-\frac{1}{\pi} + (1+n)\left(\frac{1}{2\pi} + \frac{1}{2} - \frac{\pi}{8} + \frac{\pi^2}{32} - \frac{\pi^3}{96}\right)\right]$$

$$\frac{1}{2\pi} + \frac{1}{2} - \frac{\pi}{8} + \frac{\pi^2}{32} - \frac{\pi^3}{96} = 0.251898$$

As a check on this work we may substitute the value $n = -1$, which should give us values of deflection and bending moment of a ring in simple tension, as in a chain. We find

$$\delta_{-\pi/2} = \delta_{\pi/2} = \frac{FR^3}{EI}\left[\frac{1}{\pi} - \frac{\pi}{2}\right]$$

$$M_{-\pi/2} = -M_{\pi/2} = FR \times \frac{1}{\pi}$$

These results are in agreement with known values for thin rings. In terms of total load F we have, finally,

$$\delta_1 = \delta_3 = 0.0254\frac{1-n}{1+n}\frac{FR^3}{EI}$$

$$\delta_4 = \left(\frac{0.0565}{1+n} - 0.0198\right)\frac{FR^3}{EI}$$

$$\delta_2 = \left(\frac{0.0565}{1+n} - 0.0367\right)\frac{FR^3}{EI}$$

$$M_1 = M_3 = 0.091\frac{1-n}{1+n}FR$$

$$M_4 = \left(\frac{0.318}{1+n} - 0.066\right)FR$$

$$M_2 = \left(-\frac{0.318}{1+n} + 0.252\right)FR$$

APM-51-8

Telephone-Apparatus Springs

A Review of the Principal Types and the Properties Desired of These Springs

By J. R. TOWNSEND,[1] NEW YORK, N. Y.

THE proper functioning of telephone-apparatus springs depends upon careful design and selection of material. In many instances the springs must occupy small space and maintain delicate adjustment throughout the life of the apparatus with a minimum of attention. Whereas the physical size of these springs is small, the forces are sometimes necessarily large due to space limitations and this requires careful choice of material. It is believed that the use of these small springs is not unique to the telephone art and a discussion of materials and methods of test used should have broad interest and application.

There are three general classes of springs employed in telephone apparatus. For the purposes of this discussion these springs may be classified as follows:

Sheet non-ferrous-metal springs
Clock-spring-steel springs
Helical springs.

Sheet Non-Ferrous Springs

Sheet non-ferrous springs usually consist of punched and formed parts made from brass, nickel silver, or phosphor bronze. These serve as electrical-contact carrying members that are deflected or operated either electromagnetically or mechanically. Such springs are essentially cantilever springs clamped at one end and bearing near the other end one or more precious-metal contacts that are spot-welded in place. The precious-metal contacts are employed to reduce contact resistance and the destructive effects of arcing when circuits are broken. The apparatus employing such springs are keys of the switchboard type, relays, jacks, and interrupters. Certain apparatus known as switches employ these springs as brushes or wiping members. Here precious-metal contacts are not usually employed, but the ends of the springs must serve as contacting and wearing parts. Other springs are employed statically or, in other words, are required to maintain constant pressure for long periods without interruption. All springs that are attached to, or form part of, electrical circuits are soldered to connecting wires. This is usually done by soldering the wire or connection to a lug or projection that forms part of the spring. These lugs in most instances are on the opposite end of the clamped area from the operated end. These springs are almost always clamped between strips of phenol fiber because of its good insulating properties, mechanical strength, and permanency of form. A typical example of the use of the more common type of these springs is illustrated by Fig. 1 showing the familiar switchboard key.

The properties required of these small springs which are numerous and vary for each type of application are summarized as follows:

The proportional limit must not be too high to prevent the spring's being adjusted by flexing it with a tool to the point where it takes a set and occupies a position where it provides the desired operating pressure. In other words, there must be room enough to flex the spring to the point where it will take a set within the space provided. A spring of high proportional limit such as one of clock-spring steel may be bent nearly double without being permanently deformed. Obviously, such a spring could not be adjusted in the key shown by Fig. 1.

The modulus of elasticity should be within the range of 12,000,000 to 20,000,000 lb. per sq. in. in order that the load-deflection rate will not be too steep to permit reasonable ease of adjustment by hand.

The endurance limit must be high enough to permit satisfactory operation throughout the life of the apparatus. In cases where space limitation is a factor, reference must be made to a stress-cycle graph made for the material to determine if the spring may be expected to stand up in service.

Creep or deformation under sustained load must not take place since the material will lose tension. Brass, nickel silver, and phosphor bronze may be expected on the basis of years of experience to hold adjustments when stressed up to approximately their proportional limits. Other materials when considered for telephone apparatus springs are investigated to determine their "creep" characteristics.

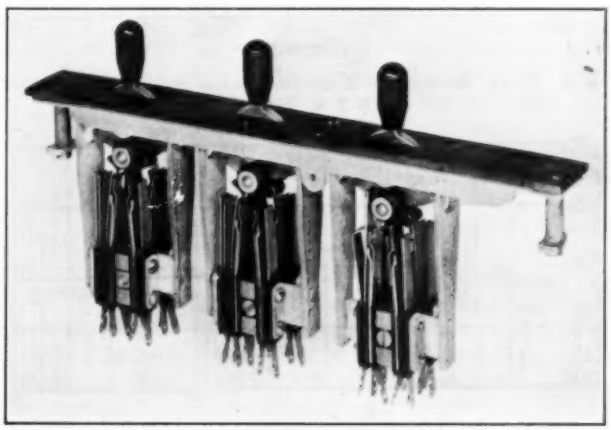

Fig. 1 Common Type of Switchboard Key Illustrating Use of Sheet-Metal Springs

Season cracking takes place with highly stressed brass under severe atmospheric conditions, and for this reason springs that are required to hold their pressures without being deflected for long periods are not made from this material. Nickel silver will also season-crack under still higher stress and phosphor bronze least of all. In designing these springs, generous fillets and easy curves are employed to prevent the building up of localized high stresses that may lead to season cracking under sustained load and fatigue failure under repeated flexure.

When these springs are used as wipers in electrical circuits where arcing can occur, brass and nickel silver are not employed for the reason that the heat of the arc breaks down the material, volatilizes the zinc, and disintegrates the material. For this reason, phosphor bronze, which does not contain zinc and has superior wear resistance to brass and nickel silver, is employed.

In addition to the foregoing properties, these springs must be resistant to atmospheric corrosion and capable of being readily soldered with soft solder. Nickel silver, as may be seen from Table 2, is superior to brass in its mechanical properties and in ad-

dition may be readily spot-welded, and as a result of years of experience it has been found that springs made of this material are capable of maintaining adjustment in a satisfactory manner in service. Phosphor bronze has still greater wear resistance than brass or nickel silver and superior spring properties.

The chemical compositions of brass, nickel-silver, and phosphor-bronze spring materials used for telephone-apparatus springs are shown in Table 1 and the mechanical properties are given in Table 2. The range of tensile strength and hardness shown comprises the specification limits. A more detailed description of the properties of brass has been given elsewhere.[2]

FATIGUE PROPERTIES OF SHEET NON-FERROUS SPRING MATERIALS

Because of the important bearing of fatigue on telephone-apparatus springs this property has been carefully studied. The stress-cycle graphs shown by Figs. 2 to 4 give typical results. The design of specimen is shown by Fig. 7. These specimens were alternately stressed at the rate of 700 cycles per minute.

[2] "Physical Properties and Methods of Tests for Sheet Brass," by H. N. Van Deusen, L. I. Shaw, and C. H. Davis. Proceedings A.S.T.M., 1927.

CLOCK-SPRING-STEEL SPRINGS

These springs are used as vibrating elements in interrupters, where a high fatigue endurance is required, and for springs that must be worked at high pressures and built up. The material has the chemical composition shown by Table 3 and mechanical properties given by Table 4. This is a carbon-steel, heat-treated and then cold-rolled, and is by nature brittle. To guard against excessive brittleness and at the same time provide a high-strength cold-rolled steel, a bend test has been developed.

The bend test requires that when the material is bent back parallel to itself to form a "U" and further compressed between flat parallel surfaces (for example, between the jaws of a vise), at a rate not to exceed 0.3 in. per min., the material shall break along a straight line making approximately a 90-deg. angle with the axis of the strip when the distance between the inside of the legs of the "U" is 25 to 16 times the thickness of the material. It must not break before the distance is reduced to 25 times the thickness of the metal. This test can be conveniently applied

MUSIC-WIRE SPRINGS

Tinned and plated music wire is extensively used for compression springs in telephone apparatus. Here the spring is in the form of an open helix. Fig. 8 shows a type widely used. These springs are either tinned or plated with nickel. It has been observed the plating baths adversely affect the fatigue characteristics of music wire and this is under investigation at the present time.

The average tensile properties of the music wire employed are: proportional limit, 217,000 lb. per sq. in.; ultimate tensile strength, 350,000 lb. per sq. in. No chemical or tensile requirement is placed on this wire, the main feature of concern being brittleness. The elongation measured in an 8-in. length must be between 1 and 4 per cent for wire up to and including No. 27 gage and $1^1/_2$ to 7 per cent for No. 28 gage wire and heavier. The wire is also subject to a kinking test in which No. 30 wire and smaller shall kink without breaking. This last test indirectly controls the tensile properties of the wire.

SUMMARY

A review has been given of the more common type of telephone-apparatus springs. Vast quantities of these springs are employed in the telephone plant and the numerous factors that must be considered with regard to selecting material have been reviewed. The materials most generally used have abundant competitive sources of supply and the quality is carefully controlled by tests that are designed to be easy to apply and effective in evaluating the properties desired.

APM-51-9

The Piston-Crosshead Motion of the Oilgear Pump

By ELEK BENEDEK,[1] MILWAUKEE, WIS.

The Oilgear pump is a variable-delivery radial pump which converts mechanical power into hydraulic power in the form of an oil stream under pressure. An oil motor is used to reconvert the power into mechanical form and apply it to the work to be done. For services requiring greater power than the applications so far made, improvements are needed which will reduce noise and vibration. The present paper derives equations for determining the path, velocities, and accelerations of any point in the piston-crosshead unit of the Oilgear pump, as investigation has shown that an accurate knowledge of the accelerations of the mechanical parts and of the oil in the cylinders and ports is necessary as a basis for further improvements in design.

THE analysis given herein derives equations for the determination of the path, velocities, and accelerations of any point in the piston-crosshead unit of the Oilgear variable-delivery radial pump. During the last seven years this pump has been widely used in previously undeveloped fields of power transmission where variable speed control is required. The pump converts mechanical power into hydraulic power in the form of an oil stream under pressure. An oil motor, which may be of the same construction as the pump, is used to reconvert the power into mechanical form and apply it to the work to be done.

The Oilgear applications so far made have been below 65 hp. In this field the units have shown a ruggedness and durability which strongly suggests that others may be built suitable for driving Diesel locomotives, or for similar variable-speed applications requiring much greater power. Certain improvements will be required for such service, notably the reduction of noise and vibration, which might be excessive in large units on the present basis of design. Sufficient investigation work has already been done to indicate that an accurate knowledge of the accelerations of the mechanical parts and of the oil in the cylinders and ports is necessary as a basis for further improvements in design.

The equations obtained are useful in determining the forces resulting from the accelerations, which are of considerable importance in the design of pumps of this type, particularly of large units and units operating at high speeds. They can cause both wear and vibration unless suitably provided for in the design. The behavior of the fluid in the cylinder chambers and in the passages to and from the cylinders also depends on the velocities and accelerations of each piston-crosshead unit, and a knowledge of these values is thus required in order to determine proper areas and contours for the fluid passages and cylinders.

The elements of the pump mechanism considered in this paper are shown in Fig. 1. The actual construction of a pump is shown in the sectional drawings of Fig. 2, 1*a* and 1*b*. For a description of the operation of the pump, see the paper entitled "Applications of Hydraulic Transmissions Variable-Speed Drive to Machine Tools and Manufacturing Processes," by Walter Ferris, presented at the annual meeting of the A.S.M.E., December 4, 1922, and published in *Mechanical Engineering*, vol. 45 (1929), p. 238.

Referring to Fig. 1, the assembly consists of a driving member C, a driven member A, and several interconnecting members B. The driving member is called the driver, the driven member is the cylinder block, and the interconnecting members are the piston-crosshead units. The motion is imparted to the pistons by the relative eccentricity of the rotating parts C and A, which is adjustable so that the piston strokes may be changed at will. The driving member C rotates at uniform speed around the fixed center O_2. The driven member A also rotates at uniform speed around the adjustable center O_1. At any given time, however, the center O_1 is fixed. (It is only shifted when it is desired to change the stroke.) This driven member or cylinder block is forced to rotate at the same angular velocity as the driver by the interconnecting piston-crosshead units which carry it around with the driver. The piston-crosshead units slide tangentially in the slots in the driver and radially in the cylinder bores as the driver and cylinder block rotate on their separate centers. The construction of the piston-crosshead unit is such that the axis of the piston is always perpendicular to the flat surfaces of the crosshead. Thus the axes of the cylinders, which are radii of the cylinder-block bores, must always be perpendicular to the grooves in the driver, and therefore parallel to radii of the driver which are perpendicular to the driver grooves. As the radii of cylinder block and driver are thus always mutually parallel, it follows that the cylinder block and driver must rotate with the same angular velocity. The geometry of the assembly is the same as that of an Oldham coupling, except that in the Oilgear pump there are several interconnecting members instead of only one.

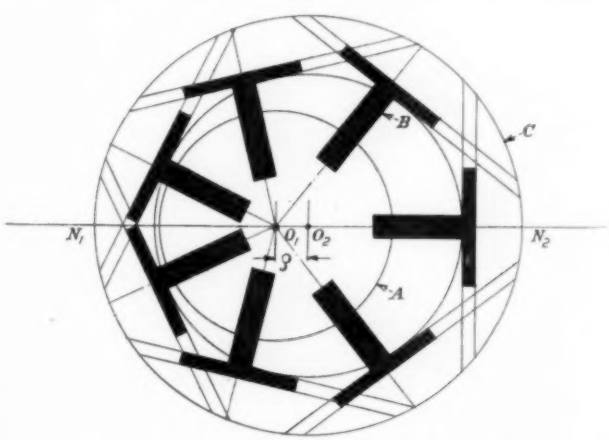

FIG. 1 ELEMENTS OF OILGEAR PUMP MECHANISM

Every point in the cylinder block A rotates around the center O_1. Thus the paths of all these points are circles around the center O_1. Every point in driver C rotates around the center O_2. The paths of these points are therefore circles around the center O_2.

The points in the piston-crosshead units B have a composite motion about the centers O_1 and O_2. To describe this motion in a general way, it can be stated that relatively to the center O_1 all these points move first radially toward the center and then away from it during the rotation of the pump. Relatively to

[1] The Oilgear Company.

center O_2, all these points move tangentially to one side and then to the other side of a radius of the driver C, which represents the center line of a piston-crosshead unit in its neutral or dead-center position in the driver. The exact motion of any point of the groove of the driver in which this piston and crosshead slides, is selected for the x-axis of a rotating coordinate system. The coordinates of point O in the stationary coordinate system are x_0,y_0. Point P is an arbitrary point lying anywhere in the

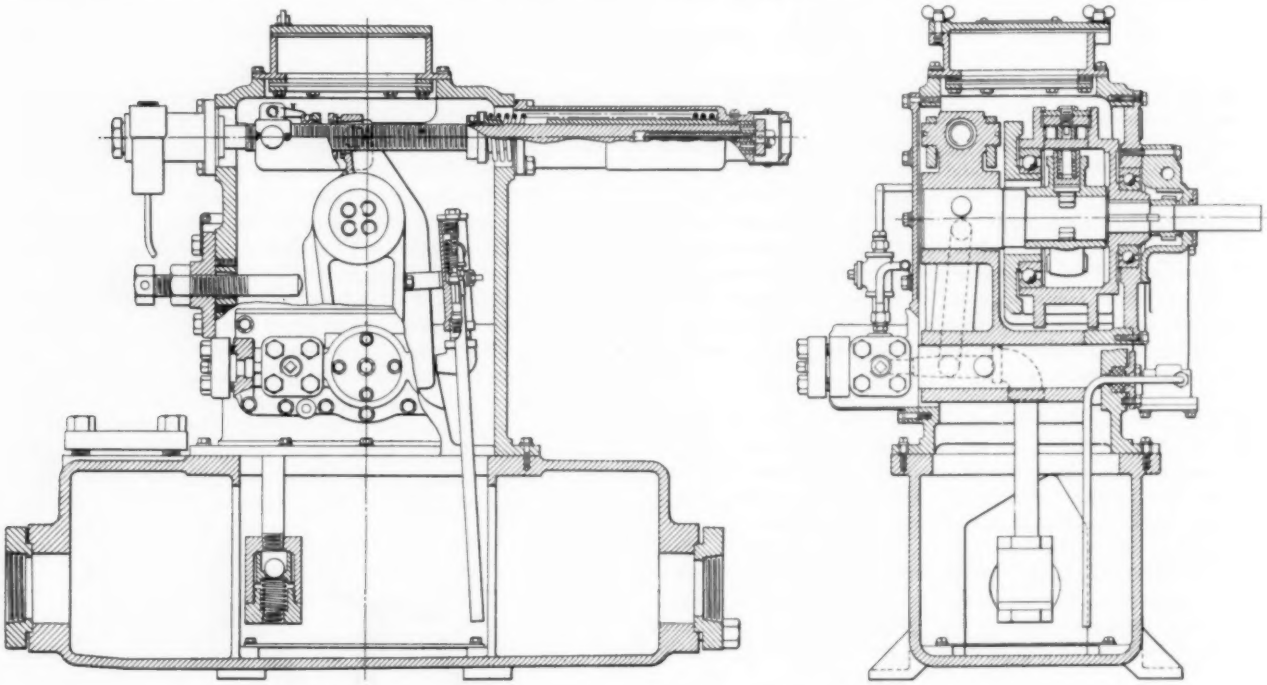

FIG. 2 VERTICAL CROSS-SECTIONS OF ACTUAL PUMP, SHOWING CONSTRUCTION

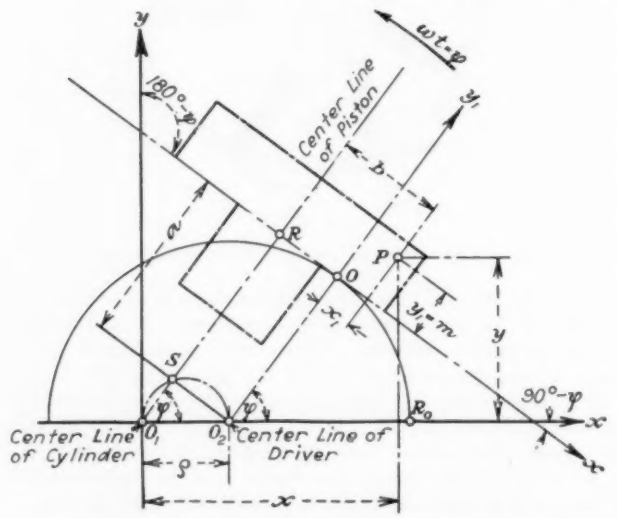

FIG. 3 ANALYSIS OF MOTION OF A POINT IN PISTON-CROSSHEAD UNIT

in a piston-crosshead unit will be described exactly by the mathematical derivations which follow.

Referring to Fig. 3, the neutral line of the pump is the line O_1, O_2, intersecting the cylinder center O_1 and the driver center O_2. This line is chosen as the x-axis of a stationary coordinate system to which all motions will finally be referred. The center line of a piston-crosshead unit always intersects O_2 and is shown as having rotated in a counterclockwise direction through the angle φ. The line Ox_1, which represents the bottom piston-crosshead unit. Its coordinates in the stationary system are x,y, and in the rotating system x_1,y_1. The motion of the point P in the moving coordinate system is a simple harmonic motion. If the motion of a point is known in a moving coordinate system which has a uniform linear or angular motion with reference to a stationary coordinate system, then the motion of the point in the stationary system can be found by the transformation of its coordinates in the moving system into coordinates in the stationary system. The motion of point P will be expressed in the moving system first and then in the stationary system. The following notation will be used:

- α_1 = angle of the positive x_1 in regard to the positive x
- β_1 = angle of the positive x_1 in regard to the positive y
- α_2 = angle of the positive y_1 in regard to the positive x
- β_2 = angle of the positive y_1 in regard to the positive y
- ρ = eccentricity of pump
- φ = phase angle of the piston, measured from the positive x-axis
- ω = angular velocity of the piston
- t = time of the rotation of piston, measured from the positive x-axis
- a = radius of the path of O
- b = distance of P from the center line of piston
- k = distance of P from the center line of driver.

TRANSFORMATION EQUATIONS

$$\left.\begin{aligned} x &= x_0 + x_1 \cos \alpha_1 + y_1 \cos \alpha_2 \\ y &= y_0 + x_1 \cos \beta_1 + y_1 \cos \beta_2 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [1]$$

From Fig. 3 it is obvious that

$$\left.\begin{aligned} \alpha_1 &= (90 - \varphi)^\circ \\ \alpha_2 &= \varphi^\circ \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots [1a]$$

and

$$\left.\begin{aligned}\beta_1 &= (180 - \varphi)^\circ \\ \beta_2 &= (90 - \varphi)^\circ\end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1b]$$

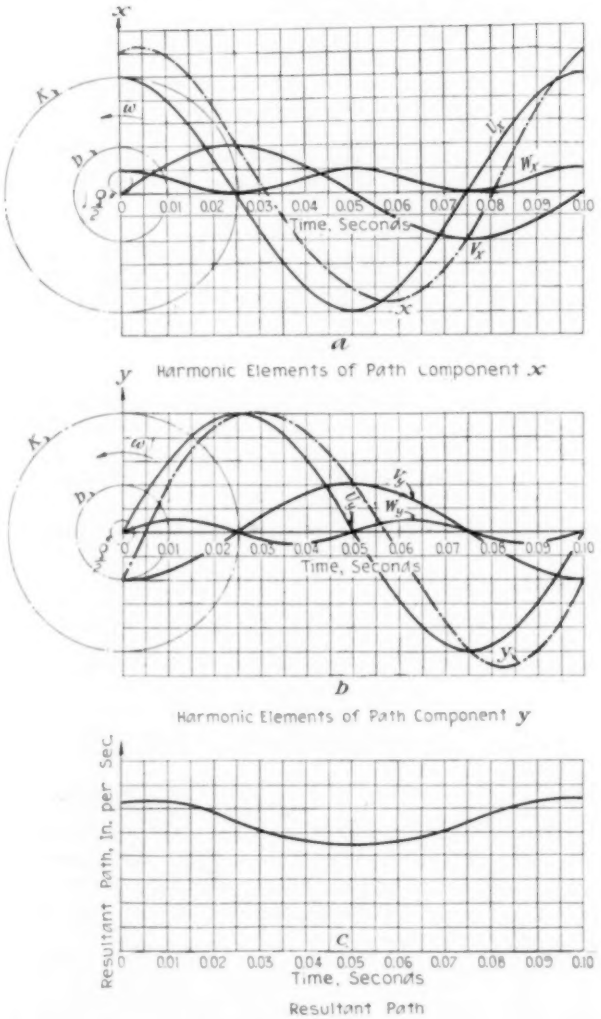

FIG. 4 HARMONIC ELEMENTS OF PATH COMPONENTS x AND y, AND RESULTANT PATH DIAGRAM

Furthermore the coordinates of O in the stationary system are given by

$$\left.\begin{aligned}x_0 &= \rho + a\cos\varphi \\ y_0 &= a\sin\varphi\end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1c]$$

DERIVATION OF THE PATH OF POINT P IN THE STATIONARY COORDINATE SYSTEM

The coordinates of P in the rotating system are given from Fig. 3, and can be expressed as functions of the phase angle as follows:

$$\left.\begin{aligned}x_1 &= b - \rho\sin\varphi \\ y_1 &= m = \text{constant}\end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

The motion expressed by Equation [2] can be transformed by Equation [1]. We shall then have the motion of P in the stationary system O_1xy. By substituting [1a], [1b], [1c] and [2] in Equation [1], we obtain the coordinates of point P in the stationary system:

$$\left.\begin{aligned}x &= \rho + a\cos\varphi + (b - \rho\sin\varphi)\cos(90 - \varphi) + m\cos\varphi \\ y &= a\sin\varphi + (b - \rho\sin\varphi)\cos(180 - \varphi) + m\cos(180 - \varphi)\end{aligned}\right\}$$
$$\ldots\ldots\ldots [3]$$

By adding the homogeneous members and designating $a + m$ by k, the path components of the motion are expressed by the equations

$$\left.\begin{aligned}x &= k\cos\varphi + b\sin\varphi + \rho\cos^2\varphi \\ y &= k\sin\varphi - b\cos\varphi + \frac{\rho}{2}\sin 2\varphi\end{aligned}\right\} \quad \ldots\ldots\ldots [4]$$

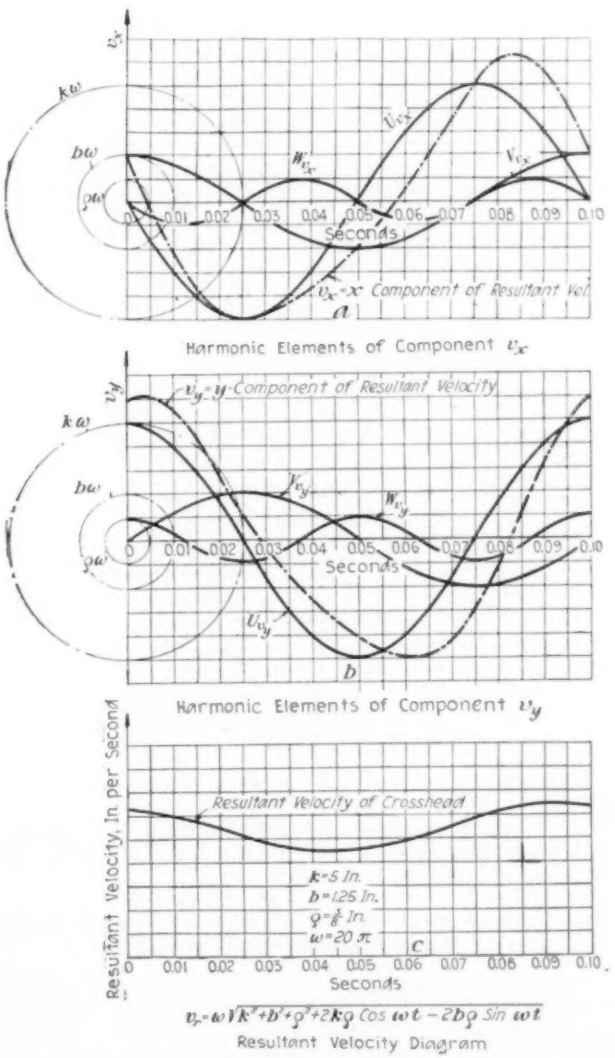

FIG. 5 HARMONIC ELEMENTS OF COMPONENT VELOCITIES v_x AND v_y, AND RESULTANT VELOCITY DIAGRAM

Equation [4] expresses the motion of the path components of P in the stationary system O_1xy.

If we designate by r the hypothenuse O_1P of the right triangle whose other two sides are the coordinates of P, then

$$r = \sqrt{x^2 + y^2} \quad \ldots\ldots\ldots\ldots\ldots [5]$$

By susbstituting x and y from Equation [4], the radius vector r to point P will be

$$r = \sqrt{(k + \rho\cos\varphi)^2 + b^2} \quad \ldots\ldots\ldots\ldots [5a]$$

Equation [5a] is the polar equation of the path of P in the stationary coordinate system. From [5a] it follows that if $k = b = 0$, the path of P is a circle. If $b = 0$ and $k = \rho$, the path of P is a cardioid. The path expressed by [5a] is the so-called Pascal limacon.

Fig. 4 shows at (a) and (b) the actual diagrams of the right-hand members of [4]. We call these members the harmonic elements of the path components x and y, and designate them

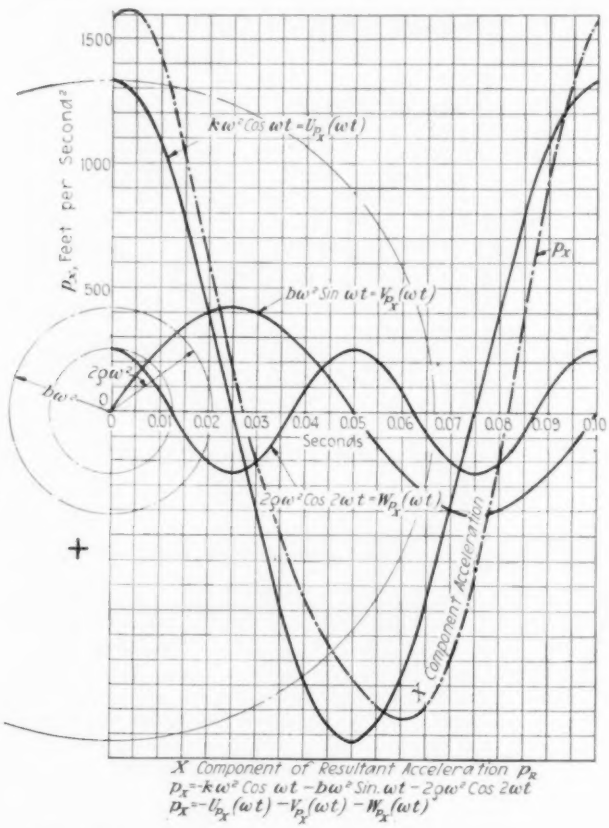

Fig. 6(a) x-Component of Resultant Acceleration p_r

by U, V, and W. Fig. 4(c) shows the diagram of the resultant path. The characters and significance of the elements will be discussed at the end of this paper.

Derivation of the Resultant Velocity of Point P in the Stationary Coordinate System

According to Equation [4], the path components are simple harmonic functions of the phase angle. The phase angle itself is a function of the time: thus $\varphi = \omega t$.

The velocity can be derived from the path by the differentiation of the path equation according to time.

Since

$$\left.\begin{aligned} \frac{dx}{dt} &= v_x \\ \frac{dy}{dt} &= v_y \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

Equation [6] gives the x- and y-components of the resultant velocity v_r.

Therefore

$$\left.\begin{aligned} v_x &= \omega(-k \sin \varphi + b \cos \varphi - \rho \sin 2\varphi) \\ v_y &= \omega(k \cos \varphi + b \sin \varphi + \rho \cos 2\varphi) \end{aligned}\right\} \quad \ldots\ldots [6a]$$

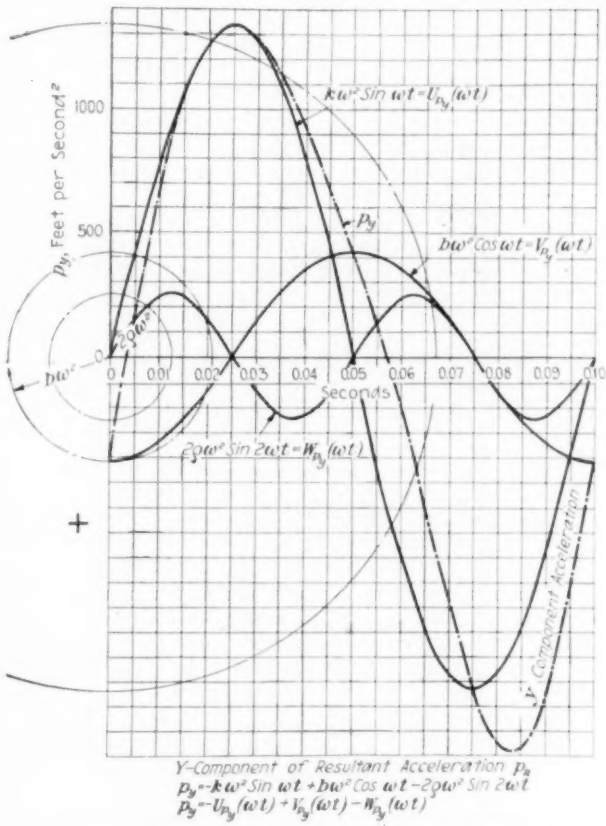

Fig. 6(b) y-Component of Resultant Acceleration p_r

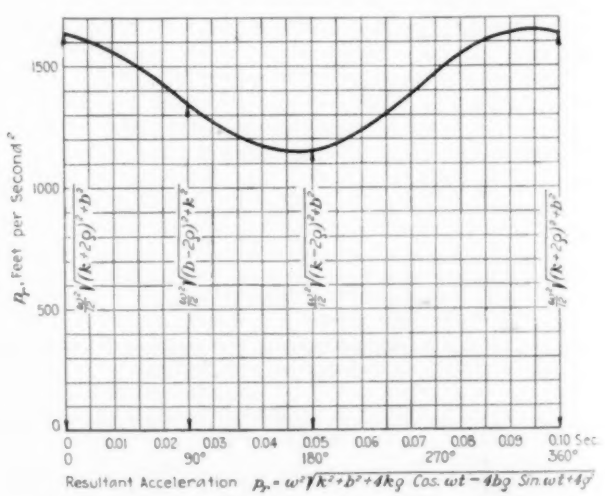

Fig. 6(c) Resultant Acceleration p_r

and the resultant velocity in the stationary coordinate system will be

$$v_r = \sqrt{v_x^2 + v_y^2} \quad \ldots\ldots\ldots\ldots\ldots [6b]$$

By substituting v_x and v_y from [6a], we shall have

$$v_r = \omega\sqrt{(k + \rho \cos \varphi)^2 + (b - \rho \sin \varphi)^2} \quad \ldots\ldots [7]$$

Equation [7] shows that the velocity v_r can be represented also by the hypothenuse of a right triangle, the sides of which are proportional to $(k + \rho \cos \varphi)$ and $(b - \rho \sin \varphi)$, respectively.

The component velocities v_x, v_y, and the resultant velocity v_r are shown at (*a*), (*b*), and (*c*) Fig. 5, as well as the harmonic elements of the components, which are the members of the right-hand side of Equation [6*a*]. The resultant velocity is obtained by the graphical superposition of the curves of the elements in the right-hand side of Equation [7].

Derivation of the Resultant Acceleration of the Point *P* in the Stationary Coordinate System

The components of resultant acceleration can be derived from the components of velocity by differentiating them according to time.
Thus

$$\left.\begin{aligned}\frac{dv_x}{dt} &= p_x\\ \frac{dv_y}{dt} &= p_y\end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots [8]$$

By carrying out the differentiation, the components of the resultant acceleration become

$$\left.\begin{aligned}p_x &= \omega^2(-k\cos\varphi - b\sin\varphi - 2\rho\cos 2\varphi)\\ p_y &= \omega^2(-k\sin\varphi + b\cos\varphi - 2\rho\sin 2\varphi)\end{aligned}\right\} \quad \ldots [8a]$$

The resultant acceleration is

$$p_r = \sqrt{p_x^2 + p_y^2} \quad \ldots\ldots\ldots\ldots\ldots [9]$$

which, by substituting p_x and p_y from [8*a*], becomes

$$p_r = \omega^2\sqrt{(k + 2\rho\cos\varphi)^2 + (b - 2\rho\sin\varphi)^2} \quad \ldots [10]$$

The component accelerations of p_x and p_y and the resultant acceleration p_r are shown by Figs. 6(*a*), 6(*b*), and 6(*c*). These diagrams also show how the components are graphically superposed from the different elements according to Equation [8*a*], to give the resultant accelerations.

Equation [10] shows that the resultant acceleration can be considered as the resultant of two vectors which are perpendicular to each other and proportional to the expressions $(k + 2\rho\cos\varphi)$ and $(b - 2\rho\cos\varphi)$, respectively.

Analysis of the Motion of a Piston With Reference to the Cylinder Block

In order to analyze the motion of the oil in a cylinder, the path of a point R in the piston with reference to the cylinder itself must be known. The travel of the point R (at the intersection of the piston center line and the lower surface of the crosshead) during the rotation of the piston at an angle from center O_1 is equal to $O_1R_0 - O_1R = (\rho + a) - (\rho\cos\varphi + a)$

$$= \rho - \rho\cos\varphi$$
$$= \rho(1 - \cos\varphi)$$

If we designate this travel by s, then

$$s = \rho(1 - \cos\varphi) \quad \ldots\ldots\ldots\ldots\ldots [11]$$

This is the equation of a pure harmonic motion. A piston therefore reciprocates in its cylinder with a pure harmonic motion, without such modifying factors as might result from connecting rods or cams in other types of construction.

Harmonic Analysis of the Resultant Path, Velocity, and Acceleration of the Point *P* in the Stationary Coordinate System

The analytical Equations [5*a*], [7], and [10] express the motion of an arbitrary point of the piston-crosshead, and the diagrams of its motions are constructed from these equations. Curves are drawn for each of the harmonic elements in the equations; these curves are superposed, and the values of the resultant path, velocity, and acceleration are obtained graphically. These elements are designated by U, V, and W on the diagrams and are functions of some of the dimensions of the pump. For instance, U is a function of k, the distance of the point P from the center line of driver, and the phase angle of the piston. V is a function of b, the distance of the point from the center line of the piston, and the phase angle of the piston. W is a function of the eccentricity of the pump and the phase angle of the piston.

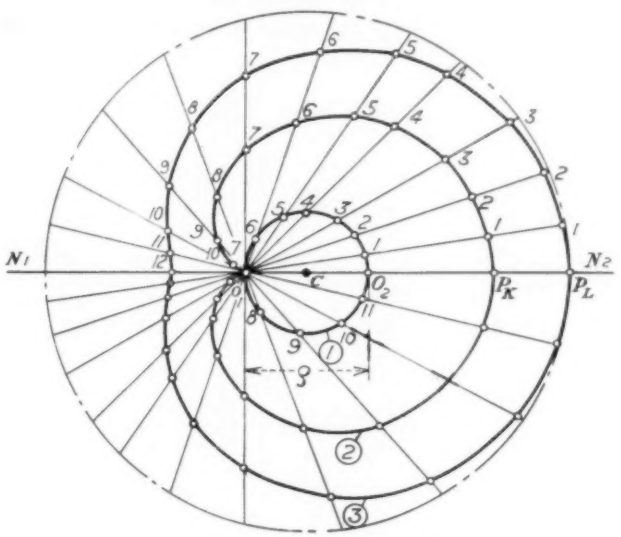

Fig. 7 Paths of Piston Points
(1) Path of the harmonic piston point O_2 is a circle.
(2) Path of the piston point P_K is a cardioid.
(3) Path of the piston point P_L is a limaçon.

According to the resultant diagrams of path, velocity, and acceleration, every one of them consists of three elements of a pure harmonic nature. These elements show the following characteristics:

1 Every harmonic element represents the motion of a point rotating on a circle with a constant angular speed.

2 The path elements U and V increase with the dimensions of the pump.

3 The velocity elements are directly proportional to the speed of the pump.

4 The acceleration elements increase with the square of the angular speed.

5 The U and V elements represent the pure harmonic motion of points which rotate at the angular speed of the pump.

6 The W elements represent the pure harmonic motion of a point which rotates twice as fast as the pump.

7 Every general point of the piston unit has a motion which can be resolved into three pure harmonic elements.

8 The only points of the piston unit, the motion of which can be resolved into two pure harmonic motions, are those which are on the center line of the piston. For these points, $b = 0$, and consequently the V harmonic element is zero.

9 The piston unit has only one point the motion of which can be resolved into one pure harmonic motion. This point is on the center line of the piston and coincides with the center line of the driver when the piston is in the outstroke dead center; see point O_2 in Fig. 3. For this point the equations of the resultant path, velocity, and acceleration are respectively:

$$\left.\begin{aligned} r &= \rho \cos \varphi \\ v &= \rho\omega \\ p &= 2\rho\omega^2 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots [12]$$

These results follow directly from the general equations of the motion by substituting in them $k = b = 0$. We call this point the harmonic point of the piston.

10 The harmonic point of the piston rotates with constant angular speed and acceleration on a circle of radius $\rho/2$.

11 The W harmonic element is identical with the resultant motion of the harmonic point of the piston.

12 The U harmonic element is the motion of a point rotating on a circle of radius k with the angular speed of the pump.

13 The V harmonic element is the motion of a point rotating on a circle of radius b with the angular speed of the pump.

14 The harmonic point of the piston is the only one which rotates on a circle. The remainder of the piston points rotate on different curves, such as the Pascal limacon or the cardioid. (See Fig. 7.)

15 Each piston reciprocates in its cylinder with a pure harmonic motion. As the piston motion determines the fluid motion, it follows that the resultant fluid motion consists of a series of pure harmonic impulses.

APM-51-10

Deflection of a Round-End Strut Subjected to a Constant Moment or a Transverse Force at the Middle

By JAMES E. BOYD,[1] COLUMBUS, OHIO

When a loaded strut is subjected to a transverse force or any other bending moment in addition to that caused by the longitudinal load, the additional deflection is greater than it would be if the additional moment were applied to the strut as a beam. In this paper an equation is derived for the deflection of a loaded round-end strut subjected to a transverse force at the middle and a moment which is constant throughout the length. To experimentally investigate the theory, tests were made on a cold-rolled steel strut 60 in. long and 1.25 in. in diameter with transverse forces of 5 lb. and 10 lb. at the middle. Measurements were taken for a series of longitudinal loads with positive, negative, and nearly zero eccentricity. Other experiments were made with a constant moment alone.

For both sets of experiments the additional deflections agree so closely with the theory as to leave no doubt in regard to the validity of the equations.

For the application of the theory, a formula which gives the ratio of the additional deflection of a loaded strut to its deflection as a beam in terms of the ratio of the longitudinal load to Euler's critical load is derived for each of these two moment conditions. A similar formula is derived for a uniformly distributed transverse force. Tables and curves are given which show the relation of these ratios with sufficient accuracy for practical computations.

THIS paper gives an account of the experimental determination of the deflection of a round-end strut subjected to a transverse force at the middle. The theoretical equations are derived, and the deflections calculated from these equations are shown to agree with the experimental results. Since the design of the apparatus used in the tests was such that the transverse reactions were applied at a small distance beyond the ends of the strut, instead of exactly at ends as would be assumed under the ideal conditions, the bending moment caused by the transverse force was made up of a constant moment throughout the length of the strut in addition to the moment as a beam supported at the ends and loaded at the middle. For this reason the theoretical deflection includes one term for a moment which increases uniformly from each end to the middle, and a second term for a moment which is constant.

For the convenience of the practicing engineer, a formula is derived for each of these two moment conditions which gives the ratio of the additional deflection of the loaded strut when this moment is applied to its deflection as a beam in terms of the ratio of the longitudinal load to Euler's critical load. For instance, when the longitudinal load on the strut is one-fourth of Euler's critical load, the additional deflection when either moment is applied is about one-third greater than it would be with no longitudinal load. When the longitudinal load is 50 per cent of Euler's critical load the additional deflection is twice as great, and when the longitudinal load is 90 per cent of Euler's critical load the additional deflection is 10 times as great as either moment would produce on the strut as a beam with no longitudinal load. Tables are calculated and curves plotted which give the relation of these ratios with sufficient accuracy for practical computations.

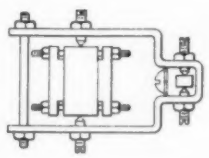
EXPERIMENTAL INVESTIGATIONS

APPARATUS AND MATERIAL

The experimental measurements were made on a strut of cold-rolled steel 60 in. long and 1.25 in. in diameter. The round-end condition was secured by means of semicylindrical heads of hardened steel which rolled on hardened plane surfaces. To measure the deflection a wooden bar was supported parallel to the strut by means of yokes which were attached to the axes of the semicylindrical heads by cone bearings. An Ames dial at the center of this wooden bar measured the deflection at the middle of the strut, and two other dials at 10 in. from the top and bottom measured the deflection at these positions. (Bulletin No. 25, "Tapered Struts," of The Ohio State University Engineering Experiment Station, gives a detailed description of the construction and use of this apparatus.)

The loads were applied by means of an Olsen 100,000-lb. universal testing machine, using the 10,000-lb. poise. A pointer was attached to the beam and moved in front of a graduated scale fastened to the frame. With this arrangement it was possible to balance to within 2 lb.

The transverse force was applied by a cord at the middle of the strut. This cord passed horizontally to a pulley and carried a load Q at the lower end. The shaft of the pulley was ground to a knife edge at the axis at each end, as shown in Fig. 1. These knife edges were supported inside hardened rings inserted in the bracket. The bracket was fastened to the frame of the weighing table of the testing machine before the zero adjustment was made, and the weight Q was taken into account in reading the poise. The Ames dials were of the usual type, graduated to thousandths of an inch. All readings were taken to the ten-thousandth of an inch.



ADJUSTMENT OF ECCENTRICITY

The strut was loaded and the deflections were read on the upper and lower dials. The load was then reduced to about 400 lb. and the strut was shifted by means of clamp screws attached to the compression heads. The amount of shift at each end was obtained from the change of the readings of upper and lower dials. The load was then raised several thousand pounds. When the deflection of the two dials for this increased load became equal, the eccentricity was known to be the same at both ends. The ends were then shifted equally a couple of times and the corresponding readings were taken. By interpolation and extrapolation the shift of the strut for any desired eccentricity could be approximately determined.

TESTS FOR THE EFFECT OF TRANSVERSE FORCE

To determine the effect of initial eccentricity upon the additional deflection caused by a transverse force, readings were taken with considerable positive eccentricity, with considerable negative eccentricity, and with practically zero eccentricity

Table 1 gives part of the log of two consecutive runs made March 21, 1928. Euler's critical load had previously been found to be 10,025 lb. Since the theoretical deflection may be calculated in terms of this load, the longitudinal load was applied in

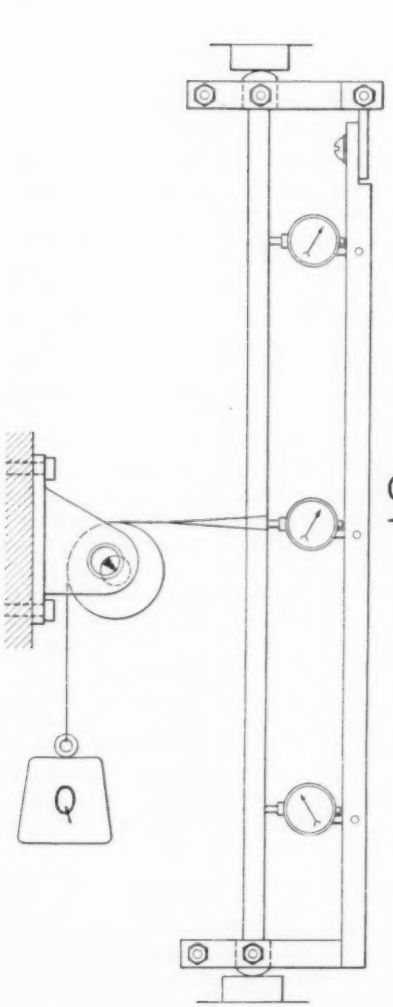


FIG. 1

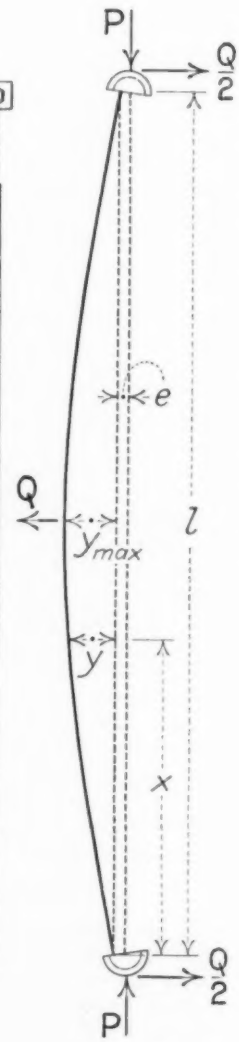

FIG. 2

increments of 5 per cent of 10,025 lb. The initial load was 501 lb. Since the deflection apparatus was made of wood, brass, and steel and the room temperature varied considerably during the day, the load was brought back to the initial value after each test. This precaution was not necessary to get the additional deflection caused by the addition of transverse forces, since these forces were applied immediately after the readings were taken for the deflection caused by the longitudinal load. It was desirable, however, in order to check the deflection caused by the longitudinal load, to calculate the eccentricity, and to detect any permanent deformation.

The figures in the deflection column of Table 1 in line with the applied load and the zero transverse force measure the deflection as a column when this load was applied. For instance, when the load of 3007 lb. was applied the reading of the middle dial was 3980. The initial reading at 501 lb. was 3874. The additional deflection as a column when the load was changed from 5 per cent of 10,025 to 30 per cent of 10,025 was 106 ten-thousandths of an inch. The deflection at 10 in. from the top was 63 and at 10 in. from the bottom was 66 ten-thousandths. With a different negative eccentricity the same change in load caused a negative deflection of 136 at the middle gage, 55 at the upper gage, and 70 at the lower gage. This deflection will be designated as the "eccentricity deflection."

The figures in the deflection columns in line with the applied load and 5 lb. transverse force measure the change in deflection caused by this force. For instance, with a load of 3007 lb. and zero transverse force the reading at the middle was 3980. When the transverse force of 5 lb. was applied the reading fell to 3886, a change of 0.0094 in. When the transverse force of 10 lb. was applied the deflection was 3980 — 3791 = 189. This will be designated as the "transverse-force deflection."

(With the apparatus as set up the additional deflection caused by the transverse force was always negative. The negative sign is omitted in Table 1 for these deflections.)

The "eccentricity deflection" at the lower dial was somewhat larger than at the upper dial when the eccentricity was positive, and considerably larger when the eccentricity was negative. This difference was caused by some difference in the eccentricity at the two ends. The "transverse-force deflections" were nearly equal, and the sum of the deflections at the upper and lower gages was very nearly the same as the deflection at the middle.

When the eccentricity was positive, as in the upper half of Table 1, the "eccentricity deflection" was positive. The trans-

verse force in the negative direction reduced the deflection and made the strut more nearly straight. This straightening increased the pressure on the heads and raised the beam of the testing machine. With the larger loads it was necessary to run the movable crosshead of the testing machine upward a little to balance after the transverse force was applied. With negative eccentricity the transverse force increased the negative deflection and reduced the pressure on the weighing table. With the larger loads it was then necessary to run the movable crosshead of the testing machine downward a little to balance after the transverse force was applied.

Euler's Critical Load

After the second run of Table 1 the heads were again shifted to bring the eccentricity to zero at each end. A set of readings for "eccentricity deflection" and "transverse-force deflection" was taken up to a load of 8521 lb. After the dial readings at 501 lb. had again been taken, the load was increased to 8521 lb., and then continued, with "eccentricity deflection" readings only, up to the critical load. On account of some little crookedness of the strut, these deflections were negative at first. At the upper and lower dials the deflection changed to positive below 9400 lb.; at the middle dial the zero deflection was between 9400 and 9600 lb.

The results of Table 2 are characteristic of the behavior of a round-end strut with extremely small eccentricity. Under this condition the deflection at the maximum load can be changed from positive to negative by a very small transverse force, and the maximum longitudinal load is practically the same in either position. In this experiment the maximum load with positive deflection was 10,025 lb. and with negative deflection was 10,016 lb. On the basis of this and other previous experiments 10,025 lb. has been adopted as the critical load in the computations which follow. (This strut with the same mounting was tested July 18, 1927, on the 400,000-lb. Riehlé machine of the Department of Civil Engineering of Cornell University. The critical load was there found to be 10,050 lb. A series of struts made of steel of high elastic limit might well be used for calibrating testing machines.)

From Euler's formula, $P = \pi^2 EI/l^2$, the value of the product of the modulus of elasticity multiplied by moment of inertia is found to be

$$EI = \frac{10{,}025 \times 60 \times 60}{9.8696} = 3{,}656{,}700$$

This value is a factor in the theoretical calculations which follow.

Theoretical Deflection

The deflection formula is derived from the equation $EId^2y/dx^2 = M$. From Fig. 2, at a distance x from the end,

$$EI\frac{d^2y}{dx^2} = -Py - Pe - \frac{Qx}{2} - M \quad \ldots\ldots [1]$$

in which y is the deflection at a distance x from the end, e is the eccentricity measured from the line of the longitudinal load to the center line of the strut, Q is the transverse force at the middle, and M is a moment, constant throughout the length of the strut. This moment M is the product of one-half Q multiplied by the radius of the cylindrical head. The differential equation may be written

$$\frac{d^2y}{dx^2} + \frac{Py}{EI} = -\frac{Pe}{EI} - \frac{Qx}{2EI} - \frac{M}{EI} \quad \ldots\ldots [2]$$

The solution is

$$y = A\cos\sqrt{\frac{P}{EI}}\,x + B\sin\sqrt{\frac{P}{EI}}\,x - \frac{Qx}{2P} - e - \frac{M}{P} \quad \ldots [3]$$

$$\frac{dy}{dx} = -A\sqrt{\frac{P}{EI}}\sin\sqrt{\frac{P}{EI}}\,x + B\sqrt{\frac{P}{EI}}\cos\sqrt{\frac{P}{EI}}\,x - \frac{Q}{2P} \quad \ldots [4]$$

In Equation [3], when $x = 0$, $y = 0$, hence

$$A = e + \frac{M}{P}$$

(It is evident that M/P is equivalent to an additional eccentricity. See "Equivalent Eccentricities Due to Secondary Stresses," by Cecil Napier Ross, Trans. Inst. of Engineers, Australia, vol. 7, 1927.)

When $x = l/2$ in Equation [4], $dy/dx = 0$, hence

$$B = \left(e + \frac{M}{P}\right)\tan\sqrt{\frac{P}{EI}}\,\frac{l}{2} + \frac{Q}{2P}\sqrt{\frac{EI}{P}}\sec\sqrt{\frac{P}{EI}}\,\frac{l}{2} \quad \ldots [5]$$

Substitution of the values of the arbitrary constants, A and B, in Equation [3] gives

$$y + e + \frac{M}{P} = \left(e + \frac{M}{P}\right)\left(\cos\sqrt{\frac{P}{EI}}\,\frac{l}{2} + \tan\sqrt{\frac{P}{EI}}\,\frac{l}{2}\sin\sqrt{\frac{P}{EI}}\,x\right) + \frac{Q}{2P}\sqrt{\frac{EI}{P}}\sec\sqrt{\frac{P}{EI}}\,\frac{l}{2}\sin\sqrt{\frac{P}{EI}}\,x - \frac{Qx}{2P} \quad \ldots [6]$$

Equation [6] may be written

$$y + e + \frac{M}{P} = \left(e + \frac{M}{P}\right)\left[\sec\sqrt{\frac{P}{EI}}\,\frac{l}{2}\cos\sqrt{\frac{P}{EI}}\left(\frac{l}{2} - x\right)\right] + \frac{Q}{2P}\sqrt{\frac{EI}{P}}\sec\sqrt{\frac{P}{EI}}\,\frac{l}{2}\sin\sqrt{\frac{P}{EI}}\,x - \frac{Qx}{2P} \quad \ldots [7]$$

At the middle, where $x = l/2$,

$$y_{max} + e + \frac{M}{P} = \left(e + \frac{M}{P}\right)\sec\sqrt{\frac{P}{EI}}\,\frac{l}{2} + \frac{Q}{2P}\sqrt{\frac{EI}{P}}\tan\sqrt{\frac{P}{EI}}\,\frac{l}{2} - \frac{Ql}{4P} \quad \ldots [8]$$

$$y_{max} = e\left(\sec\sqrt{\frac{P}{EI}}\,\frac{l}{2} - 1\right) + \frac{M}{P}\left(\sec\sqrt{\frac{P}{EI}}\,\frac{l}{2} - 1\right) + \frac{Q}{2P}\sqrt{\frac{EI}{P}}\tan\sqrt{\frac{P}{EI}}\,\frac{l}{2} - \frac{Ql}{4P} \quad \ldots [9]$$

In these equations y_{max} is the total deflection at the middle.

The term $e\left(\sec\sqrt{\frac{P}{EI}}\,\frac{l}{2} - 1\right)$ gives the eccentricity deflection, the first deflection figure of the middle gage at each load of Table 1. The remaining terms give the additional deflection which is produced when a transverse force is applied. In this experiment $M = Qr/2$. The transverse force Q therefore appears in the first degree in each of the last three terms. The additional deflection is directly proportional to the transverse force.

The term $\frac{M}{P}\left(\sec\sqrt{\frac{P}{EI}}\,\frac{l}{2} - 1\right)$ expresses the additional deflection caused by the constant moment. For an ideal pin-end column with frictionless pins the resultant reactions would pass

through the axes of the pin and there would be no constant moment term in the deflection formula.

Calculation of the Additional Deflection Caused by a Transverse Force at the Middle

For an ideal round-end strut which ends with knife edges or cylinders of infinitely small radii, or is loaded through frictionless pins, the additional deflection caused by a transverse force is given by the last two terms of Equation [9]. If y_1 represents this deflection,

$$y_1 = \frac{Q}{2P}\sqrt{\frac{EI}{P}}\tan\sqrt{\frac{P}{EI}}\frac{l}{2} - \frac{Ql}{4P} \quad \ldots\ldots\ldots [10]$$

Since the tangent series is

$$\tan x = x + \frac{x^3}{3} + \frac{2x^5}{.15} + \text{etc.},$$

$$\tan\sqrt{\frac{P}{EI}}\frac{l}{2} = \sqrt{\frac{P}{EI}}\frac{l}{2}\left(1 + \frac{Pl^2}{12EI} + \frac{2P^2l^4}{240E^2I^2} + \text{etc.}\right)$$

$$\frac{Q}{2P}\sqrt{\frac{EI}{P}}\tan\sqrt{\frac{P}{EI}}\frac{l}{2} = \frac{Ql}{4P} + \frac{Ql^3}{48EI} + \frac{QPl^5}{480\,E^2I^2} + \text{etc.}$$

$$\frac{Q}{2P}\sqrt{\frac{EI}{P}}\tan\sqrt{\frac{P}{EI}}\frac{l}{2} - \frac{Ql}{4P} = y_1 = \frac{Ql^3}{48EI} + \frac{QPl^5}{480\,E^2I^2} + \text{etc.} \ldots [11]$$

The first term after the equality sign in Equation [11] gives the deflection of the strut as a beam supported at the ends with a concentrated load Q at the middle. The terms which follow form an infinite series in ascending powers of $Pl^2/4EI$. For small values of $Pl^2/4EI$ the sum of this series may be neglected and $Ql^3/48EI$ may be taken as the entire deflection. For larger loads the deflection may be many times greater than that of a simple beam.

Computation of the Deflection

The additional deflection of an ideal round-end strut may be calculated by Equation [10]. Since Euler's critical load is known, it is not necessary to substitute in the expression $\sqrt{\frac{P}{EI}}\frac{l}{2}$ to get the corresponding angle. For Euler's critical load the secant of this angle is infinite and the angle is 90 deg. For any given load the corresponding angle is 90 deg. multiplied by the square root of the ratio of this load to Euler's load. A load of 8120 lb., for instance, is 0.81 of 10,025 lb., and the angle $\sqrt{\frac{8120}{EI}}\frac{l}{2}$ is 90 deg. multiplied by $\sqrt{0.81} = 90° \times 0.9 = 81°$. To get the additional deflection caused by a transverse force of 10 lb. at the middle when the load is 8120 lb. the formula gives

$$y_1 = \frac{10}{2 \times 8120} \times \sqrt{\frac{3{,}656{,}700}{8120}} \times 6.31375 - \frac{10 \times 60}{4 \times 8120}$$

$$= \frac{1}{1624} \times 21.221 \times 6.31375 - \frac{15}{812}$$

$$= 0.08250 - 0.01847$$

$$= 0.0640$$

The addition deflection caused by the constant moment is

$$y_2 = \frac{M}{P}\left(\sec\sqrt{\frac{P}{EI}}\frac{l}{2} - 1\right)$$

Since the radius of each semicylindrical head used in the experiments was $^{15}/_{16}$ in., the moment for a transverse force of 10 lb. is $^{75}/_{16}$ in-lb. For a longitudinal load of 8120 lb.,

$$y_2 = \frac{75}{16 \times 8120}(\sec 81° - 1) = \frac{75}{129{,}920}(6.39245 - 1)$$

$$= 0.0031$$

The total additional deflection is $0.0640 + 0.0031 = 0.0671$.

Table 3 gives the additional deflection for a transverse force of 5 lb. and for a transverse force of 10 lb. for positive, negative, and zero eccentricity. The lower part of the table, beginning with a load of 501 lb., is from the tests of March, 1928, which are given in part in Table 1. The positive eccentricity, calculated from the "eccentricity deflection" from 501 lb. to 8521 lb., was about 0.03 in. The negative eccentricity was about 0.02 in. The upper part of the table is from measurements taken in September, 1927. The positive and negative eccentricities were each about 0.02 in. The run with zero eccentricity was made a few days before the others, and with somewhat less care. To reduce the labor of computation the tests of the upper part of the table were made with equal increments of the square root of the ratio of the load to Euler's critical load. Those of the lower part were made with equal increments of the ratio.

For the smaller loads the readings indicate that the additional deflection when eccentricity was positive (and the additional deflection negative) was a trifle larger, on the average, than when the eccentricity was negative or zero. This slight difference may be caused by crookedness of the strut which affects the "eccentricity deflection" most at the lower loads. Within narrow limits, however, the table shows that the magnitude of the additional deflection is independent of the eccentricity.

Fig. 3 represents Table 3 graphically. The ordinates give the ratios of the longitudinal loads to Euler's critical load. The abscissas are the additional deflections. The curves are drawn from the theoretical deflections. The circles represent the experimental points. A preliminary test with a timber strut gave equally close agreement with the theory.

Experiment With Constant Moment Alone

For the experiments of Tables 1 and 3 the additional moment was that of a beam supported at the ends and loaded at the middle, together with a relatively small constant moment which was equal to the transverse reaction at the end multiplied by the radius of the semicylindrical head. Since the additional de-

flection caused by this constant moment was less than 5 per cent of the total additional deflection, it was deemed advisable to measure the deflection caused by a larger constant moment acting alone. To apply this moment a light horizontal arm was fastened to each semicylindrical head. A 10-lb. mass was hung from the upper arm at a distance of 8.45 in. from the axis of the strut. A cord attached to the lower arm at the same distance from the axis of the strut ran vertically upward, passed over the knife-edge pulley shown in Fig. 1, and supported a second 10-lb. mass on the descending end.

8521	0.85	412	426	415	418	835	854	856	848	850

The results of this test are given in Table 4. The moment arms were so placed as to make the deflection positive. The second column of the table gives the additional deflection at the middle when the eccentricity was about +0.015 in., and the third column gives the deflection at the middle when the eccentricity was about —0.015 in. The fourth column gives the average of these two deflections, and the fifth column gives the computed value. When the load was 2506 lb., for instance,

$$y_2 = \frac{84.5}{2506}(\sec 45° - 1) = \frac{84.5 \times 0.4142}{2506} = 0.0140 \text{ in.}$$

The average experimental value at this load was 0.0138 in.

8521	752	683	712.5	712	389	344	374	347	363	362

Table 4 also gives the deflection at 10 in. from the top and at 10 in. from the bottom of the strut. The additional deflection from Equation [7] is

$$y = \frac{M}{P}\left[\sec\sqrt{\frac{P}{EI}}\frac{l}{2}\cos\sqrt{\frac{P}{EI}}\left(\frac{l}{2} - x\right) - 1\right]$$

At 10 in. from the ends, $x = \frac{l}{6}$, $\frac{l}{2} - x = \frac{l}{3}$, and $\sqrt{\frac{P}{EI}} \times \left(\frac{l}{2} - x\right)$ is two-thirds of $\sqrt{\frac{P}{EI}}\frac{l}{2}$.

For a load of 2506 lb., for instance, $\sqrt{\frac{P}{EI}}\frac{l}{2} = 45°$,

$$\sqrt{\frac{P}{EI}}\left(\frac{l}{2}-\frac{l}{6}\right)=30^\circ \qquad y=\frac{84.5}{2506}\left(1.4742\times 0.8660-1\right)$$

$$y=\frac{84.5\times 0.2247}{2506}=0.00758 \text{ in.}$$

Fig. 4 is plotted from Table 4. The abscissas are additional deflections and the ordinates are the ratios of the longitudinal loads to Euler's critical load. There is a close agreement between experiment and theory. For the smaller loads the experimental deflections are slightly smaller than the theoretical values, and the relative differences is greater for deflections at 10 in. from the end. This may be due to the small elastic resistance to rolling of the semicylindrical heads on the plane surfaces. A very slight deviation of the stress-strain diagram of the cold-rolled steel from an absolutely straight line can explain the better agreement of theory and experiment at the larger loads.

Taken together, Figs. 3 and 4 and Tables 3 and 4 may be regarded as a verification of Equation [9], well within the limits of accuracy of the experiments.

Ratio of the Additional Deflection of a Round-End Strut Caused by a Transverse Force at the Middle to Its Deflection as a Beam

While the additional deflection of an ideal round-end strut caused by a transverse force at the middle may be calculated from Equation [10], it is better to transform the equation to give the *ratio* of the additional deflection of the loaded strut to its deflection as a beam. With this ratio known, the calculation of the additional deflection of any given strut may be performed quickly.

Euler's critical load is π^2EI/l^2. For any given load on the strut, $P=k\pi^2EI/l^2$, in which k is the ratio of the given load to Euler's critical load. The angle which is represented by $\sqrt{\frac{P}{EI}}\frac{l}{2}$ is $(k^{1/2}\,90^\circ)$ and Equation [10] may be written

$$y_1=\frac{Ql^3}{2EI}\times\frac{\tan(k^{1/2}\,90^\circ)}{k^{3/2}\,\pi^3}-\frac{Ql^3}{4k\pi^2EI}$$

$$=\frac{Ql^3}{2EI\pi^2}\left(\frac{\tan(k^{1/2}\,90^\circ)}{k^{3/2}\,\pi}-\frac{1}{2k}\right)\qquad[13]$$

If r_1 is the ratio of this deflection to the deflection as a beam

$$r_1=y_1\div\frac{Ql^3}{48EI}$$

$$=\frac{24}{\pi^3k}\left(\frac{\tan(k^{1/2}\,90^\circ)}{k^{1/2}}-\frac{\pi}{2}\right)\qquad[14]$$

In this equation $24/\pi^3=0.774037$, and $\pi/2=1.57080$. For $k=0.81$, $k^{1/2}=0.9$, $k^{1/2}\,90^\circ=81^\circ$, and $\tan 81^\circ=6.31375$, whence

$$\frac{6.31375}{0.9}=7.01528, \qquad \frac{7.01528-1.57080}{0.81}=6.72158,$$

and

$$r_1=0.774037\times 6.72158=5.20275$$

When the longitudinal load on a round-end strut is 81 per cent of Euler's critical load, the additional deflection when a transverse force is applied at the middle is 5.20275 times as great as the deflection which this force would produce if there were no longitudinal load.

For the strut which was tested, the calculated deflection as a beam with a load of 10 lb. at the middle is

$$y=\frac{10\times 60\times 60\times 60}{48\times 3{,}656{,}700}=0.012306 \text{ in.}$$

when the longitudinal load is 8120 lb. The calculated additional deflection for a transverse force of 10 lb. at the middle of the tested strut for that part of the moment which increases uniformly from the ends to the middle is

$$y_1=0.012306\times 5.20275=0.0640 \text{ in.}$$

Ratio of the Additional Deflection of a Round-End Strut Caused by a Constant Moment to Its Deflection as a Beam

The additional deflection caused by a constant moment is

$$y_2=\frac{M}{P}\left(\sec\sqrt{\frac{P}{EI}}\frac{l}{2}-1\right). \quad \text{If } P=\frac{k\pi^2EI}{l^2}, \text{ then}$$

$$y_2=\frac{Ml^2}{k\pi^2EI}\left(\sec(k^{1/2}\,90^\circ)-1\right)\qquad[15]$$

The deflection at the middle of a beam under a constant moment is $y=Ml^2/8EI$. The ratio of the additional deflection of the strut to its deflection as a beam is

$$r_2=y_2\div\frac{Ml^2}{8EI}=\frac{Ml^2}{k\pi^2EI}\left(\sec(k^{1/2}\,90^\circ)-1\right)\div\frac{Ml^2}{8EI}$$

or

$$r_2=\frac{8}{\pi^2k}\left(\sec(k^{1/2}\,90^\circ)-1\right)\qquad[16]$$

In this equation $8/\pi^2=0.810569$. For $k=0.81$, $k^{1/2}=0.90$, and $k^{1/2}\,90^\circ=81^\circ$, whence

$$r_2=\frac{8}{\pi^2}\times\frac{\sec 81^\circ-1}{0.81}=0.810569\times\frac{6.39245-1}{0.81}$$

$$=0.810569\times 6.65735$$

$$=5.39625.$$

When the longitudinal load on a round-end strut is 81 per cent of the critical load, the additional deflection caused by a constant moment is 5.39625 times as great as the deflection which this moment would produce if there were no longitudinal load.

For the strut which was tested with a transverse force of 10 lb., $M=75/16$ and $EI=3{,}656{,}700$, whence

$$y=\frac{Ml^2}{8EI}=\frac{75\times 60\times 60}{16\times 8\times 3{,}656{,}700}=0.0005768 \text{ in.}$$

The additional deflection at the middle caused by the constant moment is $0.0005768\times 5.29625=0.0031$ in. The *total* additional deflection is $0.0640+0.0031=0.0671$, which agrees with the results previously obtained by direct substitution in Equation [9] and is one thousandth of an inch smaller than the average of three experiments as given in Table 3.

Additional Deflection of a Round-End Strut Caused by a Uniformly Distributed Transverse Force

While no experiments were made with uniformly distributed transverse forces, the ratio of the additional deflection of the strut to its deflection as a beam is here given for comparison.

If w is the transverse force per unit length tending to deflect the strut in the positive direction, the additional deflection has been found to be[2]

$$y_3=\frac{wEI}{P^2}\left(\sec\sqrt{\frac{P}{EI}}\frac{l}{2}-1\right)-\frac{wl^2}{8P}\qquad[17]$$

[2] *Engineering News*, April 11, 1907, p. 404.

If Equation [17] is written by means of the secant series, the first two terms are

$$y_3 = \frac{5wl^4}{384\,EI} + \frac{61\,Pwl^6}{46{,}080\,EI} + \text{etc.} \quad \ldots\ldots\ldots [18]$$

The first term of the second member of Equation [18] is the well-known expression for the deflection of a beam supported at the ends and uniformly loaded. The terms which follow form an infinite series in terms of ascending powers of $Pl^2/4EI$ multiplied by w. The additional deflection is directly proportional to the transverse force.

To find the ratio of the additional deflection of the strut to its deflection as a beam, $k\pi^2EI/l^2$ is substituted for P in Equation [17], whence

$$y_3 = \frac{w\,EIl^4}{k^2\pi^4E^2I^2}\left(\sec\left(k^{1/2}\,90°\right) - 1\right) - \frac{wl^4}{8k\pi^2EI}$$

$$= \frac{wl^4}{\pi^4kEI}\left(\frac{\sec\left(k^{1/2}\,90°\right) - 1}{k} - \frac{\pi^2}{8}\right)$$

and

$$r_3 = \frac{384}{5\pi^4k}\left(\frac{\sec\left(k^{1/2}\,90°\right) - 1}{k} - \frac{\pi^2}{8}\right) \quad \ldots\ldots\ldots [19]$$

in which r_3 is the ratio of the additional deflection of the loaded strut caused by the uniformly distributed transverse force to $5wl^4/384EI$. In this equation $384/5\pi^4 = 0.788427$ and $\pi^2/8 = 1.233700$. When $k = 0.25$, $k^{1/2}\,90° = 45°$, sec $45° - 1 = 0.414214$, $0.414214/0.25 = 1.65686$, and

$$r_3 = 0.788427 \times \frac{1.65686 - 1.23370}{0.25}$$

$$= 0.788427 \times 1.69264$$

$$= 1.3345.$$

Table 5 gives the values of r_1, r_3, and r_2 for equal increments of k, and also equal increments of the square root of k. Of these ratios, r_2 is the largest and r_1 is the smallest. When $k = 0.81$, for instance, $r_1 = 5.2028$, $r_2 = 5.3962$, and $r_3 = 5.2792$, whence

$$\frac{r_2 - r_3}{r_2 - r_1} = \frac{0.1170}{0.1934} = 0.605$$

Except for very small values of k, for which the differences are too small for accuracy, the ratio $(r_2 - r_3)/(r_2 - r_1)$ is found to be about 0.6. The reason for this difference may be seen from a consideration of the moment diagrams of a beam for the three kinds of loading. For a beam under a constant moment the diagram is a rectangle. The moment is as large at the ends as at any other sections. The slope and deflection increase rapidly near the ends. In a strut a considerable deflection at one-tenth of the length from each end, for instance, means that eight-tenths of the length is subjected to an additional moment which is the product of this deflection multiplied by the longitudinal load. For a beam supported at the ends and loaded at the middle, the moment diagram is a triangle. (If the deflection at the middle is equal to that caused by a constant moment the maximum at the middle is three-halves as great as the constant moment.) The slope changes slowly near the ends, and the maximum deflection as a beam is equal to the deflection under the constant moment only at the middle. It is evident, therefore, that the effect of this moment upon the additional deflection when the longitudinal load is applied would be less than for a constant moment. For a beam supported at the ends with a uniformly distributed load, the moment diagram is a parabola. (If the deflection at the middle is that caused by a constant moment, the maximum at the middle is six-fifths as great as the constant moment.) The deflection as a beam is less than that caused by a constant moment and greater than that caused by a concentrated load at the middle (except at the middle, where they are equal) and is nearer the latter.

Fig. 5 shows the ratio of the additional deflection of a round-end strut to its deflection as a beam. The entire curve is drawn for r_1, which is the ratio when the bending moment is that of a beam supported at the ends and loaded at the middle. The curve for a constant moment begins at $k = 0.4$.

Fig. 6, with the abscissas on a larger scale, gives all three ratios up to $k = 0.50$, which is beyond the limits of structural struts.

Application to Practice

The engineer who has the problem of calculating the maximum unit stress in a round-end strut which is subjected to a longitudinal load and some other bending moment may first calculate the deflection of the strut as a beam under the action of this

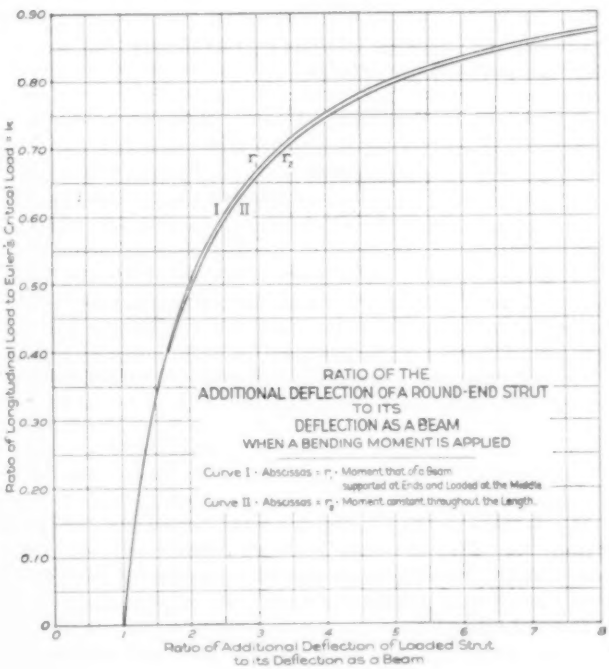

Fig. 5

TABLE 5 RATIO OF THE ADDITIONAL DEFLECTION OF A ROUND-END STRUT WHEN A BENDING MOMENT IS APPLIED TO ITS DEFLECTION AS A BEAM

r_1 = ratio when the bending moment is that of a beam supported at the ends and loaded at the middle.
r_2 = ratio when the bending moment is constant.
r_3 = ratio when the bending moment is that of a beam supported at the ends and uniformly loaded.
k = ratio of the longitudinal load on the strut to Euler's critical load.

moment. He will next find the ratio of the proposed longitudinal load to Euler's critical load. From Table 5 or from Fig. 6 he can read off the ratio which, multiplied by the deflection as a beam, gives the additional deflection. Methods of computing

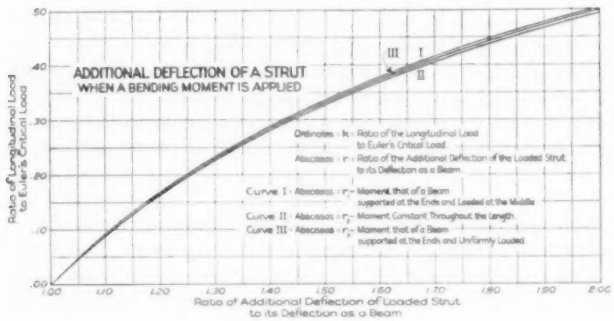

FIG. 6

stress when the deflection is known may be found in treatises on structures and technical journals.[3]

MAGNITUDE OF THE CORRECTION FOR COMMERCIAL STRUTS

The strut used in these experiments, with a slenderness ratio of 192, reaches Euler's critical load while the stress at the concave surface at the middle is far below the yield point of the material. With a factor of safety of 2.5 the value of k is 0.40, for which the additional deflection caused by a bending moment is about 67 per cent greater than the deflection calculated by the beam formulas. For short struts, which fail by compression before the critical load is reached, the coefficient k is smaller and the additional deflection differs less from the deflection as a beam.

For material with a modulus of elasticity of 29,000,000 the ultimate unit load by Euler's formula is

$$\frac{P}{A} = \frac{9.8696 \times 29{,}000{,}000}{(l/r)^2} = \frac{286{,}220{,}000}{(l/r)^2}$$

If the slenderness ratio is 100 the ultimate load is 28,622 lb. per sq. in. The allowable load per square inch on structural steel for this slenderness ratio by the American Institute of Steel Construction formulas is 11,571 lb. This is 40 per cent of the critical load for a round-end column, and the additional deflection caused by a bending moment is 67 per cent greater than the deflection as a beam.

For $l/r = 80$, Euler's load is 28,622 ÷ 0.64 = 44,720 lb. per sq. in. The American Institute of Steel Construction allows 13,279 lb. per sq. in., which is nearly 30 per cent of the critical load. From Table 5 the additional deflection when $k = 0.30$ is 43 per cent greater than that of a beam subjected to the same moment.

These examples show that the additional deflection of a strut caused by a bending moment is considerably greater than that given by the beam formulas, even for relatively short members. The calculation of the exact deflection by the formulas is laborious. This labor may be avoided by means of Table 5 or Fig. 6.

Discussion

A. M. WAHL.[4] The writer was interested in applying an approximate method to the solution of the problem of the deflection of a column subjected to a transverse load. This method consists in assuming the deflection curve of the strut in the form of a trigonometrical series and so determining the constants of this series that the work done by the external forces is equal to the stored potential energy of the system. The solution of the problem in this manner for a hinged-end strut is given in "Applied Elasticity," Timoshenko and Lessells, page 161. From this solution, the deflection at any distance x from the ends, the notation of the author's paper being used, is:

$$y = \frac{2Ql^3}{EI\pi^4}\left(\frac{\sin\frac{\pi c}{l}\sin\frac{\pi x}{l}}{1-k} + \frac{\sin\frac{2\pi c}{l}\sin\frac{2\pi x}{l}}{2^4-2^3k} + \dots\right) \quad [20]$$

Since this is a rapidly converging series, especially for practical cases where k is small, it will usually be sufficiently accurate to use only the first term of the series in practical work.

Using one term of Equation [20], the writer has computed values of r_1 given in Table 5 of Professor Boyd's paper. In the case of a transverse load at the middle, the deflection, as given by the author, is:

$$y = r_1\frac{Ql^3}{48\,EI} \quad [21]$$

Using one term of the above series, Equation [20], we find the deflection is:

$$y = \frac{Ql^3}{48EI}\left[\frac{96}{\pi^4}\frac{\sin\frac{\pi c}{l}\sin\frac{\pi x}{l}}{1-k}\right] \quad [22]$$

Since for the case considered $c = \frac{l}{2}$, $x = \frac{l}{2}$, we have by comparing [21] and [22]

$$r_1 = \frac{96}{\pi^4(1-k)} \quad [23]$$

This is the equation used by the writer in computing Table 6, wherein values of r_1 computed in this way are compared to those computed by Professor Boyd and given in Table 5 of his paper.

TABLE 6 VALUES OF r_1 AS COMPUTED BY THE USE OF EQUATION [23]

K	r_1 Computed from Equation [23]	r_1 (Computed by Prof. Boyd)
0.1	1.093	1.109
0.2	1.231	1.247
0.3	1.408	1.422
0.4	1.641	1.657
0.5	1.970	1.986
0.6	2.462	2.479
0.7	3.280	3.300
0.8	4.925	4.943
0.9	9.850	9.871

From this table it may be seen that the writer's values agree within about 1.5 per cent with those given by Professor Boyd. This suggests that in practical work it may not be necessary to use the complicated Equation [14] given by the author and used by him in the computation of Table 5 of his paper. For practical work the following approximate equation, obtained directly from [22] when

$x = \frac{c}{2}$, $c = \frac{l}{2}$, may be used:

$$y = \frac{Ql^3}{48.7\,EI}\left(\frac{1}{1-k}\right) \quad [24]$$

Of course, the computation would be facilitated by the use of the curves given by the author.

[3] E.g., E. W. Rettger, "Add-Area Method for Columns With Eccentric and Lateral Loads," *Engineering News-Record*, October 23, 1926, p. 662.

[4] Mechanics Section, Research Department, Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa. Mem. A.S.M.E.

Equation [22] suggests the possibility of obtaining the approximate deflection of a strut under longitudinal loading and subjected to a transverse load at any point distant c from one

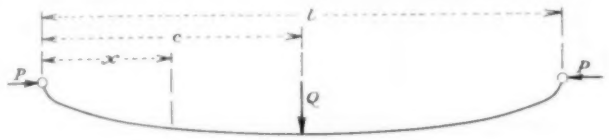

FIG. 7

end. The deflection at the middle, using [22] and [23] and remembering $x = \frac{l}{2}$, would be:

$$y = \frac{Ql^3}{48.7EI}\left(\frac{\sin\frac{\pi c}{l}}{1-k}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots [25]$$

Oftentimes it may be desirable to determine the deflection directly under the transverse load Q. In this case, $x = c$, and [22] becomes:

$$y = \frac{Ql^3}{48.7\ EI}\left(\frac{\sin^2\frac{\pi c}{l}}{1-k}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots [26]$$

These equations are more general than those given in the author's paper, since they apply to a transverse load at any point of the strut, while the author's equations hold only for a lateral load in the middle.

It must be noted, however, that these are approximate equations obtained by using one term of Equation [20]. In case of doubt, however, additional terms of [20] may easily be calculated; in this way a determination as to the accuracy of the foregoing solutions may be made for the particular case in hand.

It should also be noted that the foregoing Equations [20], [22], [23], [24], [25], and [26] apply not only to longitudinal compressive forces acting on the strut, but also to longitudinal tensile forces. In such cases, it is only necessary to change the sign of k in these equations. They thus show that where longitudinal tensile forces are acting the deflection is less than would be the case where no longitudinal forces are acting.

S. TIMOSHENKO.[5] The problem of the bending of a bar submitted to the simultaneous action of lateral and axial loads is of considerable practical importance and has been the subject of numerous investigations.[6] For many cases, there exist not only equations for calculating the deflections and moments but also tables giving directly the deflections and moments for various values of the ratio of the longitudinal force to the critical load given by Euler's formula. The cases discussed by J. E. Boyd are also well-known. They can be found in various textbooks on the strength of materials and also in such well-known handbooks as Hütte.[7]

The investigations show that if all the lateral forces have the same direction, the maximum deflection of a strut can be obtained, with an accuracy sufficient for practical applications, from the following approximate equation:

$$\delta = \frac{\delta_0}{1-\frac{P}{P_{cr}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [27]$$

in which δ_0 denotes the maximum deflection produced by lateral loads alone and $\frac{P}{P_{cr}}$ is the ratio of the compressive force to Euler's critical load. Assuming, for instance, $\frac{P_{cr}}{P} = 0.81$, we obtain, from Equation [27]

$$\delta = \frac{\delta_0}{1-0.81} = 5.26\delta_0 \quad \ldots\ldots\ldots\ldots\ldots\ldots [28]$$

This result is very close to the exact solution in the case of a uniformly distributed lateral load. In the case of a lateral load concentrated at the middle, the error of the approximate solution, [28] is about 1 per cent. In the worst case, where constant bending moments are applied at the ends, the error is about $2^1/_2$ per cent. This error also cannot be considered as excessive if we take into consideration that the quantity EI in our equations is known with an accuracy which usually is not higher than 3 per cent. Having this in mind it seems meaningless to make the numerical calculations with five and six figures as is done in the paper.

With regard to laboratory investigation, struts submitted to the simultaneous action of an axial load and a constant bending moment have been the object of numerous experiments.[8] The results of these experiments are in good agreement with the elementary theory within the elastic limit. Beyond the elastic limit the problem becomes more complicated, but here too the theory of the buckling of struts has been developed,[9] and comparison shows a satisfactory agreement between the theory and experiment. It has been shown that in the case of a shorter strut, when the critical load is beyond the yield point of the material, a very small eccentricity in the application of the compressive forces reduces considerably the magnitude of the maximum compressive load which can be carried by the strut. This fact is of great practical importance in the design of compression members of engineering structures.

The theory shows also that, in the case of materials with a sharply defined yield point, instability occurs when the compressive stress approaches the yield point. This justifies the German practice in column design, which takes the yield point as the critical stress for all members for which $\frac{l}{i}$ (the ratio of the length to the radius of gyration) is smaller than 60.

E. O. WATERS.[10] The paper shows conclusively that the accepted flexure theory as applied to beams, columns, and a combination of the two, is correct. While the tests were all run on pin-ended struts, the fact that one series was run with no transverse load, but with a constant moment of large magnitude, and gave results checking closely with theory, is an indication that fixed-end struts also act in accordance with the theory.

It is true that experimental verifications of stress analyses are best made by means of deflection measurements; but for design purposes, some function of the member in question other than deflection is generally more useful. In the present case, the writer suggests that a curve of k versus "ratio of additional moment" should be plotted. Then, to find the stress in a transversely loaded strut, it is only necessary to multiply the moment due to the transverse load alone, by the proper factor, and substitute in the equation

$$p = \frac{P}{A} \pm \frac{My}{I}$$

For the case of a concentrated load Q,

$$M = EI\frac{d^2y}{dx^2} = -\frac{Q}{2}x - Py,$$

the solution of which is

$$M = Qj\left(\frac{\sin l/2j}{\tan l/j} - \cos\frac{l}{2j}\right)\sin\frac{x}{j}, \text{ where } j = \sqrt{\frac{EI}{P}}$$

$$= Qj\frac{\tan L/2j}{2} \qquad \text{when } x = \frac{l}{2}$$

According to the author's notation, $P = k \times$ Euler load $= \frac{K\pi^2EI}{L^2}$ and therefore $\frac{1}{j} = \frac{\pi}{l}\sqrt{k}$.

Then

$$M = -\frac{QL}{2\pi}\sqrt{\frac{1}{k}}\tan\frac{\pi}{2}\sqrt{k}$$

For transverse loading alone,

$$M = -\frac{Ql}{4}$$

hence

$$R_1 = \frac{2}{\pi\sqrt{k}}\tan\frac{\pi}{2}\sqrt{k}$$

For a constant moment $-M_1$,

$$M = EI\frac{d^2y}{dx^2} = -M_1 - Py$$

the solution of which is

$$M = m, \sec\frac{l}{2j} \qquad \text{when } x = \frac{l}{2}$$

Making the same substitution for $1/j$ as before, $M = M_1 \sec\frac{\pi}{2}\sqrt{k}$ and $R_2 = \sec\frac{\pi}{2}\sqrt{k}$.

If the transverse load is uniformly distributed,

$$M = EI\frac{d^2y}{dx^2} = -\frac{wlx}{2} + \frac{wx^2}{2} - Py$$

the solution of which is

$$M = -wj^2\left(\sec\frac{l}{2j} - 1\right) \text{ when } x = l/2$$

$$= -\frac{wl^2}{\pi^2k}\left(\sec\frac{\pi}{2}\sqrt{k} - 1\right)$$

M for transverse load only $= -wl^2/8$, hence $R_3 = \frac{8}{\pi^2}\left(\frac{\sec\frac{\pi}{2}\sqrt{k} - 1}{k}\right)$.

By plotting the equations for R_1, R_2, and R_3 in a form similar to Fig. 5 and 6, they can be put into shape suitable for general designing purposes.

In the case of the concentrated transverse load, it is interesting to note the effect of shifting the point of application away from the mid-point of the strut. Suppose that Q is applied at one-quarter the strut length; then the ratio of the maximum moment in the transversely loaded strut (not to be confused with the moment at the point of application of transverse load) to the moment for the transverse load only, is 1.563, for $k = 0.49$. If Q is applied at the middle, then $R_1 = 1.786$ for the same value of k. In other words, it appears that the load can be shifted anywhere along the second and third quarter-lengths of the strut without greatly affecting the value of R_1, and the error is on the side of safety.

Author's Closure

The principal object of this investigation was the comparison of experiment with theory. For this purpose exact theoretical equations are better fitted than approximations. Exact theory also furnishes a standard for the accuracy of approximate or empirical equations. For instance, it is possible to state that Equation [23] for a transverse force at the middle is correct to within 1.5 per cent and that Equation [27] for any additional moment is correct to within 2.5 per cent by comparison with the exact equations of this paper or with other similar equations previously published.

In these problems, as in many others, it is easier to derive the exact equations than the approximate ones.

Mention has been made of the case of a transverse force which is not applied at the middle. This is covered indirectly by the tables and curves. For r_1 the diagram of the additional moment is a triangle. For r_2 the diagram is a rectangle. Almost any other loading will give a diagram between the triangle and the rectangle, and the corresponding deflection will fall in the small space between curves *I* and *II* of Fig. 5. A concentrated force which is not in the middle will evidently give a deflection very close to that of curve *I*.

Emphasis has been placed on the deflection rather than on the maximum moment or maximum stress because it was desired to keep as close as possible to the quantities actually measured. For design purposes the moment or stress would be preferable.

Mention has also been made of the unnecessary five-place accuracy of the tables. The point is well taken. For practical design Equations [23] or [27] are sufficiently accurate for most purposes. For plotting of curves and comparison with experiment the tables are carried one place farther than necessary. On the other hand, a technical paper is a matter of record which may be used for purposes other than those which the writer has in mind. In the use of published material it is much easier to cut off significant figures when too many are given than it is to calculate them when too few are given. The writer of a technical paper owes it to his readers to give his data as complete as possible, to make his calculations accurately, and to carry the results as far as any future reader is likely to need. Again, if time permits, the degree of accuracy of any computation should always be greater than that of the data. If there is a possible error of 2 per cent in the data and an equal error in the calculations, an

error of 4 per cent is possible in the final result, while if the error in the calculations is only one-tenth of 1 per cent, the error in the final result is practically that of the data.

Dr. Timoshenko has given a number of references to previous publications, a number of which are not available to the author. A very complete discussion is that of Prof. John Perry in Philosophical Magazine of March, 1892. Professor Perry derives several equations in practically the same form as those given in this paper. He even anticipates Professor Ott's explanation of the fall of the temple of Gaza.

APM-51-11

Design of Columns of Varying Cross-Sections

By DR. A. DINNIK,[1] DNIEPROPETROVSK, UNION OF SOVIET SOCIALIST REPUBLICS

(Translated by M. Maletz,[2] Milwaukee, Wis.)

IN THIS article the author develops formulas for the design of columns of varying cross-sections. Tables and graphs and many illustrative problems facilitating the correct use of these formulas are given.

1 In designing compression members for use as booms and masts for derricks, connecting rods for engines, airplane struts, etc., it is desirable to reduce their weight to a minimum and yet maintain stability. To meet these conditions it is the usual practice to make these members with a varying cross-section.

It is very common practice to use Euler's formula when investigating members of varying cross-section for buckling. While this is correct for constant cross-section members, it is entirely wrong to use this formula for compression members of varying cross-sections.

It is the purpose of this article[3] to present formulas and coefficients of stability which will enable the designer to select the proper section for a given column without setting up the differential equations and their integration.

2 Let us consider Euler's theory. Let a column of constant cross-section be compressed by axial forces applied at its ends. If these forces are comparatively small, the column remains in a straight line, but if the forces are increased beyond the so-called critical value, the column will begin to buckle.

Let us consider the more important cases.

(A) Column with both ends hinged (Fig. 1):

The differential equation[4] of the elastic curve is

$$EIy'' + Py = 0 \quad \ldots\ldots [1]$$

From the conditions at the ends, the critical load is found to be

$$P_e = \frac{\pi^2 EI}{l^2} \quad \ldots\ldots [2]$$

which is the so-called Euler's critical load.

(B) A column with both ends fixed:

The differential equation of the elastic curve for this case is

$$EIy'' + Py = n \quad \ldots\ldots [3]$$

Integrating and taking into consideration the conditions at the ends, we obtain the critical load

$$P_e = \frac{4\pi^2 EI}{l^2} \quad \ldots\ldots [4]$$

where

l = length of column
E = modulus of elasticity
I = moment of inertia of the cross-section
P_e = critical load (Euler)

The Equations [3] and [4] are commonly used for designing columns of any cross-section.

Let us next consider cases where the rigidity of columns varies according to an exponential law and a law of powers.

The Rigidity of the Column Varies According to an Exponential Law

3 The rigidity in bending is called the product EI, where E denotes the modulus of elasticity and I the moment of inertia of the cross-section of the member.

Let us consider a column (Fig. 2) the cross-section of which decreases from its middle to its ends according to a law of exponents. If I denotes the moment of inertia of the mid-section (largest) and i the moment of inertia of the end cross-section, then the moment of inertia of any cross-section distant x from the middle of the column will be

$$I_x = Ie^{-\frac{mx}{l}} \quad \ldots\ldots [5]$$

i.e., the moment of inertia changes according to an exponential law. The coefficient m characterizes the degree of change of the rigidity of the column. When the value of m is very small, the column will be slightly tapered toward its ends and will differ very little from a column of uniform cross-section.

With an increasing value of m the column becomes more tapered until the ends become points.

The elastic-curve equation for such a column with both ends hinged is

$$EIe^{-\frac{mx}{l}}y'' + Py = 0 \quad \ldots\ldots [6]$$

and the critical load is then

$$P = K\frac{EI}{l^2} \quad \ldots\ldots [7]$$

where K is the so-called coefficient of stability (for its derivation see Appendix No. 2). Table 1 contains values of K for different ratios of $i:I$; from Fig. 3, other intermediate values of K may be obtained.

TABLE 1

$i:I$	K
0.01	1.27
0.2	5.68
0.4	7.34
0.6	8.42
0.8	9.23
1.0	9.87

For columns with both ends fixed, the coefficients of stability for different ratios $i:I$ are given in Table 2 and Fig. 4.

TABLE 2

$i:I$	K
0.01	3.29
0.2	17.57
0.4	24.92
0.6	30.55
0.8	35.29
1.0	39.48

Example 1. A tapered airplane pine strut is 6 ft. long and has an elliptical cross-section. The axes of the largest (middle) cross-section are $2a = 4$ in. and $2b = 1.5$ in.; the axes of the smallest (end) ellipses are $2a = 2.75$ in. and $2b = 1.25$ in. Assuming an allowable stress of 1200 lb. per sq. in. and taking $E = 1{,}200{,}000$, examine this strut for buckling.

[1] Professor of Mechanics in the Institute of Mines.

[2] Machine Designer, A. O. Smith Corp.

[3] For a complete treatise on this subject the reader is referred to the author's articles in the bulletins of the Ekaterinoslav Institute of Mines (Russian). Some results are also given in Timoshenko-Lessells' "Applied Elasticity," p. 176, Pittsburgh, Pa., 1925.

[4] The solution of this equation can be found in any text on mechanics of materials.—Translator.

Contributed by the Applied Mechanics Division and presented at the New England Industries Meeting, Boston, Mass., Oct. 1 to 3, 1928, of The American Society of Mechanical Engineers.

Solution. We compute first the moment of inertia of the middle cross-section about its axis of the smallest rigidity, i.e., where the danger of buckling is the greatest.

$$I = \frac{2\pi \times (0.75)^3}{4} = 0.663$$

For the end section the moment of inertia $i = 0.264$ and $i : I = 0.4$. For the case of hinged ends we find in Table 1 $K = 7.34$ and from Equation [7] $P = 960$ lb. The compressive stress is

$$S = \frac{960}{\pi \times 1.375 \times 0.625} = 355 \text{ lb. per sq. in.}$$

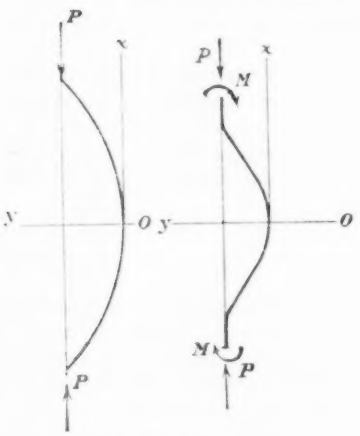

Fig. 1

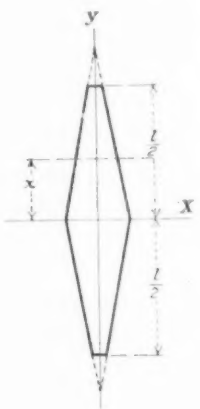

Fig. 2

which is below the allowable stress. (Note that in calculating S we used the cross-section area of the small end section.)

For the case of fixed ends, we find in Table 2 that $K = 24.92$, and from Equation [7] $P = 3210$ lb. and the stress $S = 1190$ lb. per sq. in. Using a factor of safety 5, the allowable load for hinged ends will be 192 lb., and for fixed ends it will be 642 lb. In both cases the stress is below the maximum stress allowed.

The Rigidity of the Column Varies as a Law of Powers

4 Let the moment of inertia of the cross-section of a column change along its length from the middle toward its ends according to a law of some power

$$I_x = I \left\{ 1 - (1 - k^2) \frac{x}{l} \right\}^m \quad \ldots\ldots\ldots\ldots [8]$$

where

$$k^{2m} = \frac{i}{I} \quad \ldots\ldots\ldots\ldots\ldots\ldots [9]$$

In these equations I denotes the moment of inertia of the mid-section, and x the distance from the middle to any section whose moment of inertia is I_x (Fig. 2).

This case is more important than that of Equation [7] for the following reasons: first, for $m = 0$ we get a column of constant cross-section; second, for $m = 2$ we obtain a braced pyramidical column; third, for $m = 3$ a hollow cone, and for $m = 4$ a solid cone, etc.

The differential equation of the elastic curve has the following form

$$EI \left\{ 1 - (1 - k^2) \frac{x}{l} \right\}^m y'' + Py = 0 \quad \ldots\ldots [10]$$

This equation can be readily integrated by means of Bessel's functions for any value of m, except for $m = 2$ and $m = 4$, when common (elementary) integration is used (see Appendix No. 1).

The Pyramidical Column

5 The coefficients of stability K for both hinged and fixed-end columns for different ratios of $i : I$ are given in Table 3[5] and Fig. 5, the general form of the formula for the critical load being

$$P = K \frac{EI}{l^2}$$

TABLE 3

$i : I$	K_1 (hinged ends)	K_2 (fixed ends)
0.0	1.00	1.00
0.1	5.40	14.39
0.2	6.37	18.43
0.4	7.61	25.54
0.6	8.51	30.79
0.8	9.24	35.35
1.0	9.87	39.48

A Conical Column

6 For a column with both ends hinged, we obtain for the critical load

$$P = K_3 \frac{EI}{l^2} \quad \ldots\ldots\ldots\ldots\ldots [11]$$

and for a similar column with ends fixed

$$P = K_4 \frac{EI}{l^2} \quad \ldots\ldots\ldots\ldots\ldots [12]$$

Table 4 and Fig. 6 give the coefficients of stability for these two cases.

General Case

7 For all other values of m, Equation [10] is integrated by means of Bessel's functions, and from conditions at the ends

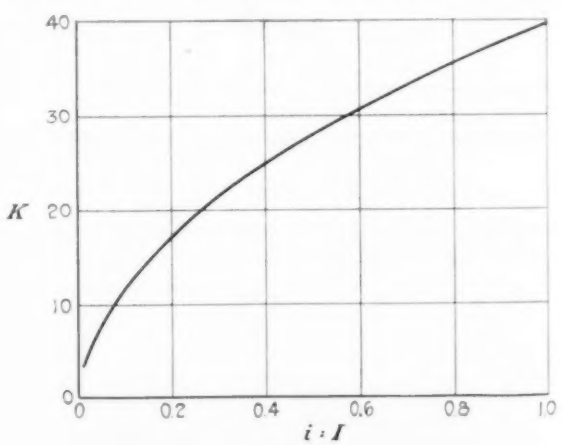

Fig. 3

[5] Bleich in his new treatise on bridge design, "Theorie u. Berechnung der eisernen Bruecken," Berlin, 1924, pp. 136–142, considers the case of a pyramidical column, the rigidity of which varies as the law of squares, i.e., when $m = 2$. The coefficients obtained by Bleich are practically the same as those in Table 3, except for small ratios of $i : I$. For instance, for $i : I = 0.04$ Bleich gives $K = 4.72$, whereas in Table 3 we find $K = 4.44$; for $i : I = 0$ Bleich gives $K = 3.32$, whereas in Table 3 $K = I$. The discrepancy is due to Bleich's making use of Ritz's method, which is an approximate one only, and computes the first two terms only, which are not sufficient to obtain accurate results for small ratios of $i : I$. The author solves the same problem by integrating the differential equation for flexure.

we can calculate the critical load. The coefficients of stability for values of $m = 1$ are given in Table 5 and Fig. 7 and $m = 3$ in Table 6 and Fig. 8.

Example 2. An airplane pine strut is 6 ft. 6 in. long and has a rectangular cross-section. The thickness of the strut is $^3/_4$ in. and remains constant throughout its entire length. The width varies according to a straight-line law, and is 4 in. in the middle and 2.4 in. at the ends; the modulus of elasticity $E = 1{,}200{,}000$. Examine this strut for buckling.

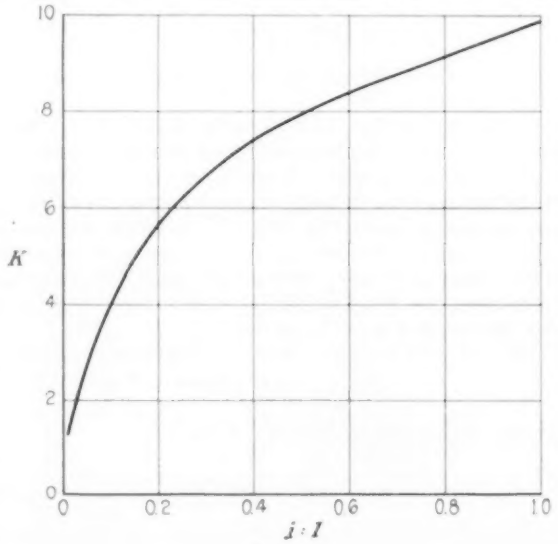

FIG. 4

Solution. The rigidity of the strut varies as a straight line, i.e., $m = 1$, the ratio of $i:I = 0.6$, the coefficient of stability for hinged ends from Table 5 is $K = 8.61$, and the critical load $P = 239$ lb. The maximum stress is about 323 lb. per sq. in. This is below the allowable stress. If the ends of the strut are fixed, then $K = 31.03$, $P = 860$ lb., and the maximum stress will be 478 lb. per sq. in., which is also below the allowable stress.

Example 3. A supporting column in a mine structure which is 65 ft. high carries a load of 66,000 lb. It is built up of four equal leg angles connected with lattice bars. Select the size of the angles and the distances between them, assuming an allowable compressive stress of 7000 lb. per sq. in. and a factor of safety 4.

Solution. Considering the column under compression only, it is found that the area of each angle must be 2.36 sq. in. This corresponds to a $3^1/_2 \times 3^1/_2 \times {}^3/_8$ angle, the area of which is 2.48 sq. in. Then the compressive stress will be 6650 lb. per sq. in.

Let us now select the distance between the angles so that the column will not buckle. If the width of the column is taken as 12 in., then the moment of inertia of the section will be (according to the well-known theorem of moments of inertia about parallel axes)

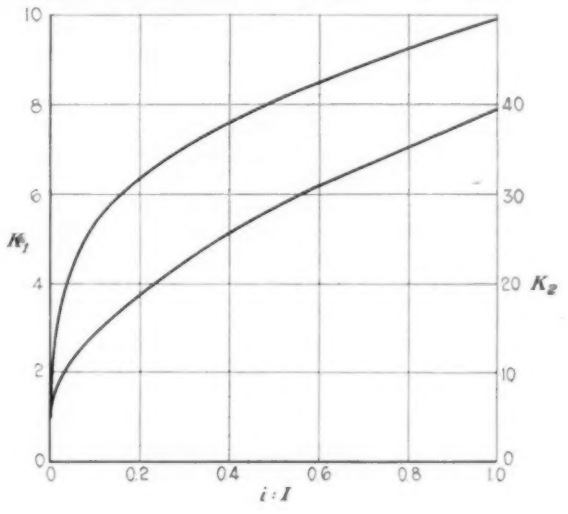

FIG. 5

$$i = 4 \times 2.9 + 4 \times 2.48 \times (6 - 1.01)^2 = 258.6 \text{ in.}^4$$

where

2.9 = the moment of inertia of each angle about the axis through its center of gravity

1.01 = the distance from the back of the angle to its center of gravity. (All figures are taken from Carnegie's Handbook.)

If the section of the column is uniform, the critical load in accordance with Euler's theory will be $P = 126{,}000$ lb.; i.e., the factor of safety is less than 2. In order to increase the stability we shall make the column wider in the middle only. Let us space the angles in the middle of the column $20^1/_2$ in. back to back. The moment of inertia of the new section consisting of the same angles will then be

$$I = 4 \times 2.9 + 4 \times 2.48 \times (10.25 - 1.01)^2 = 859.5 \text{ in.}^4$$

and the ratio $i:I = 0.3$.

As the moment of inertia varies along the length very closely as the law of squares, the coefficient of stability may be taken from Table 3. For the ratio $i:I = 0.3$, $K = 7.05$, and the critical load will be $P = 295{,}000$ lb.; i.e., by increasing the width of the column in its middle we have increased its stability more than twice with a factor of safety of more than 4.

It is evident that by just widening the column in its middle we can increase the stability of the column without increasing the area of the angles provided; that the connections between the angles are rigid enough to prevent any relative displacement of the angle so that they will act as a whole.

Example 4. A cast-iron supporting column of a transmission line has the form of a hollow double cone. The diameter of the middle (largest) cross-section is 10 in. and that of the end is $7^1/_2$ in., the thickness of the wall is $^3/_4$ in., and the height of the column is 23 ft. 9 in. Examine the column for buckling.

Solution. The moment of inertia of the largest cross-section is $I = 234.7$ and that of the smallest end is $i = 91.7$ and the ratio $i:I = 0.395$, say 0.4. The moment of inertia of the cross-sections in a cone varies approximately as the law of cubes. Hence from Table 6 ($m = 3$ and $i:I = 0.4$) we find that $K = 7.53$ and $P = 283{,}000$ lb., the average modulus of elasticity for cast iron having been taken $E = 13{,}000{,}000$ lb. per sq. in. Using a factor of safety 6, the column can safely carry 47,150 lb., and the maximum compressive stress will be 2965 lb. per sq. in. (When this column was actually designed a compressive stress of 5000 lb. per sq. in. was allowed.)

Example 5.[6] Design a wooden conical strut for a hydroplane when the load is 500 kg. The strut is 2 m. long and of circular cross-section. Assume an allowable stress of 50 kg. per sq. cm. and a factor of safety of 5.

Solution. Allowing a compressive stress of 50 kg. per sq. cm., the smallest cross-sectional area of the strut will be 10 sq. cm., its diameter $d = 3.56$ cm., and its moment of inertia will be $i = 8$ cm.[4] The moment of inertia of the larger section when a factor of safety 5 is allowed will be

$$I = \frac{Pl^2}{KE} = \frac{5 \times 500 \times 40000}{K \times 100000} = \frac{1000}{K}$$

Substituting the corresponding coefficient of stability from Table 4 for different ratios of $i:I$ we compute and tabulate a new Table 7, containing the following values:

1 The moments of inertia I of the largest cross-section (middle)
2 The largest moments of inertia i of the end sections
3 The corresponding diameters D and d of the middle and end cross-sections
4 The ratio of the weight of the designed strut Q to the weight of a cylindrical strut Q_0 designed according to Euler's formula.

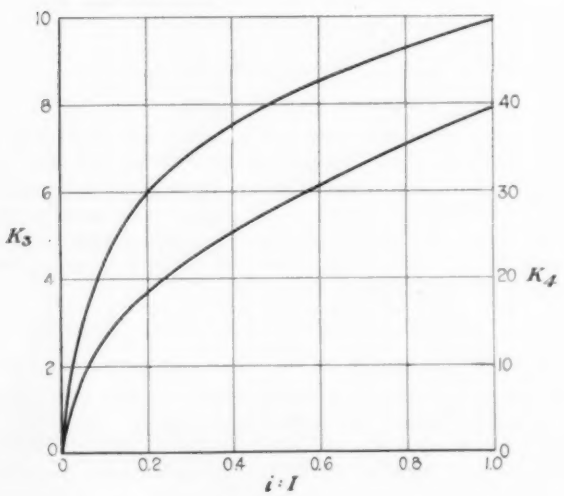

FIG. 6

The last ratio shows at a glance that by making the strut conical in shape with a ratio $i:I = 0.1$ its weight can be reduced to 63 per cent of that of a cylindrical strut. Further reduction is impossible as the material will be stressed beyond the allowable range of stresses.

TABLE 7

$i:I$	I cm.[4]	i cm.[4]	D cm.	d cm.	$Q:Q_0$
0.1	208	21	8.0	4.5	0.63
0.2	166	38	7.5	5.1	0.71
0.4	134	54	7.2	5.7	0.81
0.6	118	71	7.0	6.2	0.88
0.8	108	86	6.8	6.6	0.97
1.0	101	101	6.7	6.7	1.00

[6] Values in metric units.

The same procedure may be followed when the cross-section is other than circular, e.g., an elliptical (elliptical cone). The moment of inertia should be taken about the major axis, i.e., about the axis of the smallest rigidity.

Conclusions

The method of using Euler's formula for designing tapered columns is shown as being incorrect. Coefficients of stability

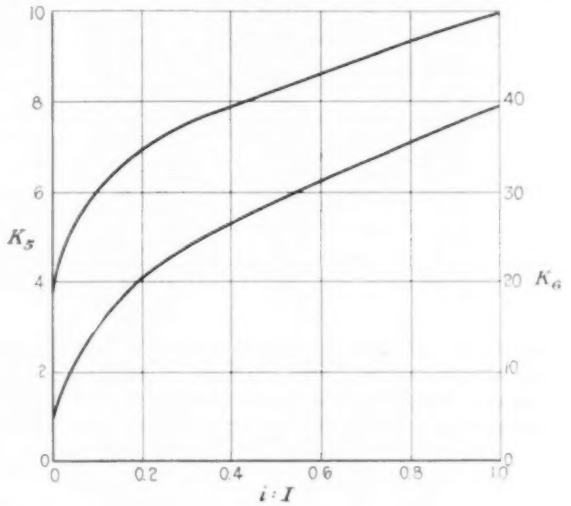

FIG. 7

for columns the rigidity of which varies according to a law of exponents or a law of powers are given in Tables 1 to 6, and their use is facilitated by graphs. A column of varying cross-section being lighter than one of constant cross-section is evidently of great advantage in cases where reduction in weight is important. Should the rigidity of a column vary according to some other laws than those mentioned in this article, Tables 1 to 6 may also be used, and the designer should then decide which of the laws in this article is closer to his case.

Appendix No. 1

Solution of Equation [6]

$$EIe^{-\frac{mx}{l}}y'' + Py = 0 \quad \ldots\ldots\ldots\ldots\ldots [6]$$

This equation can be readily integrated by using Bessel's (cylindrical) functions. Its integral is[7]

$$y = AJ_o(u) + BN_o(u) \quad \ldots\ldots\ldots\ldots\ldots [13]$$

where

$$u = \frac{2l}{m}\sqrt{\frac{P}{EI}}\, e^{+\frac{mx}{2l}} \quad \ldots\ldots\ldots\ldots\ldots [14]$$

From the conditions at the ends it is found

$$\Delta(U) = J_o(U)N_1(Ue^{\frac{m}{2}}) - N_o(U)J_1(Ue^{\frac{m}{2}}) = 0 \ldots\ldots [15]$$

[7] For a definition of the terms in the solution of these equations the reader not familiar with Bessel's functions is referred to some treatise. Tables of cylindrical functions for calculating the roots of Equations [15] and [16] are given in G. N. Watson's "Theory of Bessel's Functions," Cambridge, 1922.

and the critical load

$$P = [mUe^{\frac{m}{2}}]^2 \frac{EI}{l^2} = K \frac{EI}{l^2} \quad \ldots\ldots\ldots\ldots [7a]$$

For a column with both ends hinged the roots of Equation [15] for different ratios $i:I$ are given in Table 8.

TABLE 8

$i:I$	U
0.01	2.448
0.20	3.31
0.40	4.68
0.60	7.33
0.80	15.22
1.00	∞

For columns with both ends fixed, U may be calculated from the following equation, obtained from the conditions at the ends,

$$\Delta(U) = J_1(U)N_1(Ue^{\frac{m}{2}}) - N_1(U)J_1(Ue^{\frac{m}{2}}) = 0 \quad \ldots\ldots [16]$$

The roots U of this equation are given in Table 9.

TABLE 9

$i:I$	U
0.01	3.94
0.20	5.82
0.40	8.61
0.60	13.97
0.80	29.76
1.00	∞

Solution of Equation [10]

$$EI\left\{1 - (1 - k^2)\frac{x}{l}\right\}^m y'' + Py = 0 \quad \ldots\ldots\ldots [10]$$

1 In case $m = 2$ (for a pyramidical column)

$$y = \sqrt{u}\,\{A \cos(\mu \log_e u) + B \sin(\mu \log_e u)\} \quad \ldots\ldots [17]$$

where

$$u = 1 - (1 - k^2)\frac{x}{l}$$

$k^{2m} = i:I$, A and B are constants of integration

and

$$\mu^2 = \frac{Pl^2}{EI(1 - k^2)^2} - \frac{1}{4} \quad \ldots\ldots\ldots\ldots [18]$$

In the case of a column with both ends hinged, we obtain from the conditions at the ends

$$P = \frac{(1 + 4\mu^2)(1 - k^2)^2}{4l^2} EI = K \frac{EI}{l^2} \quad \ldots\ldots [10a]$$

where 2μ is the root of equation

$$\tan(2\mu \log_e k) = 2\mu \quad \ldots\ldots\ldots\ldots [19]$$

For a column with both ends fixed, instead of Equation [19] we have

$$2\mu \log_e k = \pi \quad \ldots\ldots\ldots\ldots [19a]$$

2 In case $m = 4$ (conical column), the integral of Equation [10]

$$y = A \frac{\cos u}{u} + B \frac{\sin u}{u} \quad \ldots\ldots\ldots\ldots [20]$$

where

$$u = \sqrt{\frac{Pl^2}{EI(l - k^2)}} \quad \frac{1}{1 - (1 - k^2)\frac{x}{l}} \quad \ldots\ldots [21]$$

and from the conditions at the ends we obtain for a column with both ends hinged

$$P = 4(1 - k^2)^2 U^2 \frac{EI}{l^2} = K \frac{EI}{l^2} \quad \ldots\ldots\ldots [22]$$

where U is the root of equation

$$\tan \frac{1 - k^2}{k^2} U + U = 0 \quad \ldots\ldots\ldots\ldots [23]$$

For a column with both ends fixed U is the root of equation

$$(k^2 + U^2) \tan \frac{1 - k^2}{k^2} U = (1 - k^2)U \quad \ldots\ldots\ldots [24]$$

3 For a general case, for any value of m except for $m = 2$ and $m = 4$, as stated before, Equation [10] is integrated by means of Bessel's function. The integral of Equation [10] is

$$y = \sqrt{1 - (1 - k^2)\frac{x}{l}}\left\{AJ_{\frac{1}{2-m}}(u) + BJ_{-\frac{1}{2-m}}(u)\right\} \quad \ldots [25]$$

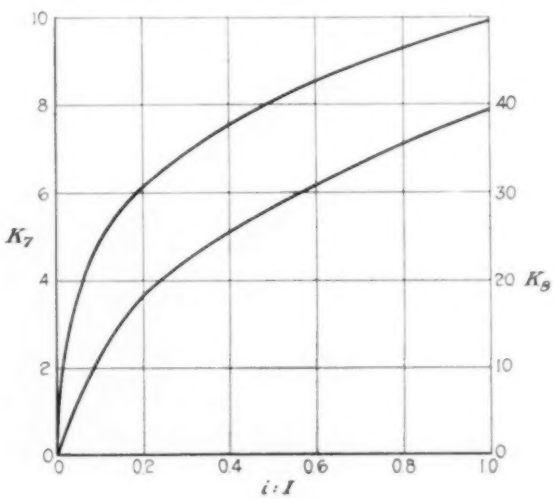

FIG. 8

where

$$u = \frac{2l}{(2 - m)(1 - k^2)}\sqrt{\frac{P}{EI}}\left\{1 - (1 - k^2)\frac{x}{l}\right\}^{\frac{2-m}{2}} \quad \ldots [26]$$

Appendix No. 2

To find the coefficients of stability, one proceeds as follows:

1 From the given moments of inertia of the end and mid-sections find k from Equation [9].

2 Inserting this value of k in Equation [19], calculate its first root (2μ) different from zero; and finally

3 Substituting k and 2μ in Equation [10a] obtain K.

This procedure should be followed in computing other coefficients in all other cases.

Discussion

JAMES E. BOYD.[8] The author has derived the equations for the ultimate strength of five forms of columns of varying cross-section and has computed the constants for both fixed ends and hinged ends. He has given these constants numerically and graphically and has applied the results to several examples of practical design. The paper represents a considerable contribution to the theory of tapered compression members.

[8] Professor of Mechanics, The Ohio State University, Columbus, Ohio. Mem. A.S.M.E.

Since the equations for hinged-end columns with rigidity varying as a law of powers have been derived by the writer,[9] he is naturally interested in comparing his work with that part of the author's paper which covers these forms.

In order to make these comparisons, it is necessary that the numerical results be reduced to the same units. The author expresses the relative strength by the letter K, which is a constant to be used in Euler's formula in place of 9.87. The writer uses the "strength ratio." This is the ratio of the strength of the tapered column to the strength of a uniform column of cross-section equal to the maximum of the tapered column.

Table 10 gives the author's values of K for hinged-end columns from Tables 5, 3, 6, and 4 (for m = 1, 2, 3, and 4 respectively) together with the corresponding values of the strength ratio, calculated by dividing K by 9.87.

TABLE 10

	m = 1		m = 2		m = 3		m = 4	
i:I	K_5	Str. ratio	K_1	Str. ratio	K_7	Str. ratio	K_9	Str. ratio
0.0	3.78	0.383	1.00	0.101	0.00	0.00	0.0	0.0
0.1			5.40	0.547			4.81	0.487
0.2	7.01	0.710	6.37	0.645	6.14	0.622	6.02	0.610
0.4	7.87	0.797	7.61	0.771	7.53	0.763	7.48	0.758
0.6	8.61	0.872	8.51	0.862	8.50	0.861	8.47	0.858
0.8	9.27	0.939	9.24	0.936	9.23	0.935	9.23	0.935

(Table 4 as printed gives 4.31 for K_3 when i:I = 0.1. Since 1000 ÷ 208 in Table 7 gives 4.81 and a recalculation by the writer results in the same value, he assumes there has been a typographical or clerical error.)

The author uses i:I, the ratio of the moment of inertia at either end to the moment of inertia at the middle, as the second variable. His expressions for moment of inertia are given in terms of the distance of the section from the middle of the column. The writer takes his origin of coordinates at the point beyond the end of the column at which the moment of inertia would be zero if the surfaces were extended to it. His expressions for the moment of inertia at a section at a distance x from the origin are $I = Cx$, Cx^2, Cx^3, and Cx^4, corresponding to m = 1, 2, 3, and 4 of the author's equations. These expressions apply to one-half of each column. The two halves are symmetrical with respect to

(The data for Table 11 are from Table XXXVII and from Tables XXXIII, XXVI, and XVII of Bulletin No. 25 of The Ohio State University Engineering Experiment Station.)

the middle section. For instance, I = Cx^4 represents a cone with the origin at the vertex. One half of the column is a frustum of this cone extending from $x = kd$ to $x = d$. In the derivation of the equations for the ultimate strength the writer uses the ratio k as one variable and gives most of his results with it instead of i:I. In Table XXXVII of Bulletin No. 25, however, he has summarized his results for the four forms in terms $\sqrt{\frac{i}{I}}$, and has plotted the corresponding curves in Fig. 22. Table 11 gives this summary, using the ratio i:I in place of the square root of the ratio.

A comparison of Table 10 with Table 11 for m = 1 shows that three of the strength ratios are identical, while the figures for i:I = 0.8 differ by less than unity in the third place. The only difference is for i:I = 0, for which the author's figure is 0.383, while the writer's, which is not given in Table 11, is 0.586. Since a value of less 0.1 for i:I would never be used, this discrepancy is unimportant.

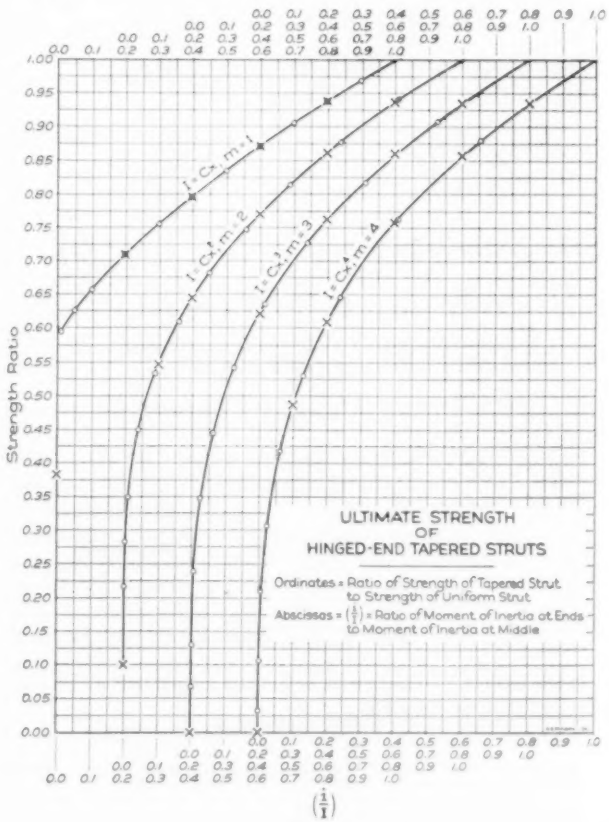

FIG. 9

For the other ratios of i:I the tables may best be compared by means of curves. This is shown on Fig. 9. The circles represent the writer's results as given in Table 11, while the crosses show the author's values from Table 10. The two sets of points for each value of i:I lie on the same curve.

While the fundamental mechanics and mathematics for both sets of results are the same, the methods of solution are considerably different. The exact agreement of the final numerical results as shown by the curves proves the correctness of both. The curves of Fig. 9, therefore, may be used wth confidence as representing accurately the relation of the strength ratio to the ratio of the moment of inertia at the ends to the moment of inertia at the middle.

In order to compare theory with experiment, the writer ran a series of tests on three types of tapered struts made of cold-rolled steel. The deflection of each strut was measured for a number of

[9] Bulletin No. 25, The Ohio State University Engineering Experiment Station, September 15, 1923; and pp. 24–36, Technologic Paper No. 152, U. S. Bureau of Standards.

loads at a known eccentricity, and compared with the theoretical value. The strut was then adjusted to a very small eccentricity for the determination of Euler's critical load at which it could be deflected a relatively large amount by a slight touch applied transversely with the little finger.

These ultimate loads from Tables XXXIII, XXVI, and XVII of the bulletin are included in Table 11, and are plotted on Fig. 10. The agreement of the experiments with the accurately drawn theoretical curves adds confidence in the theory. A comparison of the experimental deflections at the middle and at one-sixth the length from the ends with the theoretical values is equally satisfactory.

The author calculates in Table 7 the saving of material by the use of a tapered strut. The last column of this table, however, does not give the ratio of the volume of the tapered strut to the volume of a uniform cylindrical strut of equal strength. It does give the ratio of the volume of the tapered strut. For

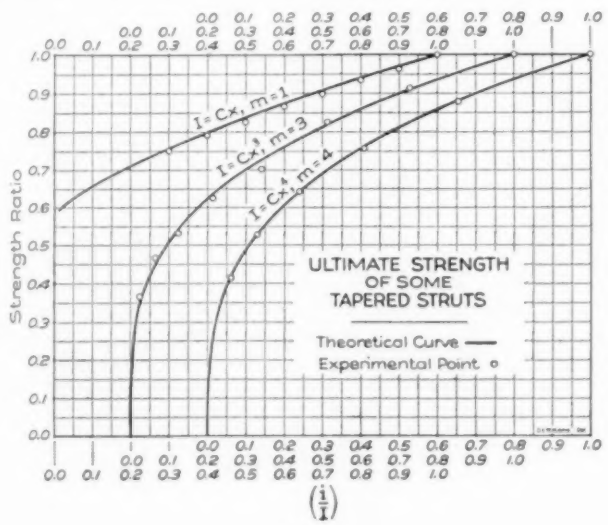

FIG. 10

instance for $i:I = 0.1$ the maximum diameter from Table 7 is 8.0 cm. and the diameter at the ends is 4.5 cm. The average diameter squared for the frustum of the cone is

$$\frac{8\times 8 + 8\times 4.5 + 4.5 \times 4.5}{3} = \frac{120.25}{3} = 40.08$$

The quotient of 40.08 divided by 64 is 0.626, the author's figure. The diameter of the uniform strut which will carry the same load is given in the last line of Table 7 as 6.7 centimeters. The quotient of 40.08 divided by the square of 6.7 is 0.896. The saving of material by using a tapered strut of this ratio is approximately 10.4 per cent instead of 37 per cent.

In place of the volume ratio, which is the ratio of the volume of the tapered strut to that of a uniform strut of equal strength, the writer has used the relative efficiency which he defines as the ratio of the strength of the tapered strut to the strength of a uniform strut of equal volume. For struts with all sections similar the moment of inertia varies as the square of the area while the volume is directly proportional to the area. The relative efficiency is the square of the reciprocal of the volume ratio. The writer has given the relative efficiency for five types of tapered struts in Tables XXXVI and XXXVII of Bulletin No. 25, and has plotted the curves in Fig. 23. Inspection shows that a conical strut, $I = Cx^4$, has a maximum relative efficiency of 1.243 when $i:I = 0.115$ approximately, and $d:D = 0.58$. The volume ratio is the square root of the reciprocal of 1.243, which is $\sqrt{0.8045} = 0.897$.

For $I = Cx^3$ the maximum relative efficiency is 1.249 at $i:I = 0.11$ and $d:D = 0.57$. The volume ratio is 0.895, and the maximum saving of material with this form 10.5 per cent.

For $I = Cx^2$ the maximum efficiency is 1.264 at $i:I = 0.09$ and $d:D = 0.56$. The volume ratio is 0.889, and the maximum saving in material is 11.1 per cent.

For $I = Cx$ the greatest efficiency is 1.315 when $i:I = 0$, which, of course, cannot be used. When $i:I = 0.1$ the relative efficiency is 1.277, the volume ratio is 0.885 and the maximum saving of material is 11.5 per cent.

For solid tapered struts with all sections similar, with length sufficiently great to fail by flexure before the ultimate compressive stress is reached at the ends, and with area at the ends about one-third the area at the middle, the possible saving of material varies from 10 to 11.5 per cent. Forms have been designed which give a saving of 12 per cent.[10]

A. M. WAHL.[11] In looking over this paper, the writer was wondering how the formulas given would apply to columns where the axis of minimum moment of inertia of the middle cross-section is in a plane different from that of the axis of minimum moment of inertia of the end cross-sections; in other words, how does it apply to twisted columns? Certain machine members might quite conceivably have this form of column. Presumably an approximation would be obtained by using the minimum value of moment of inertia at the middle section, and taking this as I in the formula of the paper. On this basis, the value of moment inertia at the ends of the column about an axis in the plane of the axis of I would be taken for i. The safest course, however, would be to take the minimum value of moment of inertia at the ends of the column for i, and use this value in conjunction with the value I of minimum moment of inertia at the middle.

The writer was also wondering whether any data exist in the literature regarding the strength of columns of variable cross-section under lateral loading. This would be of practical importance, for example, in the case of airplane struts under lateral load due to wind pressure. Such data exist for the case of columns of constant cross-section.[12] In the case of columns of variable cross-section, laterally loaded, it is possible that Ritz's approximate method may be simpler to apply than the more exact method of integrating the differential equations of flexure used by Dr. Dinnik for his case.

It would also be of interest to find the buckling strength for columns of variable cross-section when loaded beyond the proportional limit. Where the cross-section is constant this problem has been solved for columns having rectangular cross-section.[13]

E. O. WATERS.[14] Dr. Dinnik's paper is sure to be of value in many applications of machine design where one of the standard column formulas has been used in the past. It also places due emphasis on an error that has long been neglected, namely, the use of the simple Euler formula for tapered columns. This prac-

tice has been largely due, no doubt, to the lack of widespread knowledge as to the proper method of correcting the Euler theory for tapered columns; probably, too, it has been justified by a tacit assumption that the mid-section of a column, like that of a uniformly loaded beam, was "critical" and hence was the determining factor in the strength of the entire member.

As a matter of fact, however, the column presents a strain, as distinguished from a stress, phenomenon. In a beam, we can determine the stress at any section by investigating the moment of inertia of that section alone; but to find the deflection, we must know the moment of inertia at all sections. And likewise in a column, the critical load is a function of the deflection, and hence of the moment of inertia at all sections.

The tables in this paper lead to some interesting comparisons in economy of design. Consider, for example, a series of hollow conical columns, all having unit diameter at the ends, and varying from unity to 1.8 times unity diameter at the middle. Then, according to the uncorrected theory, the buckling load varies according to curve (1) in Fig. 11 and the buckling load per unit weight varies as curve (2). For the corrected theory, the corresponding curves are (3) and (4). Suppose that the maximum compressive load is twice the buckling load of a cylindrical column of unit diameter (see line ABC); then, according to the old theory, the mid-diameter should be increased 26 per cent (point B) in order to develop the full strength of the column, giving an efficiency factor 80 per cent better than the maximum possible with a cylindrical column (point D). However, according to the corrected theory, the mid-diameter would have to be increased 38½ per cent (point C) and the efficiency of utilization of material would be only 70 per cent greater (point E).

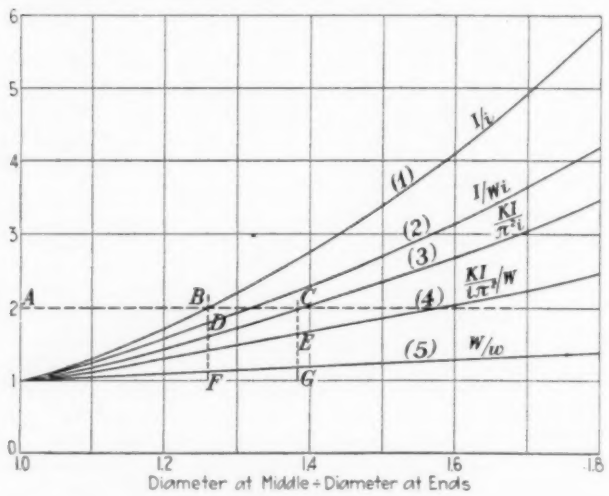

FIG. 11

In mentioning the braced pyramidal column, and in Example 3, the author seems to have overlooked a point which is quite as serious as the correction of the elastic-curve equation for variation in cross-section. I have reference to the fact that open, built-up structures have considerably less rigidity than is obtained by calculation, using the appropriate deflection formula in the paper. All such formulas assume that the material is homogeneous, and that there are no discontinuities of form. Stated in other words, the shear and direct stresses are supposed to vary by infinitesimal increments from point to point along any section. Now, as is well known, the so-called shear and direct loads in a pin-connected truss are practically divided between the web and flange members, respectively; even if the flange members are continuous they do not carry much of the shear, due to their small I in comparison with the fictitious I of the whole section (cf. 4×2.9 with 258.6, in Example 3). The proviso at the end of Example 3, "that the connections between the angles are rigid enough to prevent any relative displacement of the angle so that they will act as a whole," is almost always a practical impossibility.

In order, therefore, to make Dr. Dinnik's refinements of value for latticed columns, the rigidity function EI should be reduced by a factor taking account of the spacing, size, and method of fastening of the lattice bars.

L. B. TUCKERMAN.[15] Dr. A. Dinnik's paper is interesting in contributing another special solution of Euler's differential equation, applicable to slender columns of varying cross-section. So far as I can find from my bibliography, the case when the moment of inertia (or Euler's "moment of stiffness") varies exponentially along the column has never previously been given.

The wording of the paper, however, leaves the impression on the casual reader that recognition that the treatment must be modified in the case of varying cross-section is unusual. A study of the literature shows, however, that the difference in treatment necessary was recognized by Euler, and by many later writers. Unfortunately for the development of the subject, few of the later authors considered it necessary to find out what had previously been done or to refer to the original sources. As a consequence we find a host of special solutions worked out independently when a general solution was already known.

Euler's original paper on the calculus of variations[16] contains the famous appendix (pp. 245–310) "Additamentum I. de curvis elasticis"[17] in which the problem of the elastica is treated in great detail not only for elastica of constant stiffness but for those of varying stiffness. Incidental to this investigation he notes, (Par. 37, "de vi columnarum," p. 267) in passing, the peculiar properties of straight elastica under axial load, giving the formula $P = \frac{\pi\pi}{aa} Ekk$ (now commonly called Euler's formula) as the minimum load under which the column would bend. The existence of this critical load puzzles Euler and he returns to it again and again in his published papers, first in 1757[18] and later in three papers in 1778[19] seeking a satisfactory explanation of this phenomenon which "ne paroitra pas peu paradoxe" and "est difficile a concevoir." He never reached a satisfactory explanation because of his failure to see clearly the effect of end constraint which was first cleared up by Lagrange[20] to whom we owe our present conceptions of "round" and "fixed" ends and the critical loads of higher order corresponding to multiple lobed flexure. However, in these investigations Euler formulates clearly[17] the differential equation for columns of varying stiffness (par. 19, p.

262) in the form $\frac{Ekk}{P} X ddy + y dx^2 = 0$, where X is an arbitrary function (une fonction quelconque) of x, notes that they are soluble for cases where (in modern notation) $I_x = I(a + bx)^m$ and m has certain rational values (Bessel's functions were then unknown) and gives the solution for the cases $I_x = I(a + bx)^4$ which corresponds to a truncated cone or pyramid (par. 20, p. 263) and $I_x = I(a + bx)^2$ which corresponds to a braced pyramidal column (par. 30, p. 271) and discusses approximate solutions for other cases. With the end conditions clearly stated by Lagrange[20] a theory of slender columns of varying cross-section was already in existence in all its essentials as early as 1770.

The failure of Euler's theory to represent satisfactorily the behavior even of ordinary structural columns of uniform stiffness led to a neglect of this theory. After the work of Engesser and Considère had commenced to clear up the subject of medium-length columns and the need arose for long slender columns to which Euler's theory was applicable, interest in tapered columns revived and a number of investigators independently worked out these same special cases and a number of others without troubling to find out what others had done. I find in my files references[21] to closed solutions for the following:

$$I_x = I\left(1 - \frac{x^2}{l^2}\right), I_x = I\,\frac{4(lx - x^2)}{2}, I_x = \frac{Ix}{l},$$

$$I_x = I\,\frac{(l + x)^4}{16l^4} I, {}_x = I(l - x), I_x = I\,\frac{x^2}{l^2}$$

and $I_x = I\left(\frac{x}{l}\right)^n$

It would be interesting to know how may other people have worked out independently for special purposes special forms of Euler's more general case[17]

$$I_x = I(a + bx)^m.$$

A critical discussion of the relative advantages and disadvantages of these particular forms for particular purposes would be of considerable value.

Engesser in his second paper[21] introduces an idea, familiar in other lines, from which theoretically an infinite number of forms of closed solutions may be obtained. By assuming the deflection (y) as any arbitrary function of x, $y = f(x)$, a solution is obtained for the case

$$I_x = \frac{P}{-E}\,\frac{f(x)}{f''(x)}$$

He discusses merely the simple case of a parabolic deflection

$$y = c(l^2 - x^2)$$

which gives the special case already noted

$$I_x = I\left(1 - \frac{x^2}{l^2}\right)$$

The usefulness of the method depends of course on the type of variation found.

Paralleling these exact analytic solutions are numerous methods for successive analytic, graphic, or tabular approximations, or for graphic or tabular solution of the differential equation for arbitrary variation including discontinuities of section.[22] In addition, several authors, beginning with Lagrange, have attacked the problem of the most economical shape of a long, slender column.[23]

There is thus a considerable body of material published on the theory of slender columns of varying cross-section which would well repay a critical study.

However, a theory of the medium-length tapered column, corresponding to the theory worked out by Engesser, Considère, Jasinsky, Kármán, and Southwell (although touched upon by Engesser[21]) is yet to be developed. The problem of the tapered column can not be considered settled until that has been done.

G. B. Karelitz.[24] The tables and diagrams given in the paper are of value for a designer, where weight comes in as an important consideration. It is quite natural that most examples are taken from airplane structures. However, the Equation [8] is difficult to apply in a general case, since the ratio $i:I$ is insufficient to find both k and m. The author himself in his examples chooses first the value of m by assuming a definite shape of his strut. A sentence should be added, therefore, to the Appendix No. 2 reading: "First, choose a value for the coefficient m."

Since the sections are generally close to those discussed in the paper, the practical value of the paper is but slightly impaired by the difficulty of finding m for a strut of an arbitrary shape.

M. F. Sayre.[25] In dealing with Euler's formula, it is important to realize its limitations. These are possibly better visualized if we think of it as a special case of the more general formula

$$S = \frac{P}{A} + \frac{ePc}{I} \sec. \sqrt{\frac{Pl^2}{4EI}},$$

giving unit stresses in terms of the load P and the eccentricity e. For columns, whether short or long, where the load is applied off-center on the column, this general formula should be used. It is valid up to the point where the computed unit stress S exceeds the proportional limit of the material.

In developing Euler's formula, it is tacitly assumed (1) that there is a slight eccentricity e present, but that this eccentricity

is so small that taken by itself it would be impossible to measure, or at least negligibly, and (2) that the column is of such length that e sec. $\sqrt{\frac{Pl^2}{4EI}}$ which measures the deflection at the mid-point of the column, will become of appreciable magnitude (i.e., the column buckles) before the computed unit stress S reaches the elastic limit of the material. This naturally limits the application of Euler's formula to long columns. There is another theoretical limitation in that in an ideal case where the eccentricity was actually zero, the last term of the general formula would disappear, and the unit stress would equal P/A. This, however, is a case of unstable equilibrium. Within these limitations, the theoretical and practical errors in Euler's formula are very small; in fact, it is by far more accurate than the formulas which we are compelled to use in the design of short or medium-length columns. I understand that, because of this fact, European designers have extended its use well beyond its theoretical limitations, but with appropriately large safety factors. The story goes that at one place in South America an attempt was made to combine this European formula with American safety factors, with disastrous results.

I might second Dr. Waters' suggestion about the need of care in applying this formula to built-up columns, because of the low apparent stiffness of these columns. I am inclined to think, however, that this low stiffness is due to the large shearing deflections in the column. We have had some experiments which show us that these shearing deflections are not always as negligible as we have considered them. For instance, in timber beams, the shearing modulus of elasticity parallel to the grain is so low that bending deflections are much greater than would be expected based on the usual bending formulas, and on moduli of elasticity obtained in tension or compression tests. In built-up latticed columns, the shearing deflections in the latticing will again have an important effect upon the apparent lateral stiffness of the column. Allowance must be made for this fact when using Euler's formula, and it is likely that for built-up columns values of E appreciably less than 30,000,000 lb. per sq. in. should be used.

APM-51-12

Calculation of Flywheels for Air Compressors

By H. R. GOSS[1] and H. V. PUTMAN,[1] EAST PITTSBURGH, PA.

The authors present a short history of the application of low-speed synchronous motors direct connected to ammonia compressors. It is shown how the use of XY curves has brought about a practical solution of the flywheel problem and how in practically all present-day cases the necessary flywheel effect can be incorporated in the rotor of the synchronous motor. A short history of the application of synchronous motors to air compressors is also given, and the special problems encountered due to the unbalanced weights of reciprocating parts and to part-load operation of air compressors are discussed.

A derivation of the fundamental differential equation of the XY curve is given and a simple method presented for its solution. An example illustrating the method of making XY curves is given. Curves and data are given which materially reduce the labor involved in making XY curves. A set of eight XY curves for two-cylinder double-acting two-stage air compressors is included. These curves cover full-load, no-load, and six different part-load conditions. A second set of two XY curves is presented covering full-load and no-load operation for single-cylinder double-acting single-stage compressors.

The paper has two appendixes. Appendix No. 1 presents formulas for calculating the theoretical indicated horsepower for single- or for two-stage multi-cylinder compressors. Appendix No. 2 presents methods of calculation of the theoretical torque curves for compressors. An expression for the inertia torque due to the reciprocating parts of a compressor is given. Tables are presented giving the results of the harmonic analysis of the torque curves due to the gas forces at full load, half load, and no load for the high-pressure and low-pressure cylinders. It is shown how these harmonics of the separate cylinders can be combined to give the harmonics in the torque of the complete machine when operating at full load or under part-load conditions.

VERY few practical problems involving an application of simple mathematics are more fascinating than the flywheel problem in synchronous motors direct connected to reciprocating apparatus. It is in reality the old problem of forced vibrations in a mechanical system, or, to use an electrical analogy, it is the problem of the simple resonance circuit—not the transient but the steady-state condition.

Any engineer will write for the current in the simple alternating-current circuit

$$I = \frac{E}{Z}$$

almost more readily than he will write the equation

$$E = ir + L\frac{di}{dt} + \int \frac{1}{C}\, idt$$

of which it is the steady-state solution. For a fact he usually knows the solution better than the differential equation. The flywheel problem involves the same equation and the same solution just dressed up differently. It is more interesting, however, because the impressed force instead of being a well-behaved sine wave, like the voltage, is now the compressor torque, which involves not only a fundamental sine wave, but also three additional harmonics of importance and many others so small as to be disregarded. In other words, the impressed force is a Fourier's series and the solution must likewise be a Fourier's series but of the same form as

$$I = \frac{E}{Z}$$

and no more difficult.

Another thing about this problem which stirs one's enthusiasm is the fact that it can easily be checked experimentally. The solution to be sure is a Fourier's series and it actually represents the current pulsation in the line of the synchronous motor. The pulsation is hence not a sine wave but an irregular wave which can be obtained by adding together the several harmonics in the series. One needs only to make an oscillogram of the current in the line to obtain experimentally the actual irregular wave of current pulsation which will check remarkably well with the calculated wave. For some actual comparisons of this kind the reader is referred to the third item in the bibliography at the end of this article. The comparisons are truly remarkable.

There is no gainsaying that the work involved in working curves for the calculation of flywheels is tedious. It is very tedious and time-consuming and yet so fascinating is the problem that the writers have kept at it intermittently for several years.

History of the Flywheel Problem in Ammonia Compressors

One object of this paper, in addition to the presentation of a set of flywheel curves for air compressors, is to arouse interest in the subject and to show how vitally it is connected with the development of the compressor industry.

The application of direct-connected synchronous motors to compressors is but little more than twelve years old. At first it was not altogether successful. Sometimes the motors would hunt severely and some cases occurred where it was actually impossible to hold the motors in step. It was soon found, however, that by getting a flywheel of the right size the operation was entirely satisfactory. Increasing the size of the flywheel often bettered the operation, but many cases occurred where increasing it resulted more or less disastrously.

The problem was up to the motor manufacturers and they found that it submitted to very simple analysis. Methods were devised for making flywheel curves, called *XY* curves, by means of which the correct amount of flywheel effect could be easily and quickly determined. At first the work of making these curves was so laborious as to be almost prohibitive, but later on methods were developed which shortened the work. The invention of an instrument called the "harmonic curve tracer" by one of the present writers did much to put the making of these curves on a workable basis.

The early *XY* curves which were made for ammonia compressors showed clearly that in many cases the necessary flywheel effect could be included in the motor rotor. They showed also that if the speeds of compressors could be increased to some extent, it would be possible to put the flywheel effect in the rotor in the great majority of cases. What was the result? The first machines with flywheel effect in the rotor were put into

[1] Power Engineering Dept., Westinghouse Electric & Manufacturing Co.

Contributed by the Applied Mechanics Division and presented at the Rochester Meeting, Rochester, N. Y., May 13 to 16, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

operation. The compactness of the direct-connected unit and the elimination of the flywheel appealed to the compressor user. The idea spread rapidly and in the short space of two years there was such an insistent demand for flywheel effect included in the rotor that practically all installations were sold on that basis. And it had its effect on the design of compressors and motors alike.

Compressor builders knew that the old style heavy valves used in their machines would not stand the increase in speed necessary, in many cases, for flywheel effect in the rotor. For this reason many of them stood out firmly against any increase in compressor speeds. But the more enterprising manufacturers set to work to develop new lighter valves which would stand the higher speeds. The modern feather-weight valve was the result and compressor speeds are now considerably higher than they were ten years ago.

The problem of the motor builder was to incorporate the maximum flywheel effect possible in his machines. At first it was customary to build the motor with a frame of larger diameter than would ordinarily be used. This resulted in a heavier, more expensive machine, but it had higher efficiency and lower exciter capacity and the customer was usually willing to pay for it. Gradually the standard motor design tended more and more to that required by the compressor. Larger diameters, narrower cores, lower exciter capacity, and higher efficiency resulted for the standard motor.

The constant speed of the synchronous motor also brought new problems to the ammonia-compressor industry. In the old steam-driven plants the amount of refrigeration could be regulated as desired by merely changing the speed of the steam engine. With the constant-speed synchronous motor there was no immediate method of changing the amount of refrigeration. Several schemes were devised, but the principal idea was to divide the required refrigeration between several units so that a customer might perhaps purchase three small units for his plant instead of one larger one as he would have done in the past. This then would give him a three-step variation in refrigeration capacity. It also had other advantages. The efficiency was just as good at two-thirds or one-third capacity as at full capacity. It also made a much more dependable plant as an accident to one compressor would not render the whole plant inoperative. This was an important point and one which appealed strongly to the ultimate user. And so it was that soon after the advent of the synchronous motor compressors began to increase in number and decrease in size.

Another method used to change the amount of refrigeration was to disconnect one connecting rod of a two-cylinder double-acting machine, and operate it on one cylinder. This was rather a ticklish method because the flywheel effect had to be almost exactly right. A trifle too much would produce trouble at full load and a trifle too little would cause trouble at half load when operating on one cylinder. It was not at all satisfactory until XY curves were made covering this condition of operation. With these curves the exact amount of flywheel effect could be determined and this method came into quite general use.

Another scheme which has come into favor involves the use of two two-cylinder single-acting machines placed end to end with the motor between. The motor rotor is arranged to slide back and forth in such manner as to operate either one of the compressors singly or both together with the cranks of one at right angles to the cranks of the other. Still another method, which has been used to some extent, employs hand-operated clearance pockets on the head ends of a two-cylinder double-acting compressor. Every one of these methods requires an XY curve for the calculation of the required flywheel.

There is at the present time a budding development in the refrigeration industry known as automatic refrigeration. This is simply a refrigeration plant which can be started automatically from a thermostat. Ordinarily compressors are unloaded at starting by hand-operated bypasses, but in the automatic refrigeration plant this will have to be eliminated and the compressors started with full gas pressure in the cylinders. This means that a starting torque of 175 to 200 per cent is required. This development has been anticipated and unity power-factor synchronous motors are available with these unusual starting torques. Probably installations of this type will come into general use for small sizes which are becoming popular for use in delicatessen stores and meat and fruit markets.

Another line along which the refrigeration industry is developing is that of theater refrigeration. The building restrictions in most states prevent the use of ammonia for this purpose and carbon dioxide has proved fairly successful although it has some disadvantages. The principal one is the enormous pressures required which are about 450 lb. at suction and 1000 lb. at discharge. Carbon-dioxide compressors are usually of the two-cylinder double-acting type, but their torque curves are quite different from those of ammonia compressors of the same type. This is due to the fact that the ratio of absolute discharge to absolute suction pressure is altogether different and also to the fact that the piston rod is very large in diameter so that the work done in the crank end of a cylinder is considerably less than that in the head end. Very little work has been done in calculating flywheel requirements of carbon-dioxide compressors, and recommendations based on ammonia-compressor XY curves have not always proved successful. In one case where trouble occurred it was found advantageous to set the cranks at 180 deg. instead of 90 deg. The effect of different crank angles in machines of this type should be thoroughly investigated. XY curves for the various conditions studied should be made as these will show what combination is most desirable from the standpoint of flywheel requirements.

History of the Flywheel Problem in Air Compressors

The history of the air-compressor industry in its relation to the synchronous motor is an altogether different story. The outstanding development of the refrigeration industry, which was the incorporation of the flywheel effect in the rotor, did not happen in the case of the air compressor. The reason for this was that the torque curves of air compressors, especially when operating at partial loads, were so irregular and unbalanced that the amount of flywheel effect required for satisfactory operation was usually far in excess of what could be put in the rotor. Even at full load the unbalance created by the difference in weight between the high-pressure and low-pressure pistons made it impossible to use the flywheel which would ordinarily be used for an ammonia compressor of the same type, without excessive current pulsation. The problem of developing methods of operation at partial loads which would give more balanced torque curves seemed difficult of solution. The result was that the customer who demanded flywheel effect in the rotor for his compressor was simply told that it was impossible and he was obliged to be content with the extra wheel.

The condition still exists to some extent, but it is a safe prediction that there will be some change in the future. The new valves developed for higher speed ammonia compressors were used in air compressors and resulted in a similar increase in speed. Even this did not reduce the flywheel effect required to the point where it could be put in the rotor, but it did result in higher volumetric efficiency and hence a lower priced air compressor for the same capacity.

The real solution to this problem is going to come about by the development of more balanced methods of unloading and a

more balanced full-load condition. So far only one compressor builder has developed a five-step method of unloading which is balanced enough to permit the flywheel effect to be put in the rotor. It is not surprising that this same manufacturer is the one who has cooperated most with the motor builders in the matter of making *XY* curves and studying the flywheel problem. It would be very strange indeed if other balanced methods of unloading cannot be devised. They can without doubt, but it is going to be necessary for the compressor manufacturers to get an understanding of the flywheel problem and of *XY* curves.

A few installations without external flywheel have already been made and are giving entire satisfaction. The demand for this type of installation may possibly increase just as it did in the case of the ammonia compressor.

Some suggestions might be made for producing more balanced conditions in air compressors, but they are so obvious that compressor designers must have thought of them many times. The full-load condition can be greatly improved by making the weights of the high-pressure and low-pressure pistons the same. This can easily be done by using some aluminum alloy or other light-weight material for the low-pressure piston and adding some extra weight to the high-pressure piston. The work done by the high-pressure and low-pressure cylinders should also be balanced. Strange as it may seem, many compressors are so designed that the work is equally divided between the cylinders when the discharge pressure is about 120 lb. instead of 100 lb. which is the usual discharge pressure. This condition can easily be rectified by changing the ratio of cylinder diameters slightly. One can never be sure that the work will be absolutely balanced between the cylinders because the interstage temperature may vary to some extent, but it can be at least very nearly balanced. Now with balanced gas forces and balanced inertia forces it would be a logical thing to try the cranks at 180 deg. instead of the customary 90 deg. This would eliminate completely the first harmonic and would probably permit the use of a flywheel calculated on the basis of an $x = 10$ or 12 which could in most cases be put in the rotor.

A three-fourths load obtained by the use of clearance pockets on either the head ends or the crank ends of each cylinder would still preserve the balance and would give a condition at least no worse than the full load. Similarly a balanced half load could be obtained by opening the suction valves of either both head ends or else both crank ends to atmosphere. The one-quarter load would be similar to the three-quarter condition except that the ends of the cylinders opposite the clearance pockets would be unloaded to atmosphere. The no load would be as at present, that is, all ends open to atmosphere.

It seems very probable that some such arrangement as this could be made to work out satisfactorily, but one can only tell by making an *XY* curve covering this condition. No doubt compressor designers will be able to devise other schemes, but the test of all of them will be *XY* curves. It is evident that such designers should understand the theory of the *XY* curves and how to make them if they are to cooperate with the motor manufacturers in solving this problem of incorporating flywheel effect in the rotor for air compressors. For this reason the theory of the *XY* curve is given in this article together with an example illustrating a short method of making the curves.

Another solution to this whole problem which has been adopted by one manufacturer is the entire elimination of all the part-load operations so that the compressor operates all the time at either full load or no load. Possibly this is the best method after all. It is certainly the simplest and by balancing the inertia and gas forces the flywheel effect can easily be put in the rotor. However, there must be some demand for part-load operation or so many other manufacturers would not be spending so much time and money in developing and selling their multiple-step unloading devices.

Theory of the *XY* Curve

In the olden days when automobiles were cranked by hand, the man who cranked exerted exactly the same torque on the engine as the engine did on the man. The engine's torque was due to the gas forces in the various cylinders and also to the effect of the flywheel. The man's torque, however, was due to the flexure of the muscles of his arm and back. But the point is that the two torques were equal. Exactly the same thing is the basis of the fundamental differential equation governing the action of a synchronous motor direct connected to a compressor. The motor has two muscles—one the synchronizing torque T_s which is proportional to its angular displacement, and another much smaller muscle, the damping torque T_d, which is proportional to the rate of change of the angular displacement. T_s is given in units of foot-pounds per mechanical radian displacement and T_d in foot-pounds per mechanical radian per second slip. If ψ is the angular displacement of the rotor, the motor torque is

$$T_s\psi + T_d p\psi \quad \ldots\ldots [1]$$

where

$p = \dfrac{d}{dt}$ and denotes differentiation with respect to time.

The torque of the compressor is

$$f(t) - Ip^2\psi \quad \ldots\ldots [2]$$

where $f(t)$ is some function of time which denotes the torque due to the gas and inertia forces of the cylinders. The expression $p^2 = \dfrac{d^2}{dt^2}$ denotes the second derivative with respect to time. The term $p^2\psi$ is thus acceleration and $Ip^2\psi$ has the units of moment of inertia multiplied by acceleration, and equals the torque required to accelerate the flywheel.

Now Equation [1] must be exactly equal to Equation [2] so that

$$T_s\psi + T_d p\psi = f(t) - Ip^2\psi$$

or

$$Ip^2\psi + T_d p\psi + T_s\psi = f(t) \quad \ldots\ldots [3]$$

The permanent solution of Equation [3] can be obtained in the usual way by putting $p = j\omega$, in which ω is the frequency or angular velocity of $f(t)$ in radians per second, so that

$$\psi = \frac{f(t)}{(T_s - I\omega^2) + jT_d\omega} \quad \ldots\ldots [4]$$

Now $f(t)$ is the compressor torque and as shown in Appendix No. 2 it can be expressed in the form of a Fourier's series of four harmonics. For any particular harmonic

$$\left.\begin{aligned} f(t) &= a_n + jb_n \\ \omega &= n\omega \end{aligned}\right\} \quad \ldots\ldots [5]$$

and,

n being the number of the harmonic.

Where,

a_n = sine harmonics in the torque curve
b_n = cosine harmonics in the torque curve
ω = angular velocity of the first harmonic.

Substituting Equation [5] in [4] gives

$$\psi_n = \frac{a_n + jb_n}{T_s - In^2\omega^2 + jT_d n\omega} \quad \ldots\ldots [6]$$

or, taking account of all harmonics.

$$\sum \psi_n = \sum \frac{\sqrt{a^2_n + b^2_n}}{\sqrt{(T_s - In^2\omega^2)^2 + T^2_d n^2\omega^2}} \sin\left(n\omega t + \tan^{-1}\frac{b_n}{a_n} - \tan^{-1}\frac{T_d n\omega}{T_s - In^2\omega^2}\right) \quad [7]$$

Multiplying Equations [7] through by $\frac{T_s}{a_0}$, where a_0 is the theoretical average torque of the compressor as described in Appendix No. 2, gives

$$\sum \frac{\psi_n T_s}{a_0} = \sum \frac{\sqrt{A^2_n + B^2_n}}{\sqrt{\left(1 - \frac{In^2\omega^2}{T_s}\right) + T_d{}^2 n^2\omega^2}} \sin\left(n\omega t + \tan^{-1}\frac{B_n}{A_n} - \tan^{-1}\frac{T_d n\omega}{T_s - In^2\omega^2}\right) \quad [8]$$

where $A_n = \frac{a_n}{a_0}$ and $B_n = \frac{b_n}{a_0}$.

These are the values of the harmonics given in the Tables 5 and 6 of Appendix No. 2.

It will be found convenient to put in this equation.

$$\left.\begin{aligned} Y &= \sum \frac{\psi_n T_s}{a_0} \\ Z &= \frac{I\omega^2}{T_s} \\ \lambda &= \frac{T_d\omega}{T_s} \end{aligned}\right\} \quad [9]$$

which gives

$$Y = \sum \frac{\psi_n T_s}{a_0} = \sum \frac{\sqrt{A^2_n + B^2_n}}{\sqrt{(1 - n^2Z)^2 + (n\lambda)^2}} \sin\left(n\omega t + \tan^{-1}\frac{B_n}{A_n} - \tan^{-1}\frac{n\lambda}{1 - n\,Z}\right) \quad [10]$$

This is the equation of the XY curve[2] and as such it merits special attention. In the first place it will be noticed that $\Sigma\psi_n T_s$ represents with very close approximation the torque pulsation of the motor, since $\Sigma\psi_n$ represents the pulsation in the angular displacement in radians and T_s is the torque per radian. The motor damping torque which is $\Sigma T_d \frac{d\psi_n}{dt}$ has been neglected since it is small and the power drawn by it from the line adds at right angles in time to the power drawn by the main torque pulsation $\Sigma\psi_n T_s$. So that Y, which is Y of the XY curve and which is equal to $\sum \frac{\psi_n T_s}{a_0}$, represents the torque pulsation in percentage based on the theoretical average torque of the compressor. Since the speed of the motor is practically constant Y is also the power pulsation in percentage based on the indicated horsepower calculated from the theoretical indicator cards described in Appendix No. 1. Assuming the power-factor constant during the pulsation, the current pulsation in percentage is equal to the power pulsation. Usually, however, the desired current pulsation is expressed in percentage of the name-plate rated current so that the value of Y required for a given current pulsation is

$$Y = \frac{\text{Motor rated horsepower}}{\text{Theoretical i.hp.} \times \text{power factor}} \times \text{(Desired current pulsation in per cent of name-plate rated current. Usually 66 per cent.)} \quad [11]$$

where power-factor is the power-factor of the motor.

From Equation [11] it is very easy to calculate Y for any given case corresponding to any desired current pulsation. Then with an XY curve available the corresponding value of X can be obtained and from X the actual WR^2 required for a given motor may be quickly obtained. It will be shown in Equation [17] that after X is determined the required WR^2 is the product of X multiplied by the flywheel constant of the motor called F_c. It will be shown that F_c is a characteristic constant of the motor alone involving its speed, frequency, horsepower, and natural frequency constant.

The XY curve, on the other hand, is fundamentally a performance curve of a reciprocating machine just as a speed-torque curve or an efficiency curve might be performance curves of a motor. The type of XY curve obtained for a given machine is determined by the harmonics in its torque curve. These harmonics enter in Equation [10] in the numerator and also in the phase angle $\tan^{-1}\frac{B_n}{A_n}$.

It probably will be wondered where X is in Equation [10]. As a matter of fact it will be shown that $X = 9.25Z$, so that Z is really taking the place of X in this equation. The meaning of Z can be seen at once by writing

$$Z = \frac{I\omega^2}{T_s} = \left(\frac{\omega}{\sqrt{\frac{T_s}{I}}}\right)^2 \quad [12]$$

ω is the frequency of the lowest harmonic expressed in radians per second, corresponding to the number of revolutions per minute of the machine and $\sqrt{\frac{T_s}{I}}$ is the natural frequency. Z is thus the square of the ratio of the revolutions per minute to the natural frequency in cycles per minute and X is 9.25 times this value.

The use of X came about in the following way. It is customary for some manufacturers to list a natural-frequency constant P_0 which is related to T_s by the formula

$$T_s = \frac{2625 \times \text{hp.} \times P_0 \times p}{s \times \text{kw.}} \quad [13]$$

where

s = r.p.m.
p = number of poles
hp. = rated horsepower of motor
kw. = rated kilowatts of motor.

P_0 is defined as the input kilowatts per electrical radian displacement of the rotor. With this in mind definition [13] follows at once. Substituting Equation [13] in [12] and solving for I

$$I = \frac{Z}{\omega^2} \times \frac{2625 \times \text{hp.} \times P_0 \times p}{s \times \text{kw.}} \quad [14]$$

But $I = \frac{WR^2}{32.2}$, $p = \frac{f\,120}{s}$ where f is the electrical frequency and $\omega = 0.1048\,s = \frac{2\pi}{60}\,s$.

[2] In Equation [10], Z is taking the place of X. Later it will be shown that $X = 9.25Z$.

Making these substitutions and solving for WR^2 gives

$$WR^2 = \frac{9.25Z \times \left(\frac{\text{hp.}}{100}\right) \times \left(\frac{f}{10}\right) \times \left(\frac{p_0}{\text{kw.}}\right)}{\left(\frac{s}{100}\right)^4} \times 10^3 \quad \ldots\ldots [15]$$

It is easily seen that if X is put for $9.25Z$ and the curves plotted against X instead of Z, one slide-rule operation is saved in calculating the WR^2 required from Equation [15]. It should be noted, however, that the use of X originated from a formula employing P_0 so that X and P_0 are really tied up together and

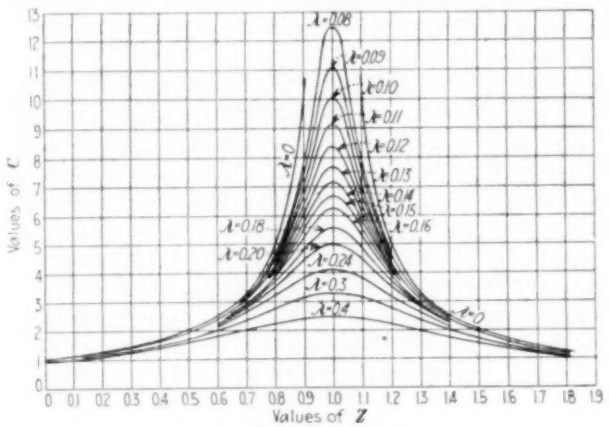

FIG. 1 FIRST HARMONIC

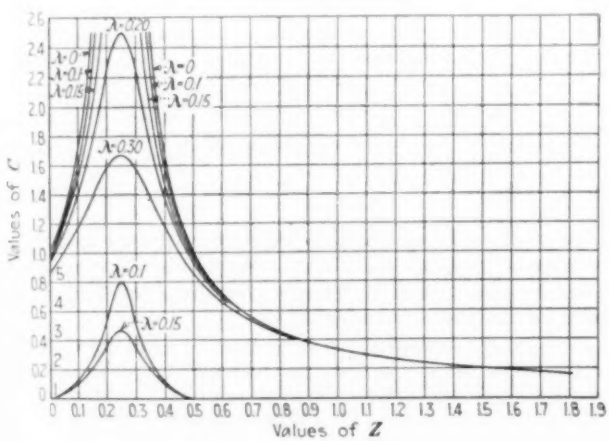

FIG. 2 SECOND HARMONIC

Formula [15] is useful only where the natural frequency constant is given as P_0.

Motor manufacturers should standardize on some flywheel constant which would permit of a simple calculation for the WR^2 required in a compressor installation. XY curves are in such general use and have been presented in so many different papers that it seems undesirable to change abscissa X to any other value although it would be possible to use an abscissa not directly related to the natural frequency constant P_0.

With this in mind the Westinghouse Company has adopted a flywheel constant called F_c defined as follows:

$$F_c = \frac{\frac{\text{hp.}}{100} \times \frac{f}{10} \times \frac{P_0}{\text{kw.}}}{\left(\frac{s}{100}\right)^4} \times 10^3 \quad \ldots\ldots [16]$$

It should be noted that F_c is a constant which depends entirely on the rating and electrical characteristics of the motor and its value can therefore be listed in the price book with each motor

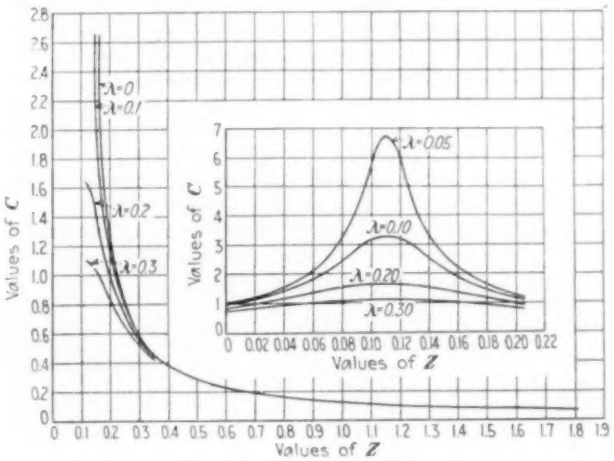

FIG. 3 THIRD HARMONIC

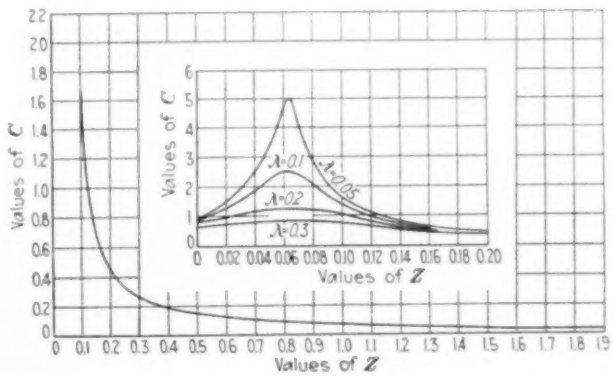

FIG. 4 FOURTH HARMONIC

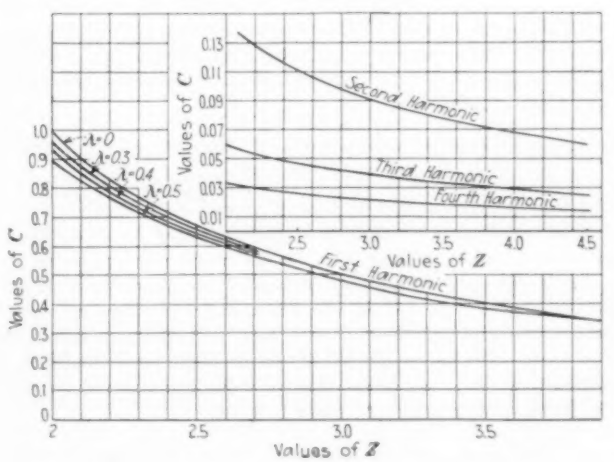

FIG. 5 ALL HARMONICS, HIGHER VALUES OF Z

rating. The formula for calculating the required flywheel effect becomes simply

$$WR^2 = XF_c \quad \ldots\ldots [17]$$

It would be to the advantage of the compressor builders if

all the electrical manufacturers would list the constant F_c defined as in the foregoing.

Returning to Equation [10] the term λ must still be explained. It will be seen by studying Equation [10] that λ is a variable, depending on the damping torque and speed of the motor but independent of Z. Hence an XY curve is not entirely independent of the speed since λ varies with the speed. The effect of λ is, however, very small except in the regions around the resonance points so that XY curves for different values of λ will be very nearly coincident except in these regions. Fortunately those portions of an XY curve in the resonance region are not used for making flywheel recommendations since they would correspond to conditions of extremely high current pulsation. It was for this reason that the early XY curves presented by Dr. Stevenson[3] were not plotted through the resonance points. Later on, however, one of the present writers suggested plotting the curves through the resonance points with an average value of λ. The value $\lambda = 0.1$ was found to be a good average and since then all XY curves which could be classed as standard have been plotted with a value of $\lambda = 0.1$.

For rapid solution of Equation [10] the term

$$\frac{1}{\sqrt{(1 - n^2Z)^2 + (n\lambda)^2}} = C$$

can be plotted as a family of curves for each value of n corresponding to the first four harmonics. These families of curves are shown in Figs. 1, 2, 3, 4, and 5. They are plotted as function of Z for several different values of λ.

Similarly the phase angle $\tan^{-1} \dfrac{n\lambda}{1 - n^2Z} = y_n$ can be plotted as function of Z, a family of curves being obtained for each harmonic and each curve being for a different value of λ. It has been found that for all values of X and λ within reasonable limits, the fourth harmonic y_n is practically 180 degrees and will be taken as such, so that no family of curves is given for the fourth harmonic. Figs. 6, 7, and 8 give these families of curves for y for the first three harmonics.

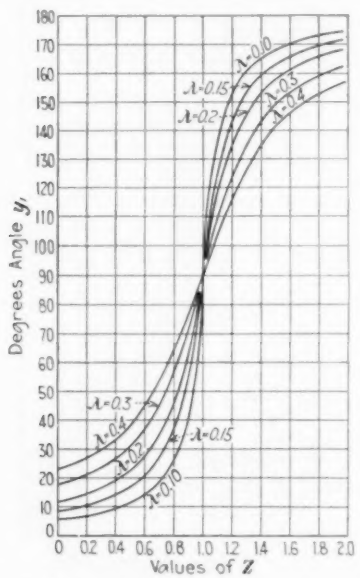

Fig. 6 First Harmonic Angles

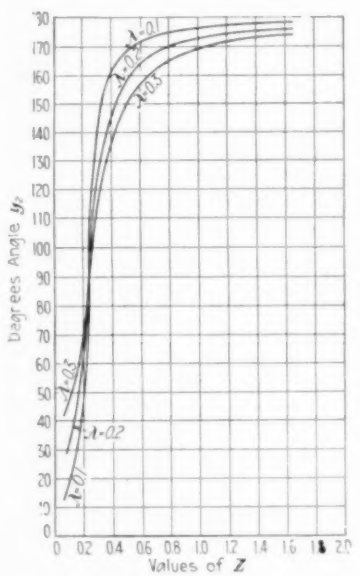

Fig. 7 Second Harmonic Angles

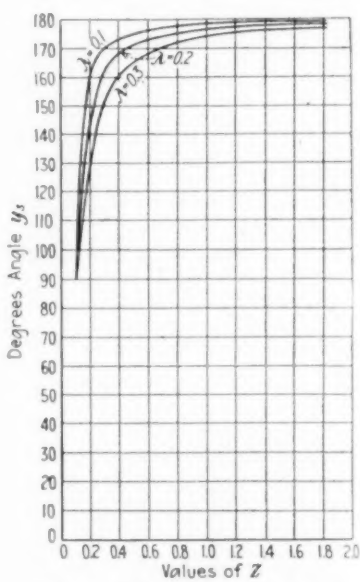

Fig. 8 Third Harmonic Angles

Example Illustrating Method of Making an XY Curve

The construction of an XY curve consists in solving Equation [10] for different values of Z or X, since $X = 9.25Z$. Each solution thus gives a value of Y corresponding to an assigned value of X and from these data the XY curve can be plotted.

As an example of the construction of such a curve consider the case of a two-cylinder double-acting two-stage air compressor operating at three-fourths load and having a value[4] of $q = 18.4$. The harmonics of the torque curve for a compressor of this type operating under this condition are given in column 2 of Table 5, Appendix No. 2, as follows:

$A_1 = +4.6$	$B_1 = +15.9$
$A_2 = -18.6$	$B_2 = +2.4$
$A_3 = +25.8$	$B_3 = +45.5$
$A_4 = +11.8$	$B_4 = -1.7$

[3] See third reference in bibliography.

[4] q is a factor depending on the weight of reciprocating parts. See Appendix No. 2.

With the information given in these curves and a knowledge of the harmonics of the compressor-torque curve one is ready to solve Equation [10] for different values of X, thereby obtaining the XY curve. In making standard XY curves, as stated before, an average value of $\lambda = 0.1$ will be used. Experience has shown that to insure greatest accuracy and simplicity in solving for Y repeatedly, it is advisable to use a blank similar to the one shown in Table 1. The blank is arranged to record $Q_n = \sqrt{A^2_n + B^2_n}$ and the phase angle $x_n = \tan^{-1} \dfrac{B_n}{A_n}$. These figures are the same for any value of Z so they are recorded once at the top of the blank. The remainder of the blank consists of eight similar rectangles, one for each value of Z. In each rectangle there is a column for C which is read from the curves in Figs. 1 to 5, for $\lambda = 0.1$. The column of products is CQ_n. The values of y_n are read from the curves in Figs. 5, 6, and 7 and the last column is as indicated the angle $x_n - y_n$ in degrees. The figures in the column "Prod." are the magnitudes of each harmonic and the angles in the column $x_n - y_n$ are the phase angles of the respective harmonics. The four harmonics must be plotted to scale and at their respective phase angles for one revolution of the crank. If they are added

a true picture of the current pulsation of the motor is obtained. The distance between the maximum points on the positive and negative side of the zero axis is the value of Y as given by Equation [10].

The space shown in Table 1 has been properly filled out with data covering the illustrative example. Fig. 9 gives the four harmonics for $Z = 0.5$, drawn to scale at their proper phase

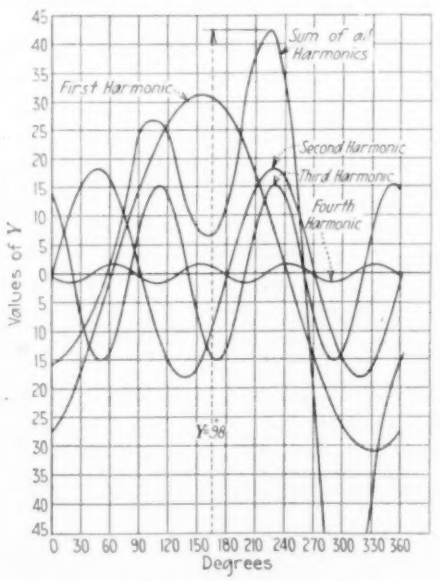

FIG. 9 FOUR HARMONICS FOR $Z = 0.5$

angles. The maximum points are indicated so that the value of Z can be read directly. Referring to Table 1, the behavior of Y should be particularly noted in that the value decreases as Z increases and then increases for larger values of Z. This increase is due to resonance with the first harmonic of the compressor torque curve. Beyond this resonance point Y decreases with increased values of Z. If one were to investigate the values of Y for values of Z smaller than 0.3, it will be found that there is a resonance peak for the second, third, and fourth harmonics.

An idea of the amount of work involved in making an XY curve can be gained when one remembers that it is necessary to draw up a Fourier's series such as the one exhibited in Fig. 9 for each value of X or for each one of the rectangles in Table 1. Fortunately the "harmonic curve tracer" shown in Figs. 10 and 11 reduces the drawing of these Fourier series to a matter of a few minutes. The instrument is provided with two ad-

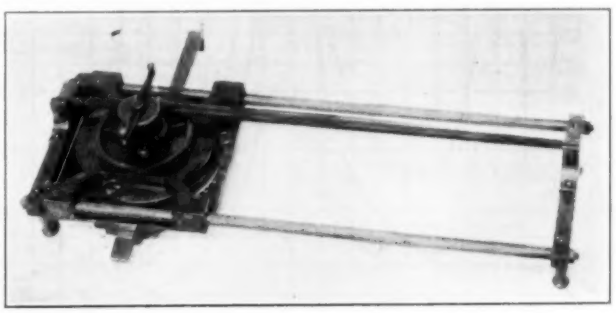

FIG. 10 HARMONIC CURVE TRACER

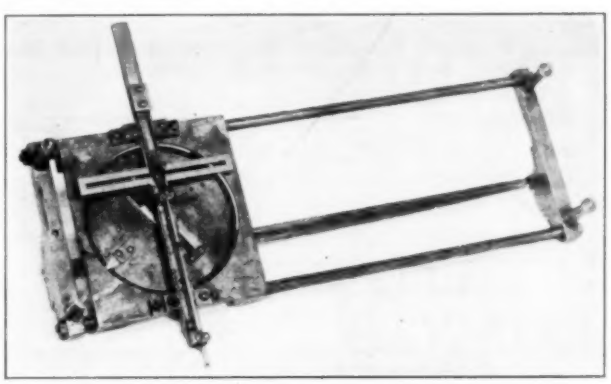

FIG. 11 HARMONIC CURVE TRACER

justments, one for magnitude and one for phase angle. Each harmonic is drawn separately, but only two or three minutes is required for a series of four. One can tell by looking at the series about where the maximum points will occur, and by adding up the curves with the dividers in about three points the maximum and minimum values are readily determined. The sum of these values is Y as shown in Fig. 9. Without the curve tracer the work involved in making XY curves is almost prohibitive.

A SET OF XY CURVES FOR AIR COMPRESSORS

Figs. 12 to 19 inclusive exhibit a set of eight XY curves for two-cylinder double acting two-stage air compressors with cranks at 90 deg. In addition to the full-load and no-load curves, two curves each are given for the part-load conditions at $^3/_4$, $^1/_2$, and $^1/_4$ load. The methods of unloading are described on each curve. The number on each curve is the same as that of the corresponding Fourier series listed in Tables 5 and 6 in Appendix No. 2. This is the most common type of compressor and is built in medium and large sizes.

Figs. 20 and 21 exhibit a similar set of XY curves for single-cylinder single-stage machines. Only full-load and no-load curves are given as these machines are built only in small sizes and are seldom if ever equipped with multi-step unloaders.

Example Illustrating Use of XY Curves

As an example illustrating the use of XY curves for the calculation of the proper WR^2 to limit the current pulsations to 66 per cent of rated current, consider the following case:

Two-cylinder double-acting two-stage compressor; cylinder sizes 26 and 15 × 21 in.; 5-step unloader giving the partial

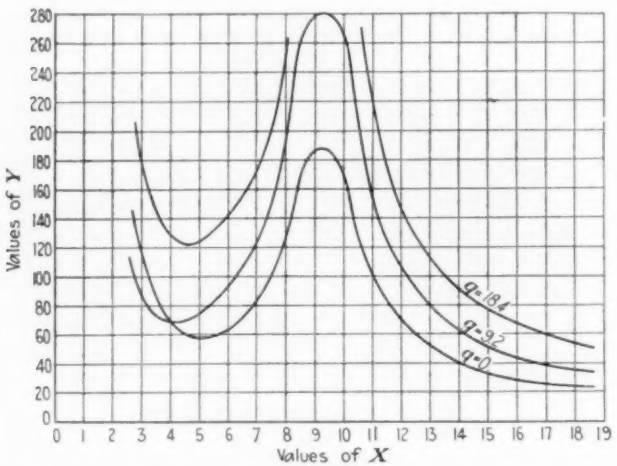

Fig. 12 Standard Two-Stage Air Compressor, Full Load, M = 0.75 C. P. or W. Method

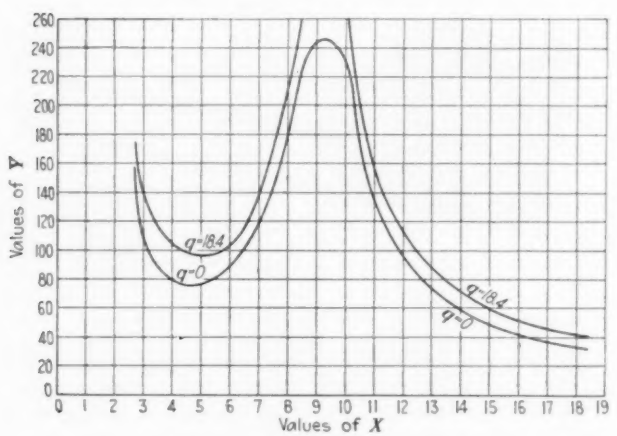

Fig. 13 Standard Two-Stage Air Compressor, Three-Quarter Load, M = 0.75 C. P. Method

(Head end high pressure and crank end low pressure on clearance pockets; opposite ends normal.)

load conditions described in Table 4, Appendix No. 2, Nos. 1, 3, 5, 7, and 8. Weight of reciprocating parts, including half the connecting rod weight, for the low-pressure cylinder is 1500 lb.

Motor, 450-hp., three-phase, 60-cycle, 200 r.p.m., 1.00 power factor, 361 kw., P_0 = 615 kw.

The directions will be followed through step by step:

First Step. Calculate the indicated horsepower of the compressor by the standard formula given in Equation [18], Appendix No. 1, which is

$$\text{i.hp.} = 8.99 \times K \times \left(\frac{V}{1000}\right) \times \frac{s}{100}$$

where K = a constant = 2 for this type of compressor. See Appendix No. 1 for K

V = volume of low-pressure cylinder in cu. in.

s = r.p.m.

$$\text{i.hp.} = 8.99 \times 2 \times 11.15 \times 2.0 = 401$$

Second Step. Calculate Y from Equation [11]

$$Y = \frac{450}{401} \times 66 = 74$$

Third Step. Calculate q from the formula in Appendix No. 2 which is

$$q = \left(\frac{s}{100}\right)^2 \times r \times w$$

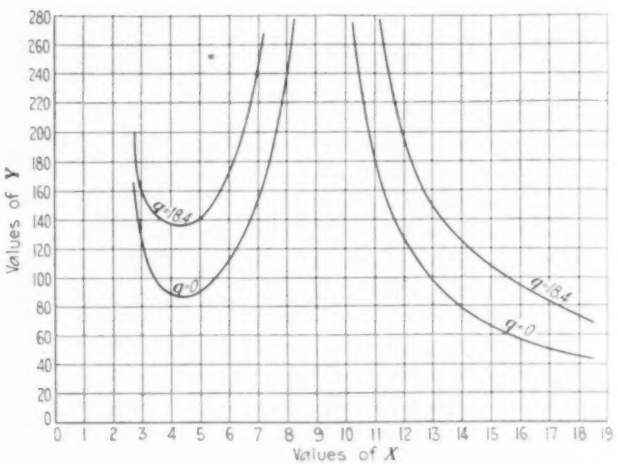

Fig. 14 Standard Two-Stage Air Compressor, Two-Cylinder Double-Acting, M = 0.75, $^3/_4$-Load

(Crank ends on clearance, head ends normal, W. method.)

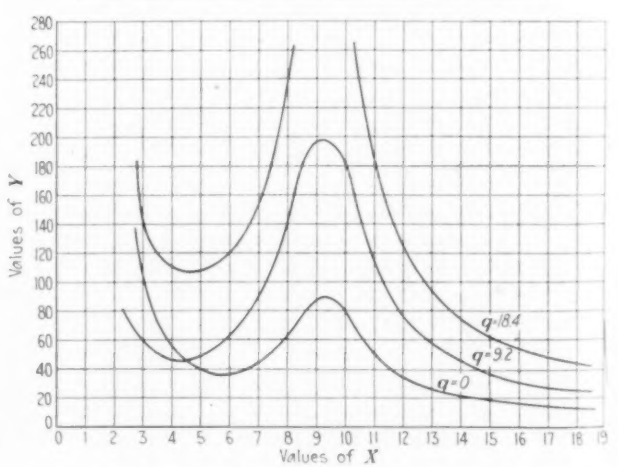

Fig. 15 Standard Two-Stage Air Compressor, Two-Cylinder Double-Acting, $^1/_2$ Load, M = 0.75

(Head end and crank end of both cylinders on clearance, C. P. method.)

where r = crank radius in feet

w = weight of reciprocating parts in lb. per sq. in. of piston area

$$q = (2)^2 \times 0.875 \times \frac{1500}{530} = 9.9$$

Fourth Step. Examine the XY curves given in Figs. 12, 14, 16, 18, and 19 which cover the five different conditions for this

case. It will be noted that one-half load (Fig. 16) is the worst condition, that is, the one which requires the largest value of X and hence the largest value of WR^2. For $q = 9.2$ which is almost the same value as calculated it is seen that $x = 25.5$ for $Y = 74$.

Fifth Step. Calculate the WR^2 required by Formula [15]

$$WR^2 = \frac{25.5 \times 4.5 \times 6 \times 1.7}{(2)^4} \times 10^3 = 73{,}500 \text{ lb-ft.}^2$$

This value of WR^2 is just sufficient to limit the current pulsation to 66 per cent at half load. At quarter load the pulsation will be nearly as great but at the other loads it will be considerably less as the other XY curves show.

Appendix No. 1—Indicated Horsepower

In determining the size of a synchronous motor required to drive an air compressor the following formula for the indicated horsepower of the compressor will be found convenient

$$\text{. . .} = 8.99K\left(\frac{V}{1000}\right)\left(\frac{s}{100}\right) \text{. . . . . [18]}$$

where

s = r.p.m.
V = volume of one cylinder. For two-stage machines V is the volume of the low-pressure cylinder
K = 2 for single-cylinder double-acting single-stage compressors
= 4 for two-cylinder double-acting single-stage compressors
= 2 for two-cylinder double-acting two-stage compressors.

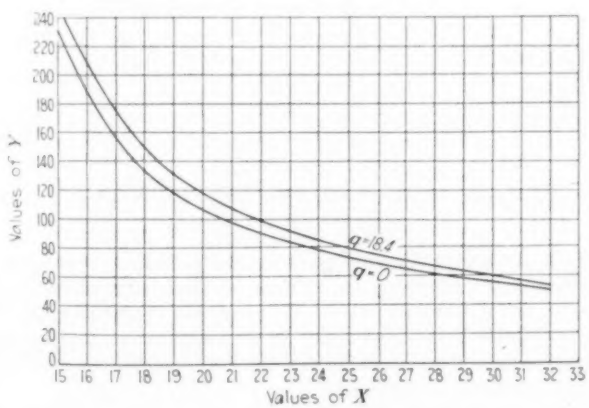

FIG. 16 STANDARD TWO-STAGE, TWO-CYLINDER, DOUBLE-ACTING AIR COMPRESSOR, 1/2 LOAD; $M = 0.57$
(Both crank ends with suction valves held open opposite ends normal.)

Experience has shown that in a great majority of cases, compressor manufacturers will recommend a motor the rated horsepower of which is from 5 to 15 per cent greater than the indicated horsepower calculated by Formula [18].

This simple formula was derived by calculating the area of the theoretical indicator card shown in Fig. 22. In constructing this card a polytropic exponent of 1.4 was used for both the compression and expansion lines. Compression was taken between atmosphere and 100 lb. gage, and a clearance of 4 per cent was used. For the purposes of this article it will be convenient to speak of this theoretical single-stage card as the "standard air cycle."

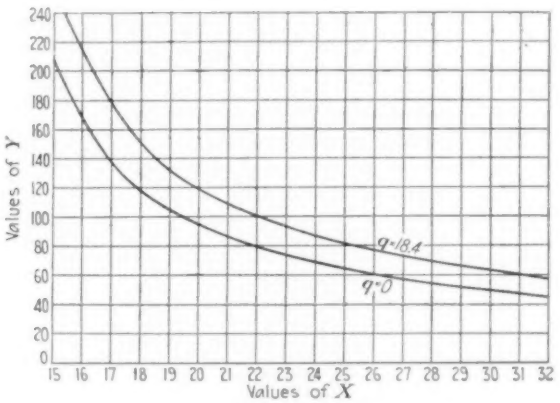

FIG. 17 STANDARD TWO-STAGE, TWO-CYLINDER, DOUBLE-ACTING AIR COMPRESSOR, 1/4 LOAD, $M = 0.75$
(Head end high pressure and crank end low pressure suction valves held open, opposite ends operating with clearance pockets.)

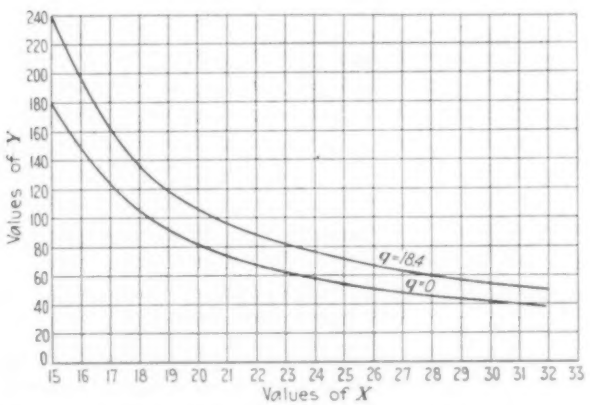

FIG. 18 STANDARD TWO-STAGE, TWO-CYLINDER, DOUBLE-ACTING AIR COMPRESSOR, 1/4 LOAD, $M = 0.75$
(Both crank ends with clearance pockets and both head ends with suction valves held open.)

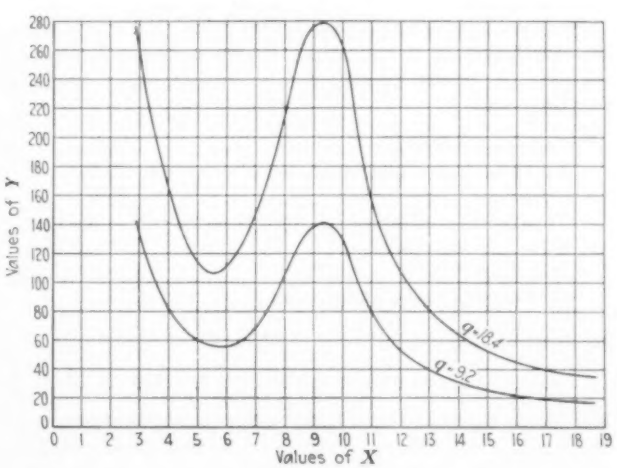

FIG. 19 STANDARD TWO-STAGE AIR COMPRESSOR, $M = 0.75$
(No load, all valves open.)

It is often necessary to calculate the indicated horsepower under different conditions than those on which Formula [18] is based, that is, different pressures or different clearances. For this purpose the following formula, in connection with the family of curves given in Fig. 23, may be used.

$$\text{i.hp.} = 0.252\, A_0 P_s h \left(\frac{V}{1000}\right)\left(\frac{s}{100}\right) \quad \ldots\ldots\ldots [19]$$

where

A_0 = constant given by curves in Fig. 23
P_s = absolute suction pressure
h = number of active cylinder ends
V = volume of one cylinder
s = r.p.m.
r = ratio $\dfrac{\text{Absolute discharge pressure}}{\text{Absolute suction pressure}}$
α = percentage of clearance.

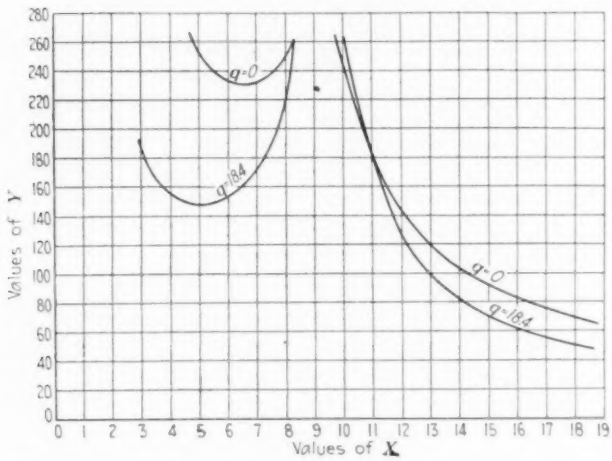

FIG. 20 SINGLE-CYLINDER DOUBLE-ACTING SINGLE-STAGE AIR COMPRESSOR, FULL LOAD

In applying this formula to two-stage compressors, the low-pressure and high-pressure cylinders must be figured separately. This is also advisable because the clearance of the high-pressure cylinder is usually larger than that of the low-pressure due to the fact that the same size valves are used in both cylinders but the high-pressure cylinder is smaller in diameter than the low-pressure cylinder.

As an example of the use of Formulas [18] and [19] consider the calculation of the indicated horsepower of the following two-cylinder, double-acting, two-stage compressor operating at 150 r.p.m.

Diameter low-pressure cylinder	37 in.
Diameter high-pressure cylinder	22 in.
Stroke	27 in.
Clearance low-pressure	4 per cent
Clearance high-pressure	8 per cent
Pressures	0 to 100 lb. gage
Interstage pressure approximately	30 lb. gage

By Formula [18]

$$\text{i.hp.} = 8.99 \times 2 \times 29 \times 1.5 = 781$$

The motor recommended by the compressor manufacturer for this machine was 875 hp. which is 12 per cent greater than by [18].

By Formula [19]

Low-pressure cylinder i.hp. $= 0.252 \times 1.24 \times 14.7 \times 2 \times 29 \times 1.5 =$ 400

High-pressure cylinder i.hp. $= 0.252 \times 1.0 \times 44.7 \times 2 \times 10.25 \times 1.5 =$ 346

Total i.hp. = 746

The lower value of indicated horsepower obtained by Formula [19] is due largely to the fact that Formula [18] assumes single-stage compression while Formula [19] takes into account automatically the greater efficiency of two-stage compression.

If the interstage pressure is not given by the compressor manufacturer, it can be calculated from the fact that the ratio of the absolute interstage pressure to the absolute suction pressure must be approximately equal to the ratio of the volume of the low-pressure cylinder to that of the high-pressure cylinder. This cannot be exactly true since it would assume that both cylinders have the same clearance and that the air in the intercooler is reduced to the same temperature as in the intake. Obviously the first condition depends on the construction of the compressor and the second on the amount and temperature of the cooling water used. The lower the interstage temperature the lower will be the interstage pressure and the greater the efficiency of compression. It is obvious that the gain in efficiency of two-stage over single-stage compression depends on the relative temperature of the gas in the intercooler and in the intake. In air compressors the gas in the intercooler is reduced to practically the temperature of the intake without difficulty, but in two-stage ammonia compressors the temperature of the gas in the intercooler is reduced only to that of the cooling water while the temperature of the gas in the suction line is below freezing. Hence for ammonia compressors there is very little gain in efficiency of two-stage over single-stage compression. This accounts for the very limited use of two-stage ammonia compressors.

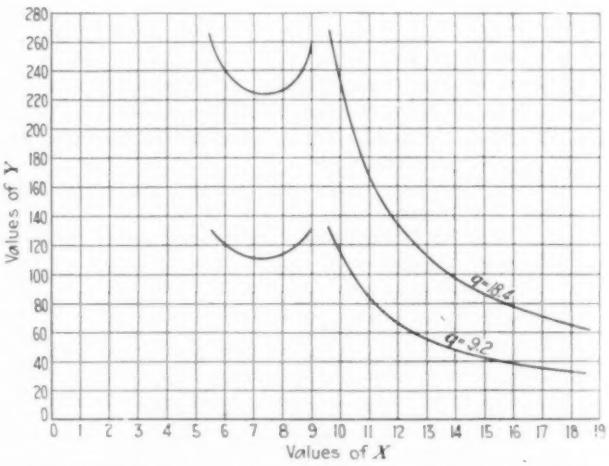

FIG. 21 SINGLE-STAGE SINGLE-CYLINDER DOUBLE-ACTING AIR COMPRESSOR, NO LOAD

In the calculation of the above example by Formula [19] it may be noted that the indicated horsepower of the high-pressure cylinder is somewhat less than that of the low-pressure cylinder. This does not indicate a wrong interstage pressure but is due to the fact that most compressors are designed to give balanced work between the two cylinders at a discharge pressure of from 115 to 120 lb. gage. Under ordinary conditions of operation the work done by the two cylinders is slightly unbalanced, being larger for the low-pressure cylinder.

Appendix No. 2—Theoretical Torque Curves

The calculation of a set of theoretical torque curves which can be applied quite generally to the different types of air compressors can at best be only a good approximation, because the details of construction differ with the various manufacturers.

Such items for instance as clearance, ratio of connecting-rod length to crank length, ratio of the weights of reciprocating parts of high-pressure and low-pressure cylinders, and others, vary over small ranges and have some effect on the crank effort of the machine. The best one can do is to choose a middle path and proceed with average values and this is what has been done in this paper. The resulting torque curves will therefore not apply absolutely to any one make of compressor but will apply approximately to all makes of the types discussed in this paper. They will be accurate enough to form a basis for flywheel calculations and they will show the relative merits of the different methods of unloading.

The torque required by a compressor may be separated into two parts, one due to the gas forces, and the other due to the

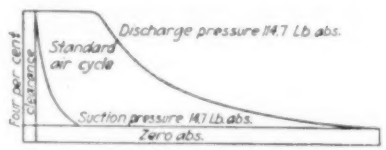

FIG. 22

inertia. It will be found convenient to calculate these entirely separately, since the inertia forces depend on the speed of the machine as well as the weights of reciprocating parts. Instead of actually calculating and plotting torque curves, the torque will be expressed in Fourier's series. In this work the coefficients of the several harmonics will be given in percentage based on the average torque of the compressor or rather on what would

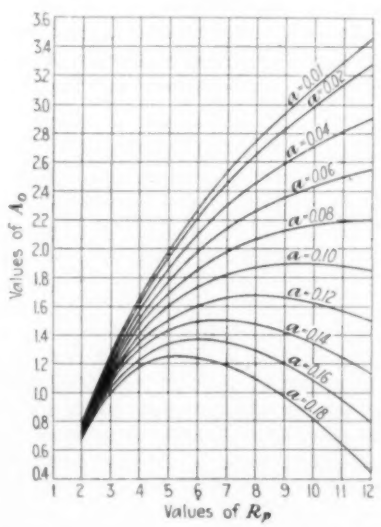

FIG. 23 INDICATED HORSEPOWER OF AIR COMPRESSOR

where i.hp. $= 252 A_0 P_s h \ (g/10^3)(s/10^3)$
A_0 = constant, read from curve
P_s = absolute suction pressure
h = number of active cylinder ends
V = cylinder volume in cubic inches
R_p = Ratio = absolute suction pressure / absolute discharge pressure
a = clearance, per cent

be the average torque if the indicator cards were all standard air cycles as shown in Fig. 22. This will be true of the inertia torque as well as the gas torque.

INERTIA TORQUE

It is not within the scope of this paper to present in detail the theory underlying the calculation of the inertia torque of a reciprocating machine such as is shown in Fig. 24.

Perhaps the best method of calculating this torque, however, is to obtain an expression for the kinetic energy stored in the moving system, in terms of the angle θ through which the crank has moved *from its head-end position*. Differentiating this

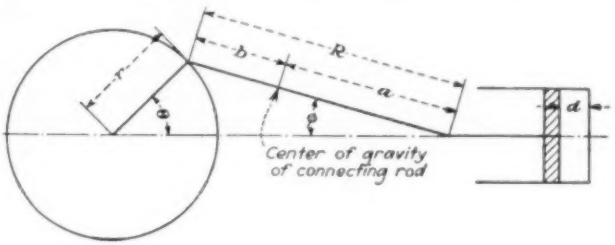

FIG. 24

energy expression with respect to the angle θ will give the torque required for the inertia as follows:

$$T = \frac{r^2\omega^2}{4g}\left\{-\frac{1}{l}\left[W_r + \frac{b}{R}W_c\right]\sin\theta + 2\left[W_r + W_c\left(1 - \frac{K^2}{R^2}\right)\right]\sin 2\theta + \frac{3}{l}\left[W_r + \frac{b}{R}W_c\right]\sin 3\theta + \frac{1}{l^2}\left[W_r + \frac{b^2}{R^2}W_c\right]\sin 4\theta\right\} \quad \ldots [20]$$

where

r = crank length in feet
R = connecting rod length in feet
b = distance from the center of gravity of the connecting rod to the axis of crank pin in feet
K = radius of gyration of connecting rod about its center of gravity in feet
l = ratio of connecting rod length to crank length = R/r
ω = angular velocity of crank in radians per sec.
g = acceleration due to gravity
W_r = weight of reciprocating parts, that is, piston, piston rod, etc.
W_c = weight of connecting rod.

Of the four terms in the above series the second is by far the largest and the fourth much the smallest. Investigations of the design of several connecting rods show that the ratio K^2/R^2 is very nearly equal to $1/2$ in most cases. Also b/R is approximately $1/2$. Hence with good approximation Equation [20] can be written.

$$T = \frac{r^2\omega^2}{4g}W\left\{-\frac{1}{l}\sin\theta + 2\sin 2\theta + \frac{3}{l}\sin 3\theta + \frac{1}{l^2}\sin 4\theta\right\} \quad \ldots [21]$$

where W is taken as the weights of the reciprocating parts plus half the weight of the connecting rod.

Let w = weight of reciprocating parts plus half the connecting rod weight per sq. in. of piston area.

A = piston area

then $W = Aw$, and the coefficients of the four harmonics in [21] may be written

$$\left.\begin{aligned} a_1 &= -\frac{r^2\omega^2}{4g}\frac{Aw}{l} & a_3 &= \frac{r^2\omega^2}{4g}\frac{3Aw}{l} \\ a_2 &= +\frac{r^2\omega^2}{4g}2Aw & a_4 &= \frac{r^2\omega^2}{4g}\frac{Aw}{l^2} \end{aligned}\right\} \quad \ldots [22]$$

The factor $\frac{r^2\omega^2 A}{4g}$ which occurs in all of these terms can be reduced as follows:

$$\frac{r^2\omega^2 A}{4g} = \frac{Ar^2(0.1048s)^2}{4 \times 32.2} = \frac{85.272}{10^6} r^2 s^2 A \quad \ldots\ldots [23]$$

The problem is now to express the harmonics in [22] in percentage based on the average torque of a standard air cycle. It has been shown that the indicated horsepower of the standard air cycle is

$$\text{i.hp.} = 8.99 \times \left(\frac{V}{1000}\right) \times \left(\frac{s}{100}\right) \quad \ldots\ldots [24]$$

where

V = volume of the cylinder in cu. in.
s = r.p.m.

But $V = A \times 2r \times 12 = 24\,Ar$ ..... [25]
since r is the crank radius in feet.
Substituting [25] in [24] gives

$$\text{i.hp.} = \frac{8.99}{10^5} \times 24\,Ars = \frac{2.1576}{10^3} Ars \quad \ldots\ldots [26]$$

The average torque in ft-lb. corresponding to this i.hp. is

$$a_0 = \frac{5250}{s} \times \frac{2.1576}{10^3} rAs = 11.327rA \quad \ldots\ldots [27]$$

Dividing the a's in [22] by a_0 gives the harmonics in per cent based on the average torque of one standard cycle. For instance

$$A_1 = \frac{a_1}{a_0} = -\frac{w}{l} \frac{85.272 \times r^2 s^2 A \times 10^2}{10^6 \times 11.327\,rA}$$

$$= -\frac{7.528}{l}\left[rw\left(\frac{s}{100}\right)^2\right] \quad \ldots [28]$$

Particular attention should be called to the expression in the bracket which will be called q. It is this factor which determines the inertia torque of a compressor. One should note that it involves only the crank radius in feet, the weight of the reciprocating parts per square inch of piston area and the speed.

Putting q in place of the bracket gives

and similarly

$$\left.\begin{aligned} A_1 &= -\frac{7.528}{l} q \\ A_2 &= +15.056\,q \\ A_3 &= +\frac{22.58}{l} q \\ A_4 &= +\frac{7.528}{l^2} q \end{aligned}\right\} \quad \ldots\ldots [29]$$

These are the inertia forces for a single cylinder in per cent based on one standard cycle.

For a single-cylinder double-acting single-stage compressor, the above values would have to be divided by 2 to get the percentages based on the average torque of the whole compressor since two standard cycles would be involved. Similarly for a two-cylinder double-acting single-stage compressor with 90 degrees between cranks, it would be necessary to add two Fourier's series like [29] at right angles and divide the result by 4 since there would be four standard cycles involved. Percentages would then be obtained based on the average torque of the whole compressor.

This gives for the two cylinder double acting single stage

$$\left.\begin{aligned} A_1 &= -\frac{1.88}{l} q & B_1 &= +\frac{1.88}{l} q \\ A_2 &= 0 & B_2 &= 0 \\ A_3 &= +\frac{5.65}{l} q & B_3 &= +\frac{5.65}{l} q \\ A_4 &= +\frac{3.76}{l^2} q & B_4 &= 0 \end{aligned}\right\} \quad \ldots\ldots [30]$$

The B's in [30] are coefficients of the cosine terms which occur when the two series are added at right angles.

For two-stage compressors with balanced inertia forces, that is, with low-pressure and high-pressure pistons of the same weight, the values given by [29] must be multiplied by 2 since in this case the percentages must be based on two standard cycles instead of four.

It is only in special cases that two-stage compressors are made with high-pressure and low-pressure pistons of the same weight. Ordinarily the high-pressure piston has about three-quarters the weight of the low-pressure piston.

In general let

$$m = \frac{\text{Weight of reciprocating parts of h-p. cylinder}}{\text{Weight of reciprocating parts of l-p. cylinder}}$$

Assume also that the high-pressure cylinder is leading the low-pressure cylinder by 90 degrees. This is the customary method of operation for two-stage machines and all the torque curves will be worked out on this basis.

If [29] is taken as the inertia torque of the low-pressure cylinder, and m is defined as above, the inertia torque of the high-pressure cylinder on the same basis is

$$\left.\begin{aligned} A_1 &= -\frac{7.528}{l} qm \\ A_2 &= +15.056\,qm \\ A_3 &= +\frac{22.58}{l} qm \\ A_4 &= +\frac{7.528}{l^2} qm \end{aligned}\right\} \quad \ldots\ldots [31]$$

Adding the series [31] to series [29] and 90 degrees ahead of it and dividing by 2 the result gives the inertia torque of the two-cylinder double-acting two-stage compressor in percentage based on the average torque of the compressor as follows:

$$\left.\begin{aligned} A_1 &= -\frac{3.76}{l} qm & B_1 &= +\frac{3.76}{l} q \\ A_2 &= -7.53\,q(1-m) & B_2 &= 0 \\ A_3 &= +\frac{11.3}{l} qm & B_3 &= \frac{11.3}{l} q \\ A_4 &= +\frac{3.76}{l^2} q(m+1) & B_4 &= 0 \end{aligned}\right\} \quad \ldots [32]$$

Table 2 has been prepared showing numerical values of the inertia torque for various types of compressors. A value of $m = 0.75$ has been used for the two-stage machines as this represents a fair average. The ratio of connecting-rod length to crank length which is l, has been taken as 5. Some compressors have ratios as high as 5.5 but 5 is a good average.

TABLE 2 INERTIA FORCES

	Single-cylinder double-acting, single-stage		Two-cylinder double-acting, single-stage		Two-cylinder, double-acting, two-stage, balanced inertia		Two-cylinder, double-acting, two-stage, $m = 0.75$	
	$q = 9.2$	$q = 18.4$	$q = 9.2$	$q = 18.4$	$q = 9.2$	$q = 18.4$	$q = 9.2$	$q = 18.4$
A_1	− 6.95	− 13.9	− 3.46	− 6.92	− 6.92	−13.84	− 5.2	−10.4

B_4	0	0	0	0	0	0	0	0

Calculations have been made for two values of q, 9.2 and 18.4. The value 9.2 represents an average case while experience has shown that a value of 18.4 represents an outside limit. Complete torque curves are given for three values of q, 0, 9.2, and

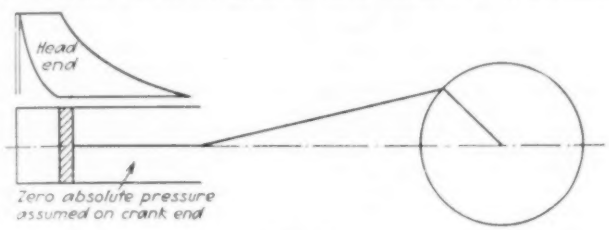

FIG. 25

18.4 in the body of the paper and flywheel calculation curves presented on the same basis. This gives a curve for the case of no inertia, another for the case of maximum inertia, and a third with average inertia. In any particular case the actual value of q can be calculated and final results obtained by interpolation between the curves given.

TORQUES DUE TO GAS FORCES

It has been found a decided advantage to obtain the gas torque due to each indicator card, that is, each end of a cylinder separately. There are fairly few types of indicator cards involved in most compressors even under partial load conditions. By obtaining Fourier's series for these component parts of the gas torque they can be combined in a variety of ways to give the complete torque of different types of compressors under different conditions of loading. As an illustration of this method consider a single-stage single-cylinder machine compressing air from atmosphere to 100 lb. gage. For this case the indicator card will be a standard air cycle as shown in Fig. 22.

The ratio R_p, which is the ratio of absolute discharge pressure to absolute suction pressure is 7.8. Assuming 4 per cent clearance and a ratio of connecting rod length to crank length of 5, a torque curve could be constructed due to a standard air cycle in the heat end of the cylinder as shown in Fig. 25. This torque curve could be analyzed in a Fourier's series and each harmonic divided by $a_0 = 11.327$ the average torque of the standard air cycle. The resulting harmonics would then be obtained in percentage based on one standard air cycle and would be as follows:

$$\left.\begin{aligned} A_1 &= -287 & B_1 &= +109.1 \\ A_2 &= -171 & B_2 &= -32.5 \\ A_3 &= -80.1 & B_3 &= -83.5 \\ A_4 &= -22.3 & B_4 &= -68.6 \end{aligned}\right\} \quad \ldots\ldots [33]$$

Similarly if the standard air cycle is put in the crank end of the cylinder and the same operations performed, the results for a crank-end card would be

$$\left.\begin{aligned} A_1 &= +302.1 & B_1 &= -84.3 \\ A_2 &= -124 & B_2 &= -69.7 \\ A_3 &= +37.4 & B_3 &= +86.6 \\ A_4 &= +6.2 & B_4 &= -43.2 \end{aligned}\right\} \quad \ldots\ldots [34]$$

In making both of the foregoing analyses, time has been counted from the instant the piston is in its head end position. Time was counted in the same way in making the series for the inertia forces and it is of course necessary to maintain the same convention throughout.

If the series [33] and [34] are added directly and divided by 2, the torque for a single-cylinder double-acting single-stage machine is obtained. In this manner it can be seen that a great variety of torque curves can be made up at once if one has the analyses corresponding to all the different indicator cards involved.

For the part-load conditions discussed in this paper half-load indicator cards are required. These are obtained in practice by the use of clearance pockets of such size that the area of the card is reduced to half that of the normal card. Such a card for single-stage compression is shown in Fig. 26.

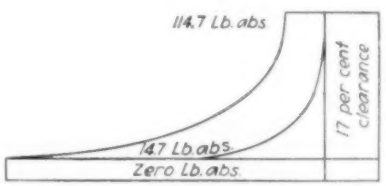

FIG. 26

The no-load conditions are obtained by opening the ends of the cylinder to the atmosphere. The indicator card for an end open to the atmosphere is simply a straight line at a pressure = 14.7 lb. The harmonics due to this type of a no-load card in percentage based on one standard cycle are easily shown to be

Crank End	Head End
$A_1 = +130$ (+124)	−130
$A_2 = +13$ (+12.4)	− 13

(Values in parenthesis are reduced 4.5 per cent to compensate for that portion of the piston area taken up by the piston rod.)

In making the cards for two-stage compressors an interstage pressure of 30 lb. gage has been assumed. This makes a ratio of absolute discharge pressure to absolute suction pressure of 3.04 for the low-pressure cylinder and 2.57 for the high-pressure cylinder. These cards must be made up for both full load and half load so that in all four are required. These four cards have to be analyzed for both head- and crank-end positions giving in all eight analyses for two-stage compressors as shown in Table 3.

All the harmonics in Table 3 are given in per cent based on one standard air cycle.

By properly selecting and combining the series in Table 3 and Table 2, torque curves for the eight different conditions of operation of two-stage machines listed in Table 4 are obtained. It will be noted that in addition to full-load normal operation, two methods each are given for $^3/_4$, $^1/_2$, and $^1/_4$ load and one method for no-load. These are not all of the part-load methods of operation in use but they are among the most important and will be found to represent the cases most needed for flywheel calculations.

In Table 5 the harmonics are given for the eight conditions of operation listed in Table 4. The set for $q = 0$ represents the gas forces alone, since if $q = 0$, the inertia forces are zero. Similarly the set for $q = 9.2$ represents the combinations of the gas forces and an average value of inertia forces. The set for $q = 18.4$ represents the extreme case of very large inertia forces.

Table 6 is similar to Table 5 except that it covers the cases for single-stage single-cylinder machines. Only full-load and no-load conditions are given, as machines of this type are usually
